Abstract

Background: Students' mental health crisis was recognized before the COVID-19 pandemic. Mindfulness virtual community (MVC), an 8-week web-based mindfulness and cognitive behavioral therapy program, has proven to be an effective web-based program to reduce symptoms of depression, anxiety, and stress. Predicting the success of MVC before a student enrolls in the program is essential to advise students accordingly.

Objective: The objectives of this study were to investigate (1) whether we can predict MVC's effectiveness using sociodemographic and self-reported features and (2) whether exposure to mindfulness videos is highly predictive of the intervention's success.

Methods: Machine learning models were developed to predict MVC's effectiveness, defined as success in reducing symptoms of depression, anxiety, and stress as measured using the Patient Health Questionnaire-9 (PHQ-9), the Beck Anxiety Inventory (BAI), and the Perceived Stress Scale (PSS), to at least the minimal clinically important difference. A data set representing a sample of undergraduate students (N=209) who took the MVC intervention between fall 2017 and fall 2018 was used for this secondary analysis. Random forest was used to measure the features' importance.

Results: Gradient boosting achieved the best performance both in terms of area under the curve (AUC) and accuracy for predicting PHQ-9 (AUC=0.85 and accuracy=0.83) and PSS (AUC=1 and accuracy=1), and random forest had the best performance for predicting BAI (AUC=0.93 and accuracy=0.93). Exposure to online mindfulness videos was the most important predictor for the intervention's effectiveness for PHQ-9, BAI, and PSS, followed by the number of working hours per week.

Conclusions: The performance of the models to predict MVC intervention effectiveness for depression, anxiety, and stress is high. These models might be helpful for professionals to advise students early enough on taking the intervention or choosing other alternatives. The students' exposure to online mindfulness videos is the most important predictor for the effectiveness of the MVC intervention.

Introduction

Students' mental health crises were recognized before the COVID-19 pandemic and deepened during the pandemic. University students are experiencing an increase in psychological distress on North American campuses. A student survey of 32 Canadian postsecondary institutions reported high anxiety (56.5%), hopelessness (54%), seriously depressed mood (37.5%), and overwhelming anger (42%) [1]. A similar survey in 2016 revealed higher distress levels [2]. In 2013, a study of 997 students at York University (site of this study) indicated that 57% reported depression scores sufficient for diagnosable clinical depression, while 33% reported anxiety scores in ranges typically indicative of panic disorder and generalized anxiety disorder [3]. The situation appears similar at universities in the United States [4,5] and worldwide; in 2018, the World Health Organization reported increasing mental disorders in college and university students worldwide [6]. Mental health challenges among university students demand attention. This is a vulnerable period, as 70% of mental health problems emerge before the age of 25 years. Without intervention, these problems can worsen and hinder students' personal and academic success [7]. COVID-19 has negatively impacted university students' mental health [8-10].

University student distress is both an individual and societal challenge. Losses in productivity during the study and at work due to distress and mental disorders are associated with indirect but significant economic burdens [11]. Canadian estimates show that mental disorders cost nearly US $37 billion yearly, with 9.8% due to direct medical costs, 16.6% and 18.2% due to long-term loss and short-term work loss, respectively, and 55.4% due to the loss of healthy function (ie, loss of the utilities of vision, hearing, speech, mobility, dexterity, emotion, cognition, and pain as assessed in the Health Utilities Index Mark 3 system) [12].

While mental distress and disorder are becoming more prevalent in students, the counseling offered in colleges and universities needs to catch up with demand. For example, from 2007 to 2012, full-time enrollment in the Ontario college system increased from 167,000 to 210,600 (a 26% increase), while the number of counselors employed in the college system increased from 146 to 152.7 (a 4.6% increase) [13]. This discrepancy leaves students underserved and counselors overwhelmed amid the increasing distress [14].

Mindfulness-based interventions have been demonstrated to positively impact psychological and physical health [15-17], with multiple meta-analyses demonstrating positive impacts in clinical and nonclinical populations [18-22]. However, with large numbers of students (50,000 to 60,000 on some campuses), there may not be enough trained personnel to convey helpful mindfulness-based practices directly. Instead, in the eHealth domain, virtual communities (VCs) [23], that is, online communities, have been used in health care to provide e-education tools and online support to empower active participants in health enhancement [24-26]. VCs can scale up mindfulness interventions at lower costs to a broader range of students, especially those restricted from attending clinics due to time-place discontinuities. VCs preserve anonymity (with reduced stigmatization) while promoting voluntary, supportive, interpersonal connections.

We developed a web-delivered mindfulness program (mindfulness virtual community [MVC]) to reduce symptoms of depression, anxiety, and stress in university students and conducted a randomized controlled trial (RCT) targeting university students at a Canadian university to examine its effectiveness. Following a successful RCT [26-29], we wanted in this secondary analysis (1) to develop a machine learning (ML) model to predict the effectiveness of the online mindfulness intervention on mental health outcomes using sociodemographic and self-reported features and (2) to investigate if exposure to mindfulness videos was highly predictive of the intervention's success.

Methods

Prediction Problem

This study aims to predict the effectiveness (ie, success vs nonsuccess) of the online mindfulness intervention on mental health outcomes; as such, this is a retrospective prognostic analysis of a classification problem per individual (ie, participants in the MVC mindfulness intervention).

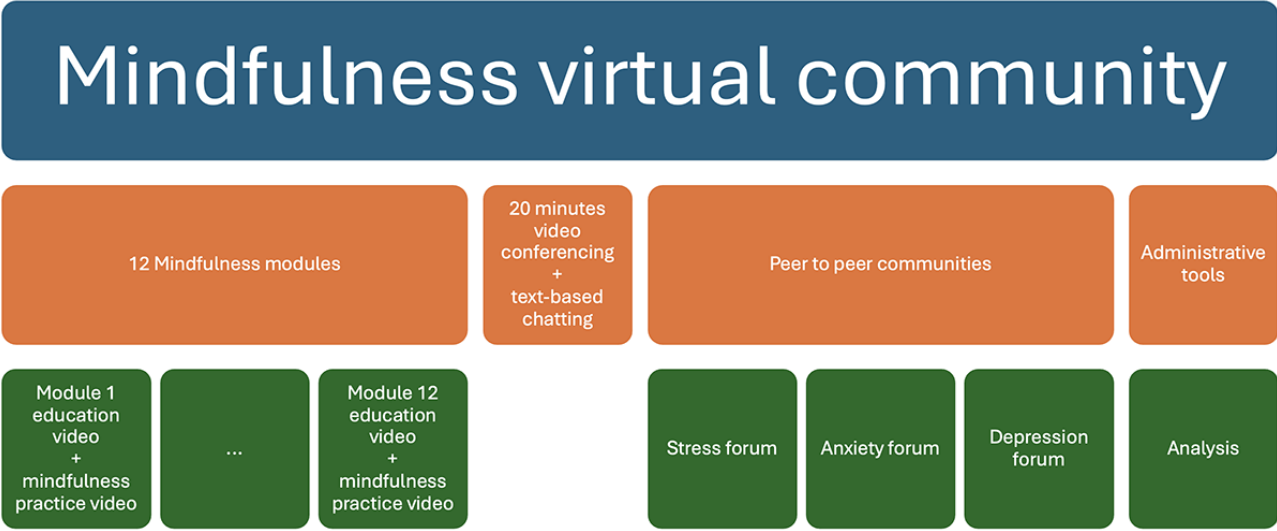
Data Set Source

This is a retrospective analysis, where we analyzed an anonymized data set. The data were deidentified, and consent was obtained during the RCT; no further consent was sought for this secondary data analysis since nonidentifiable data were used. The data set was collected via an RCT described in detail elsewhere [28]. The parent study design consisted of a 2-arm parallel-design RCT, comparing a group assigned to the web-based MVC program to a waitlist control group. Participants in the study were students who were at least 18 years of age, reported English language fluency, self-reported high confidence in completing the study, and actively enrolled in an undergraduate program. This paper is based on the MVC intervention sample recruited in fall 2017, winter 2017, and fall 2018. The MVC intervention was an 8-week program and was comprised of three components: (1) 12 online videos for mental health education; (2) 3 anonymous discussion boards on depression, anxiety, and stress; and (3) anonymous, 20-minute group-based live videoconferences led by a mental health professional with training in mindfulness during which students could raise questions related to mindfulness (Figure 1).

Each of the 12 mental health modules consisted of 1 educational content video and 1 mindfulness practice video recorded in both male and female voices and offered in both high and low resolution (a total of 8 videos per module); participants could choose the type of video they wanted to watch for each module. The videos were available for participants 24 hours a day to watch or listen to on computers, phones, or tablets at their convenience. The module scripts and audio recordings were created by one of the investigators with extensive experience as a clinical psychologist and researcher in mindfulness. They were based on mindfulness and cognitive behavioral therapy principles and informed by the prior student-based focus group

study [30,31]—the choice of moving and still images used in creating the videos involved collaborative work. The topics of the 12 modules included the following: overcoming stress, anxiety, and depression; mindfulness and being a student; mindfulness for better sleep; thriving in a fast-changing world; healthy intimacy; destigmatization; no more procrastination; pain reduction and mindfulness; healthy body image; healthier eating; overcoming trauma; and relationships with family and friends.

The primary RCT outcomes were depression, anxiety, and perceived stress, following hypotheses that symptom scores for depression, anxiety, and stress at T2 (after 8 weeks) would be significantly better in the MVC group when compared with the waitlist control group. The outcomes were measured with the following validated scales: Patient Health Questionnaire-9 (PHQ-9) [32], Beck Anxiety Inventory (BAI) [33], and Perceived Stress Scale (PSS) [34]. The secondary aim was to assess the impact of 3 elements of the MVC intervention on the outcomes. Participants also completed a sociodemographic questionnaire section at the T1 (baseline) survey.

Figure 1. The mindfulness virtual community design.


Ethical Considerations

The previous study received ethics approval from the Human Participant Research Committee (certificate e2016-345) of the York University. This ML study received ethics approval from the same committee (certificate e2023-012); the approval covers secondary analysis without additional consent. Participants in the original study had the option to receive an honorarium of CAD $50 (US $37.5) or 2% in course grade (for professors who gave this permission) or 3 credits (equivalent to 2% course grade) in the Undergraduate Research Participation Pool of the Department of Psychology. The participants' data were anonymized.

Participants

We aimed to build a model to predict who will likely benefit from the intervention, unlike the RCT study, where overall intervention effectiveness was determined (and supported by analysis) by comparing intervention and control groups. That is why we have analyzed intervention group data only to understand individual differences in response to the intervention.

Data Preparation

The data set consisted of 209 students who took the MVC intervention during fall 2017, winter 2018, and fall 2018. The effectiveness of the intervention was determined using the minimal clinically important difference (MCID), that is, the level of reduction in symptoms that psychologists consider clinically meaningful, for each of the mental health outcomes.

We adopted evidence from psychology that determines the MCID to be a 5-point reduction in PHQ-9 for depression [35,36], an 8.8-point reduction in BAI for anxiety [30,31], and an 11-point reduction in PSS for stress [37,38]. Any reduction equal to or above the MCID was labeled an effective intervention (label=1); otherwise, it was deemed ineffective (label=0).

To build a good prediction model from the training set, the data must be balanced. The class labels of the target variables, PHQ-9, BAI, and PSS, used in this study were not balanced. In our case, the percentage of instances with label=1 was extremely low: 50 (23%) for PHQ-9, 48 (24%) for BAI, and 8 (3.8%) for PSS, leading to a substantial imbalance. To alleviate the imbalanced data, we applied an oversampling method using the sklearn.resample function available in Python (version 3; Python Software Foundation).

Missing Data

Missing data in the outcomes were 12 (5.7%) for BAI and PHQ-9 and 13 (6.2%) for PSS of the 209 records. Missing data for the outcomes were dropped from the data set. There were no missing values in the predictors.

Labels and Features

The outcome variables were the 3 MCIDs associated with PHQ-9, BAI, and PSS being met or not for each instance. To investigate whether we can predict MVC's effectiveness using sociodemographic and self-reported features, the following features were used: sex (male and female), country of birth

(Canada and other), first language (English and other), education level (bachelor degree and other), ethnicity (White and non-White), marital status (married and other), age, number of weekly working hours, and self-rated health (poor, fair, good, very good, and excellent). To investigate the importance of exposure to mindfulness videos, in comparison with these features, in the prediction of intervention success, we added the total number of mindfulness videos watched to the previous data set.

Algorithms

Seven different classification algorithms, representing different learning paradigms, were used in this study: logistic regression (LR), support vector machine (SVM), random forest (RF), decision tree (DT), k-nearest neighbor (KNN), adaptive boosting (AdaBoost), and gradient boosting that showed good performance in previous studies that targeted depression, anxiety, and stress [35,39,40]. The implementations of the classification algorithms provided in the scikit-learn ML library [41] were used. The data set was split into 80% for training and 20% for testing. Hyperparameter tuning for each algorithm was performed using a grid search over a 10-fold cross-validation on the training data set. The optimal hyperparameters for the classification algorithms and their values for the data set without exposure to videos and the data set with exposure to videos are presented in Tables 1 and 2, respectively.

Each classifier's performance was compared with the best overall performance, leading to the selection of the best prediction model for the psychological outcomes. The classifiers' performances were assessed based on several evaluation metrics, including the percentage of correctly classified instances or the accuracy, sensitivity, specificity, and area under the curve (AUC) of the receiver operating characteristic curve. The best performance, as measured by the AUC score, was chosen for each algorithm.

To evaluate the features' importance in predicting intervention success, the data set with the total exposure to mindfulness videos was used to build predictive models. The RF algorithm was used to measure the features' importance. The hyperparameters used for the classification algorithms and their values that provided the optimal model are presented in Table 2.

Results

Demographics

Table 3 presents the demographic characteristics of participants at baseline. Of 209 students, 73.2% (n=153) were female, 8.1% (n=17) were married, and 21.1% (n=44) were White. Most participants were born in Canada, and English was their first language. The median (IQR) of age, work hours per week, and the total number of mindfulness videos watched were 21 (19-23) years, 10 (0-18), and 16 (9-30), respectively.

Objective 1: Predicting MVC's Effectiveness Using Sociodemographic and Self-Reported Features

Table 4 summarizes the evaluated models' performances: sensitivity, specificity, accuracy, and AUC, using 10-fold cross-validation.

The results showed that both gradient boosting (AUC=0.85 and accuracy=0.83) and DT (AUC=0.84 and accuracy=0.81) are slightly better compared to AdaBoost and KNN (AUC=0.82 and accuracy=0.80) as well as SVM (AUC=0.81 and accuracy=0.80) and outperformed the remaining classification algorithms for predicting a clinically significant reduction in PHQ-9. The best classifiers for predicting a clinically significant reduction in BAI were RF (AUC=0.93 and accuracy=0.93), followed by AdaBoost (AUC=0.92 and accuracy=0.92) and gradient boosting (AUC=0.87 and accuracy=0.87), which outperformed the remaining classifiers. Two classifiers, gradient boosting and DT, gained the perfect accuracy and AUC (AUC=1 and accuracy=1) for predicting a clinically significant reduction in PSS, followed by the near-perfect scores for SVM and AdaBoost (AUC=0.99 and accuracy=0.99). Meanwhile, LR had the lowest performance for PHQ-9, BAI, and PSS in terms of

AUC (0.64, 0.75, and 0.73, respectively) and accuracy (0.66, 0.75, and 0.73, respectively).

The results were close to those found in the models built without video exposure. Gradient boosting (AUC=0.89 and accuracy=0.88) was the best predictor for a significant reduction in PHQ-9, followed closely by AdaBoost and DT (AUC=0.84 and accuracy=0.81), which outperformed the remaining classification algorithms. The best classifiers for predicting a clinically significant reduction in BAI were AdaBoost and SVM (AUC=0.93 and accuracy=0.93), followed closely by gradient boosting (AUC=0.91 and accuracy=0.92) and RF (AUC=0.90 and accuracy=0.90), which outperformed the remaining classifiers. Four classifiers, gradient boosting, AdaBoost, RF, and SVM, gained the perfect AUC and accuracy (AUC=1 and accuracy=1) for predicting a clinically significant reduction in PSS, followed by the near-perfect score for KNN (AUC=0.99 and accuracy=0.99) and DT (AUC=0.97 and accuracy=0.97). Meanwhile, LR had the lowest performance for PHQ-9, BAI, and PSS in terms of AUC (0.62, 0.60, and 0.79, respectively) and accuracy (0.63, 0.60, and 0.80, respectively).

Using the second data set (ie, enriched with the exposure to videos), RF was used to detect features' importance in relation

to the 3 outcomes. The most predictive feature for the PHQ-9, BAI, and PSS was the total exposure to the mindfulness videos, followed by the average number of working hours per week and age for PHQ-9 and BAI. In contrast, age and the average number of working hours per week were the second and third most important predictors for PSS, respectively.

Discussion

Principal Results

The study investigated the predictability of the effectiveness of an MVC designed for undergraduate students to reduce symptoms of depression, anxiety, and stress as measured by PHQ-9, BAI, and PSS. The effectiveness was measured by the MCID for PHQ-9, BAI, and SPSS. Several algorithms were used to predict the MCID.

Predicting Intervention Success With Sociodemographic and Self-Reported Measures

We successfully built ML-based models that predicted the effectiveness of the MVC intervention. The highest AUC was achieved for gradient boosting to predict the intervention effectiveness for PHQ-9 and PSS (AUC=0.85 and AUC=1, respectively), followed closely by DT (AUC=0.84 and AUC=1, respectively) and AdaBoost (AUC=0.82 and AUC=0.99, respectively). The RF model had the highest AUC to predict BAI (AUC=0.93), followed closely by AdaBoost (AUC=0.92). AdaBoost might be the algorithm of choice for the 3 outcomes, as it is fairing a close second best for BAI and a close third best

for PHQ-9 and PSS. Gradient boosting and AdaBoost are both good choices to predict the intervention success for the 3 outcomes. It might be argued that AdaBoost might be preferable, given that it is usually less prone to overfitting than gradient boosting; however, there is no need to use the same algorithm to build the 3 predictors for the 3 outcomes.

We could not make a direct comparison with other studies that measured the 3 outcomes among university students using the same validated scales (PHQ-9, BAI, and SPSS). However, for PHQ-9, the performance of our model is higher than the one found in a previous study among adults in Korea using the Center for Epidemiologic Studies—Depression Scale 11 (AUC=0.87 and accuracy=0.86) [40] as well as the one found in a study in the United States that defined the success of the intervention as a 5-point reduction in PHQ-9 or a 4-point reduction in the General Anxiety Disorder screener-7 values (AUC=0.60 and accuracy=0.71) [35]. Regarding anxiety, the predictive model developed in this study had a higher performance (accuracy=0.92) than another study that used the Self-Rating Anxiety Scale, which did not report AUC but reported an accuracy of 0.84.

Feature Importance

Exposure to mindfulness videos was the most important factor in predicting the intervention's success. This study has demonstrated a link between the MVC intervention's success and exposure to mindfulness videos. It also confirms the results of the previous MVC pilot study that proved that exposure to mindfulness videos alone, without interaction between participants via an online discussion forum and without weekly videoconferencing with a coach, effectively reduced symptoms of depression, anxiety, and stress [26]. In other words, it indicates the ability of MVC to be deployed at a large scale without an increase in human resources. Scalability is a critical factor for eHealth intervention deployment in large populations. This finding suggests that scaling up an effective e-mental health MVC is possible in a cost-effective manner; scalability is one of the recognized failures in eHealth implementations [42].

Practical and Policy Implications

The MVC intervention does not provide clinical support; it is a platform that offers self-management of mental health symptoms (depression, anxiety, and stress). The MVC intervention proved to be effective [26-28] in reducing symptoms of depression, anxiety, and stress in university students. This study builds a predictive model that predicts intervention success using sociodemographic and self-reported measures; this will allow counseling services on university campuses to assess the usefulness of MVC for a particular student before taking the intervention and advise them accordingly to use MVC or to opt for another type of intervention. This will enable counseling services to personalize the advice to students' profiles and allow students to manage their symptoms with the most appropriate intervention.

The other finding related to videos being the most important factor in predicting intervention success confirms the ability of MVC to be deployed at a large scale without an increase in human resources. The number of working hours is another important predictor of the success of the intervention. Although the provincial governments in Canada support university education, students must pay for their education and bear the cost of living. Not surprisingly, they work long hours, especially if they belong to a marginalized community. Our findings align with other studies that suggest that longer working hours outside the university and difficulty paying bills were recognized as predictors of poor mental health among students [43]. In Ontario, where the sample was taken, Statistics Canada recently reported an increased reliance of academic institutions on students' fees in higher education to the extent that 54% of all college revenues in 2019/2020 were downloaded on students, which translates into an overall decline in public funding [44]. This situation pushed students to longer working hours; one can argue that since student debt has been recognized as negatively associated with mental well-being and academic outcomes [45,46], providing access to free higher education, supported by taxes such as in most of Europe, could enhance students' mental well-being as it would relieve them from the need for long working hours.

Strengths and Limitations

One of the strengths of this study is the ability to predict the intervention's success based on a few demographics and one question about self-rated health. Hence, the predictive model can be used in real life to indicate the suitability of online mindfulness intervention for specific individuals and possibly suggest alternatives if the model predicts noneffectiveness. The excellent AUC and accuracy measures make the models suitable for implementation and evaluation in real-life scenarios. However, the ML models must be monitored continuously if implemented for daily use (eg, a counseling service) [47,48].

A limitation of this study is that it relied on research done on 1 site; future research with larger samples with participants from multiple universities and colleges would better test the generalizability of results as it allows us to test the effectiveness of the models on external data.

Conclusions

Our results suggest that we can build high-performing models to predict MVC intervention effectiveness for depression, anxiety, and stress based on simple sociodemographics and self-reported features and that exposure to mindfulness videos is the most important predictor for the effectiveness of the intervention. Our findings provide evidence that scaling MVC can be done without additional cost for support and that the predictive models might be useful for professionals to advise students early enough on taking the intervention or choosing other alternatives.

Data Availability

The data sets generated and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

CE, FA, and PR designed the original mindfulness virtual community study questionnaire, received the funds, and contributed equally. CE supervised FT, who performed and reported the analysis. CE verified the analysis and prepared the first draft. All authors provided critical feedback and revised it.

Conflicts of Interest

It is the understanding of the university and researchers that the Project Intellectual Property belongs to the CE, FA, and PR. The industry partner ForaHealthyMe.com owns all rights and titles to the copyrights of any computer source code software developed from this research project.

Abstract

Maintaining user engagement with mobile health (mHealth) apps can be a challenge. Previously, we developed a conceptual model to optimize patient engagement in mHealth apps by incorporating multiple evidence-based methods, including increasing health literacy, enhancing technical competence, and improving feelings about participation in clinical trials. This viewpoint aims to report on a series of exploratory mini-experiments demonstrating the feasibility of testing our previously published engagement conceptual model. We collected data from 6 participants using an app that showed a series of educational videos and obtained additional data via questionnaires to illustrate and pilot the approach. The videos addressed 3 elements shown to relate to engagement in health care app use: increasing health literacy, enhancing technical competence, and improving positive feelings about participation in clinical trials. We measured changes in participants' knowledge and feelings, collected feedback on the videos and content, made revisions based on this feedback, and conducted participant reassessments. The findings support the feasibility of an iterative approach to creating and refining engagement enhancements in mHealth apps. Systematically identifying the key evidence-based elements intended to be included in an app's design and then systematically testing the implantation of each element separately until a satisfactory level of positive impact is achieved is feasible and should be incorporated into standard app design. While mHealth apps have shown promise, participants are more likely to drop out than to be retained. This viewpoint highlights the potential for mHealth researchers to test and refine mHealth apps using approaches to better engage users.

KEYWORDS

adherence; app design; attrition; mHealth; user engagement; user experience; proof-of-concept

Introduction

Smartphones have a global penetration estimated at 3.9 billion users [1], enabling mobile health (mHealth) apps to reach even low-resource areas and underserved populations [2,3]. mHealth apps have been developed to enable remote participation in clinical trials [4-7] and provide health education, health management, and other uses across the continuum from prevention through active treatment to palliative care [8]. Decentralized clinical trials using mHealth technologies promise faster participant accrual and a higher return on investment than traditional site-based trials [9]. mHealth apps have been shown to reduce inpatient readmission rates and decrease the length of hospital stay [10]. mHealth can increase knowledge and improve confidence and communication with health professionals [11]. However, while participants readily sign up for mHealth education and decentralized clinical trial apps, retention remains a major challenge [12-14]. For mHealth apps to succeed, users must consistently engage with them [15,16].

Engagement in mHealth apps has been conceptualized to include behavior, cognition, and affective components [17]. However, measures of patient engagement are underreported and lack consistency [18,19]. Participants are more likely to drop out than be retained despite app elements such as feedback,

reminders, in-app support, gamification, and participant compensation [20-23].

We developed a conceptual model to optimize patient engagement based on different phases of the engagement process [24]. Because digital literacy and anxiety have been shown to be negatively correlated with engagement [25], we established an approach to develop and test the educational components of our conceptual model to enhance app engagement by increasing health literacy, enhancing technical competence, and improving feelings about clinical trials. This Viewpoint aims to report on a series of exploratory mini-experiments, demonstrating the feasibility of testing our engagement conceptual model.

How We Conducted the Exploratory Mini-Experiments

Testing Design

We used a product testing approach rather than the traditional research evaluation approach. We used a group of existing product testers who are patients or caregivers working for Medable to rapidly test different iterations of our educational videos. Questionnaires were used both before and after participants viewed the videos, and semistructured interviews were also conducted.

Data Collection

We developed apps to collect specific data from participants over 1 week's duration through questionnaires available on their smartphones before and after exposure to videos, as shown in Table 1. The videos were based on a review of the literature defining and studying each of these 3 target areas: health literacy, technical competence, and feelings about participation in clinical trials [24]. Each concept area was tested separately, with questionnaires specific to the educational component.

Table 1. Schedule of tasks or questionnaires.

Task or questionnaire	Frequency	Day 1	Day 2	Day 3	Day 4	Day 5	Day 6
Sign up	Once	Task 1	N/A[a]	N/A	N/A	N/A	N/A
Demographics (age, gender, education, housing, race, ethnicity, location, health condition, and notification)	Once	Task 2	N/A	N/A	N/A	N/A	N/A
Technology competence questions (TAM3[b] CANX,[c] worries about pressing the wrong button and device preference)	Twice	Task 3[d]	Task 2[e]	N/A	N/A	N/A	N/A
Technology competence video combined with practice questions (video on how to answer questions and practice questions)	Once	N/A	Task 1[d,e]	N/A	N/A	N/A	N/A
Health literacy questions (BRIEF[f], own health knowledge, clinical trial knowledge, and BMI)	Twice	N/A	N/A	Task 1[d,ed]	Task 2[e]	N/A	N/A
Health literacy video with knowledge check questions (St. Luke's University Health Network's video, "Wellness 101 – How to Improve Your Overall Health"; knowledge check questions)	Once	N/A	N/A	N/A	Task 1[d,e]	N/A	N/A
Clinical trials question (temperature scale regarding participant's feelings about study participation, Figure S1 in Multimedia Appendix 1)	Twice	N/A	N/A	N/A	N/A	Task 1[d,e]	Task 2
Clinical trials video (National Institute of Diabetes and Digestive and Kidney Diseases video: "Why Should I Join a Clinical Trial?")	Once	N/A	N/A	N/A	N/A	N/A	Task 1[d,e]
Study complete	Once	N/A	N/A	N/A	N/A	N/A	Task 3

[c]CANX: Computer Anxiety.

[d]Set up with an automated morning reminder: "You have new tasks available today in the Patient Engagement app!"

[e]Set-up with an automated 8 pm reminder: "You have uncompleted tasks in the Patient Engagement app. Please finish them before midnight!"

[f]BRIEF: Brief Health Literacy Screening Tool.

XSL•FO

RenderX

In addition to collecting data through the questionnaires noted in Table 1, we conducted individual semistructured interviews with each participant at the end of the series of user evaluations using a video conferencing platform. Based on feedback, we revised specific videos and content and then conducted a second round of feedback. In this second round, after all the questions were answered in each section, participants were asked for immediate feedback with the open-ended question, "What did you think of this video?"

Recruitment

We used a product testing approach rather than a research evaluation approach. We recruited 6 individuals from the Medable Patient Care Network (PCN) who participated in this product development effort from May 2022 through July 2022. The PCN is a group of patients and caregivers who provide insights and user feedback from their perspective for a variety of apps being developed as products at Medable.

Ethical Considerations

This work was conducted and approved under the the Advarra IRB (Pro00062352). PCN members were paid an hourly rate of approximately US $150 by Medable for their work on behalf of the network in support of Medable product development efforts. Informed consent was obtained from all participants. All data were deidentified.

Assessment and Interventions

Health Literacy

The Brief Health Literacy Screening Tool [26] was selected to measure change before and after the health literacy intervention video. This questionnaire has four items that are rated on a 5-point Likert scale from "always" to "never": (1) How often do you have someone help you read hospital materials? (2) How often do you have problems learning about your medical condition because of difficulty understanding written information? (3) How often do you have a problem understanding what is told to you about your medical condition? (4) How confident are you filling out medical forms by yourself? Two questions were asked in addition to the Brief Health Literacy Screening Tool using a 10-point scale: "How much do you know about your own health," "How much do you know about clinical trials," and 1 true or false question: "Do you know your body mass index (BMI)?" (Multimedia Appendix 1).

Before showing a video, a module with a knowledge check portion was included to facilitate pre- and postvideo knowledge comparison. St. Luke's University Health Network's video, titled "Wellness 101 – How to Improve Your Overall Health" [27] was chosen for the content area of health literacy. The video provided 5 tips to improve an individual's overall health. Five knowledge-related questions based on the video were asked. A BMI calculator was included as the final task in this section. Participants were instructed to "Try calculating your BMI on this website" using the CDC BMI calculator [28].

Technology Competence

We measured internet skills using a section of the Technology Acceptance Model 3 [29]. Statements presented to the participant included "The study website does not scare me at all," "Working with the study website makes me nervous," "The study website makes me feel uncomfortable," and "The study website makes me feel uneasy." We also asked, "While using the study website, I'm worried that I might press the wrong button and make a mistake that crashes the program" and "I am most comfortable using my (multi-select) iPad/Tablet, Smart Phone (iPhone or Android), Computer, Other."

The video we used to increase technology competence was created in-house and showed participants examples of how to click on checkboxes, "radio button" response buttons, or move the cursor to a particular spot to answer different types of questions, including multiple choice, multiple selections, and a sliding scale. Participants were then asked to practice answering the same type of questions on their own (Multimedia Appendix 1 for the Technology Competence Questionnaire).

Clinical Trials

We also asked the question, "When it comes to your feelings about participating in this study, how do you rate your comfort?" using a scale ranging from "0, meaning no distress; totally relaxed" to "100, reflecting the highest anxiety/distress that you have ever felt" (Figure S1 in Multimedia Appendix 1). We showed the video from the National Institute of Diabetes and Digestive and Kidney Diseases, "Why Should I Join a Clinical Trial?" [30].

Semistructured Interviews

RM and AB conducted 45-minute interviews using Zoom (Zoom Technologies Inc) video conferencing with all 6 study participants using semistructured guides. Open-ended questions explored how participants felt about the process of using the app and how they felt about the questions that were asked through the app. A 5-point Likert scale was used to determine whether they agreed or disagreed with several statements focusing on how useful and informational they felt each of the videos and questionnaires were, for example, "I found the knowledge check questions to be useful" and "I felt less anxious about the idea of participating in a clinical trial after completing the knowledge check."

Data Analysis

Given the small sample size and our product testing approach, we used simple descriptive statistics to give us insights into the differences between the "before" and "after" questionnaire results. The semistructured interviews were reviewed for commonalities.

What We Found

User Demographics

Users testing the smartphone apps ranged in age from 54 to 69 years. Of the 6 participants, 3 identified as female and 3 as male. Five stated their race as White, 1 selected Black or African American, and none identified as Hispanic. Participants lived in the United States and Europe; 5 owned their homes and 1 rented. The majority (n=5) indicated they had 1 or more health conditions, and 5 had completed at least 4 years of college. All participants indicated they preferred to receive notifications

before noon, 4 preferred SMS text message notifications, and 2 preferred email notifications.

Health Literacy

The mean score and SD for each survey item before and after viewing the instructional video are listed in Table S1 in Multimedia Appendix 1. Lower scores indicated a more positive response for 2 of the questions, specifically, "How confident are you filling out medical forms by yourself?" and "Do you know your Body Mass Index (BMI)?" The mean score for each survey item was slightly more positive after viewing the instructional video, except for the item "How often do you have a problem understanding what is told to you about your medical condition?" However, the SD was greater than the change in mean scores, indicating that it could be due to chance. There were no changes in questionnaire responses before and after watching the instructional video for 3 of the 6 participants, improvement in 2 questions and a decline in 1 question for 1 participant, improvement in 4 questions and no change in 3 questions for 1 participant, and improvement in knowledge of their overall health and a decline in the clinical trial knowledge item for 1 participant.

Participants' feedback from the semistructured interviews revealed negative feelings toward the video "Wellness 101 – How to Improve Your Overall Health." One participant described the video as "juvenile," while another noted concerns that some participants might object to the health video if they already smoke or have a high BMI. All participants agreed or strongly agreed to the question, "I found the knowledge check questions to be useful." In total, 4 of the 6 participants neither agreed nor disagreed with the statement, "I felt less anxious about the idea of participating in a clinical trial after completing the knowledge check." Participants liked the alternative health literacy video, "5 Ways to Make the Most of Your Doctor Visit" [31].

Technology Competence

The mean scores for all items were more positive after viewing the video. The scores for 3 participants improved after watching the instructional video but declined for 2 participants. There was no change for 1 participant (Table S1 in Multimedia Appendix 1).

Participants (N=6) shared positive feedback about the video showing how to answer and practice questions. When asked, "Watching somebody else demonstrate how to answer questions made me feel like I knew what was expected of me in the study," participants answered, "agree" (2 participants) and "strongly agree" (4 participants). Additionally, participants answered "strongly agree" (4 participants) to the survey, "Practicing answering questions on my own made me feel less anxious about participating in the study." Some participants felt the questions in this section were redundant and thought all the questions could be combined into 1 question. In addition, participants thought the questions felt negative with the emphasis on the terms "anxious" and "nervous" and suggested changing the questions to make them seem more positive. One participant suggested making the technology anxiety section

optional for those who feel more comfortable using the study website.

Clinical Trials

Mean scores were slightly higher prior to viewing the instructional video compared with after the video. One participant improved by 10 points, 1 decreased by 10 points, and the other 4 stayed the same.

Participants had positive things to say about the video "Why Should I Join a Clinical Trial?" [30] When asked, "I found the video to be useful," 2 participants answered "agree" and 4 answered "strongly agree."

Additional Overall User Feedback

The participants had several specific suggestions. One participant suggested making sure that the videos were clearly specific to diseases or therapy areas in the trial and gave specific information on the trial structure. Two participants suggested including additional content on participant safety. We did an ad hoc assessment of this suggestion and sent the National Cancer Institute's "Patient Safety in Clinical Trials" video for feedback [32]. The majority (n=5) participants liked the video. The National Institute of Mental Health's video, "What are the risks and benefits of participating in clinical research?" was also considered [33]. Most (n=4) participants liked the video and 2 did not. Some participants thought the video was juvenile and better for children or young adults. Others also thought the video did not explain concepts such as placebos well. In response to this feedback, the following resources from the National Institute on Aging were added: "What are Clinical Trials and Studies?" [34] and "Clinical Research Benefits, Risks and Safety" [35], after which we sought a second round of feedback. Most participants (n=5) liked the additional resources.

Discussion

Key Lessons

Maintaining continuous and complete use of mHealth apps has remained a persistent problem that has not yielded even sophisticated solutions such as timed and individualized user messaging. A newer and evolving understanding of the foundational importance of user engagement with mHealth suggests that this problem comes from a lack of appreciation by mHealth app designers of the complex and multicomponent structures behind user engagement. We have built on prior knowledge and work to develop a model of engagement that accounts for the complexity of engagement [24].

This viewpoint was an exploratory study to determine the feasibility of this approach and to guide the refinement of this interactive test strategy. We learned several key lessons: (1) Specificity—the participants endorsed the recommendation that the interventions should be specific to the educational needs of the target of the mHealth app. The most positive feedback was given to the video we developed de novo to teach participants the technical competence required to correctly and effectively use the app to report their evaluations. (2) Attention to inadvertent adverse affective variables—the participants noted the importance of avoiding or rephrasing medical terms that

could be seen as demeaning by some participants (eg, obesity, age, and infirmity). (3) Individualization—the participants clearly reflected different levels of need for improving their technical competence and health literacy. Our results indicate the potential importance of personalization in health app design addressing individuals' levels of need and cultural and personal sensitivities. For example, a way to allow more individualization is to allow users to potentially opt out of certain learning features if they do not think they need them.

Comparison With Prior Work

Other studies have assessed how to adjust apps to increase engagement. One study found positive effects on adherence from personalization or tailoring of the app content to users' needs, push notification reminders, user-friendly design, and personal support along with digital intervention [36]. However, the high dropout rate in app usage remains a major challenge [37]. A recent literature review found that despite factors such as appropriate reminders and feedback, app participants were more likely to drop out than be retained [20]. App literacy skills have been identified as a major factor in the uptake and engagement of smartphone apps [38]. Although we identified studies recommending web-based interventions to increase health literacy and technical skills [39,40], we have not found other studies testing approaches to increase those skills.

Limitations and Strengths

Our sample size was limited to 6 participants, 5 of whom were highly educated. We were unable to use any statistical significance measures because of the small sample size or draw conclusions that would apply to a larger population. Our highly educated sample is a limitation because these individuals may have better digital literacy than the general population. The main goal of our series of mini-experiments was to assess the feasibility of our approach and see whether we could retain the interest of the participants and obtain useful feedback on the interventions, which was successful. This type of testing is intended to evaluate tailored iterations of the app after gathering rapid participant feedback, with the ultimate goal of developing an app that will engage users. The next phase of our work will be to undertake the systematic testing of each component of this model in a larger and more diverse sample. We will then be able to refine the interventional enhancements for those components for a broader population. Ultimately, the functional use of this approach requires much larger, population-specific samples.

Conclusions

To fulfill the promise of mHealth apps to improve health outcomes, apps need to be improved so they reduce participant attrition. Health care apps do not work for people who do not use them. To date, app feedback, notifications and reminders, in-app support, gamification, and participant compensation have not been consistently successful in eliminating participant dropout. This study highlights the potential to develop and refine mHealth apps using evidence-based interventions derived from a broad range of behavioral and social science to increase engagement as a way of improving participant retention. This viewpoint highlights the potential for mHealth researchers to test and refine mHealth apps using approaches to better engage users. The preliminary experience reported in this viewpoint supports the feasibility of this iterative approach to create and refine engagement interventional enhancements for each element of the multidimensional, multicomponent theory of the engagement process.

Data Availability

The data sets generated and analyzed during this study are not publicly available due to the data release requirements of the Patient Care Network and the intellectual property associated with this work but are available from the corresponding author on reasonable request.

Authors' Contributions

RM, AB, JPD, and IO-G conceived the mini-experiments designed to test the model developed by JPD and IO-G. RM and AB developed the app to collect data, coordinated with the Patient Care Network, and collected and analyzed the data. RM, JPD, IO-G, and SWD wrote the first draft of the manuscript. All authors reviewed and edited the manuscript and approved the final version of the manuscript.

Conflicts of Interest

RM, JPD, SWD, and AB were employed by Medable at the time the data collection and manuscript writing was done. ML and IOG are currently employed at Medable. Medable is a clinical trial software-as-a-service platform and evidence-generation company and supported the authors' conduct of this work without interference.

Abstract

The collection of sexual orientation in routine data, generated either from contacts with health services or in infrastructure data resources designed and collected for policy and research, has improved substantially in the United Kingdom in the last decade. Inclusive measures of gender and transgender status are now also beginning to be collected. This viewpoint considers current data collections, and their strengths and limitations, including accessing data, sample size, measures of sexual orientation and gender, measures of health outcomes, and longitudinal follow-up. The available data are considered within both sociopolitical and biomedical models of health for individuals who are lesbian, gay, bisexual, transgender, queer, or of other identities including nonbinary (LGBTQ+). Although most individual data sets have some methodological limitations, when put together, there is now a real depth of routine data for LGBTQ+ health research. This paper aims to provide a framework for how these data can be used to improve health and health care outcomes. Four practical analysis approaches are introduced—descriptive epidemiology, risk prediction, intervention development, and impact evaluation—and are discussed as frameworks for translating data into research with the potential to improve health.

Introduction

Research into health for individuals who are lesbian, gay, bisexual, transgender, queer, or of other identities including nonbinary (LGBTQ+) has consistently found that these populations experience poorer outcomes [1], with particularly strong and consistent evidence around poorer mental health for lesbian, gay, and bisexual adults [2]. LGBTQ+ health research typically uses 2 broad frameworks, sociopolitical or psychosocial models (where experiences of discrimination, victimization, stigma, and harassment are central to our understanding of health), and models of clinical, biomedical, and lifestyle risk factors [3]. Sexual health and HIV research falls mostly within biomedical frameworks; in practice, inequalities are interconnected [4,5]. Experiences of discrimination, harassment, and stigma have a profound impact on clinical health outcomes for LGBTQ+ communities [6]. Poorer health care access and quality among vulnerable groups exacerbate these impacts [7,8].

Data-driven LGBTQ+ health research has historically been based on convenience or purposive, rather than population-based samples [9], even in large-scale studies such as the National LGBT Survey in 2018 [1]. The collection of data on sexual orientation, gender, and transgender status has not been prioritized in routine sources [3]. Challenges in identifying understandable, meaningful, and acceptable measures, and concerns about LGBTQ+ respondents being able to answer questions safely, have been additional barriers to data collection [10].

However, data are improving [11]. The Equality Act in 2010 placed a statutory duty on public bodies in the United Kingdom

to publish equality outcomes and report on progress in addressing disadvantage experiences by (among other characteristics) sexual orientation and gender reassignment [12], which had a strong positive impact. The Office for National Statistics has carried out development work on measures [13], and although the census in 2011 did not include questions about sexual orientation and transgender status, in part because of the concerns about respondent safety [10], by 2021 questions on both were included, with instruction statements that the questions were voluntary. In general, data collection for sexual orientation is more established than collection of data on transgender status and gender, although, for both, collections are improving.

This paper aims to provide a guide for how these improvements in routine data collection can potentially translate to improved health and health care outcomes.

Pathways From Data to Improved Health

LGBTQ+ health research using routine data sits within wider health data science research frameworks which are designed to leverage person-level routine health data (collected either from routine contacts with services or from infrastructure data resources designed and collected for policy and research) to improve outcomes [14]. Analyses fall under four broad translational pathways: (1) descriptive epidemiology, (2) risk prediction, (3) informing innovation and improvement, and (4) impact evaluation.

These pathways have the potential to improve outcomes by (1) providing evidence to inform policy and practice (descriptive epidemiology), (2) better targeting of interventions and understanding of population health needs (risk prediction), (3) more rational health service developments (intervention development), and (4) information on effectiveness informing commissioning or funding decisions (impact evaluation), respectively.

Health data science as a field has struggled with equality, diversity, and inclusion [15] and there are problems across the whole discipline. Algorithmic biases in risk prediction models, including in how models are developed, with differentially poorer functioning for minoritized groups, or inequitable outcomes when the models are implemented, are currently a particular area of concern [16,17]. In addition, missing data contribute not only to poorer risk model development, but to a lack of basic descriptive epidemiology, informed intervention development, or equalities impact evaluation. For LGBTQ+ health research using routine data, the pathways to improved outcomes are the same, as are the challenges of missing data [18].

Data

There are 5 groups or types of routine UK data sources—where information about sexual orientation and gender or transgender status are either well established or now starting to be recorded, beginning to address this lack of data. In the same way that LGBTQ+ health research balances both societal and biomedical models the data sources, which now include a collection of sexual orientation (more likely) or gender and transgender status (beginning to be introduced) reflect a balance of routine data from social and health sources. The five groups are (1) social science or societal data collections (including Understanding Society [19], birth cohort studies [20], educational cohort studies [21], and census data); (2) general and specific health surveys primarily designed to understand population health (including the Health Survey for England [22] and the National Survey of Sexual Attitudes and Lifestyles (NATSAL) [23]); (3) health services or patient surveys primarily designed for health service quality improvement (including the General Practice Patient Survey [24,25] and the Cancer Patient Experience Survey [26]); (4) health cohort studies (UK Biobank [27] and Our Future Health [28]); and (5) health records (including primary care research databases such as the Clinical Practice Research Datalink [29,30], and secondary and community services data sets, including the improving access to psychological therapies and mental health services data sets [31], and registry data, for example, cancer registry data [32]).

Put together, the data are starting to form a comprehensive collection but for each resource, there are strengths and limitations or challenges. For example, the Equality and Human Rights Commission was able to draw on quantitative evidence and data about sexual orientation and gender reassignment in work, education, and health in the State of the Nation report on equality and human rights in Britain published in November 2023 [33]. However, data access, sample size, measures of sexual orientation, gender, and health outcomes, and the ability to carry out longitudinal analysis and data quality vary across sources.

In terms of access to data, social science collections are primarily accessed without cost through the UK Data Archive; for sensitive fields, which often include sexual orientation or gender and transgender status, additional safeguards are in place. The UK Biobank and Our Future Health are 2 large biomedical data research cohorts accessed through trusted research environments (secure data hosting platforms) with relatively low but nonzero costs to researchers [28,34]. For all sources, access to data can require time and perseverance [11]. In terms of longitudinal follow-up, the UK Biobank is a mature cohort study, for which recruitment began in 2006 before sexual orientation and transgender status were routinely collected. Questions are included instead about sexual history, which provides some insight [34]. In contrast, Our Future Health for which recruitment began in 2022 has an inclusive gender question and questions about both sexual history and sexual orientation but only baseline data collection to date (recruitment is ongoing) [28].

Sample size is often a trade-off with detail. Understanding Society is a household panel survey designed to provide estimates about how life in the United Kingdom is changing and what stays the same over many years, with linked health and social data [19,35]. In common with other longitudinal and cohort data collections, the sample size is relatively small (about 40,000 people at baseline), compared, for example, to the General Practice Patient Survey which is a large cross-sectional survey designed to evaluate health care quality, which has a much larger sample size (about 700,000 responses) but with

much less nuanced health and particularly, social measures recorded.

Pooling data across sources is an approach to increasing sample size [36], and again resources are improving, estimates across an in-depth range of health outcomes from the Health Survey for England using data from across 7 years have recently been published [22].

Data from electronic health records (EHRs), or data routinely recorded as part of clinical or health care encounters offer both detailed health outcome data and large sample size. The challenge is often that for EHR data collections, in contrast with research data infrastructure resources, or survey-based health data collections, measurement of sexual orientation and gender or transgender status is less good. In part, this is because these are resources not designed for research but primarily collected as clinical documentation. Pilots have begun to improve recording, to support audit and quality improvement. However, given both historic discrimination experienced by the LGBTQ+ community based on sexual orientation recording in medical records, and the interpersonal interlinking of recording and coming out to a care provider [37,38], this solution to data improvement is not simply a neutral administrative process. The reluctance of health care providers to ask about sexual orientation is a second barrier [39]. Recent research using EHR has provided insight by looking at transgender patients in primary care records based on prescribing and clinical codes, and this is an exciting area of progress [29,30]. These approaches have their own challenges, however, with historic clinical codes including outdated and discriminatory terminology still present in some older coded EHR records [18]. Legal barriers to identifying transgender patients after transition provide a further barrier to research using EHR; legislative changes have been required for recent quantitative analyses [40].

There are notable areas where data are poorer. Data governance and ethical challenges mean that data collections are much less likely to collect information on sexual orientation or gender from children. For example, some research studies have used proxies or less detailed response options where exact measures of ethnicity, gender identity, or disability cannot be asked [41]. Although HIV and sexual health research are well-studied topics in LGBTQ+ health research overall [42], routine data are usually more strongly safeguarded and less available for research, although measured in some collections.

Applied Methodology

The improvement in data collection for LGBTQ+ health research in the last decade mean that the applied methodological research around the use of these data is also developing. Questions about the longitudinal consistency of self-reported sexual orientation and history have been explored; changes are more frequently reported at younger ages [34,43,44]. For sexual orientation, missing data have reduced over time since the question has been routinely introduced in surveys [45]. Secular trends are also being better understood [44,45], meaning that age, period, and cohort effects in LGBTQ+ health research can begin to be untangled [24]. Differential item functioning for new questions

among groups for whom English is a second language is a current area of concern for new gender questions, although this is unlikely to be a methodological issue specific to these particular items. The challenges of longitudinal consistency in question wording needing to be balanced against requirements for relevant and up-to-date survey items is again a methodological challenge not specifically limited to questions about sexual orientation and gender. New, nuanced, tools for understanding gender are beginning to be developed [46]; however, space constraints in surveys mean that often only single items are asked. While free text or more in-depth response options (or allowing multiple rather than single responses) are more inclusive [47,48], these nuanced data are often excluded from quantitative reporting. Data for people who identify as asexual are very limited, as are data for people with variations in sexual characteristics.

How Have These Data Translated Into Applied Research?

As LGBTQ+ routine data are improving, the insights that come from descriptive epidemiological LGBTQ+ health research are also developing. For example, historically, studies using routine data have been able to consider cancer risk factors such as, smoking and alcohol consumption [49-51], more easily than rarer cancer outcomes such as incidence. Limited sample size and poorer measurement of outcomes mean that earlier studies looking at cancer were cross-sectional and could only consider cancer prevalence without disaggregation by diagnosis [52]. Larger cross-sectional data sets have allowed disaggregation of diagnoses among lesbian, gay, and bisexual patients with cancer, identifying disparities primarily in HIV and human papillomavirus–associated cancers [26]. More recent work has for the first time in the United Kingdom been able to look at the impact of higher smoking prevalence identified in earlier studies on lung cancer incidence, using the UK Biobank resource [53], connecting both biomedical and sociopolitical frameworks; the LGBTQ+ community has historically been targeted by tobacco marketing.

Inequalities in LGBTQ+ mental health outcomes have also been well established through a series of studies and meta-analyses using routine data from the United Kingdom [54]. In our recent work collaboratively exploring LGBTQ+ research priorities, intersectionality (understanding the interdependent and overlapping systems of discrimination and disadvantage) was identified as an area of research need; and race, ethnicity, and socioeconomic inequalities were particularly highlighted [55]. Larger sample sizes mean that intersectionality can now begin to be explored quantitatively [56]; newer longitudinal collections are providing additional insight [57].

Again, it is not just biomedical models that are important. Routine educational data sets have been important in highlighting the higher levels of bullying experienced by young LGBTQ+ people in schools [21].

However, we also know that on its own research describing inequalities experienced by LGBTQ+ adults will not lead directly to improved outcomes. Process measures of care quality

are often easier to improve than more tangible health outcomes. However, although disparities in primary care access, communication, and satisfaction were measured routinely between 2011 and 2017, inequalities experienced by lesbian, gay, and bisexual adults persisted across the time period [58].

Impact evaluation is a second pathway, therefore, where routine data are beginning to be used to provide insight with the potential to change the care process and improve LGBTQ+ health outcomes. The collection of sexual orientation information in the Improving Access to Psychological Therapies data set has allowed inequalities evaluation of these services for lesbian, gay, and bisexual adults, finding that they were not as effective as for heterosexual service users [31]. In contrast, an inequalities evaluation of the introduction of telephone triage in general practices using the GP Patient Survey found that although there was variation between practices in outcomes, for different groups of patients within the same practice, including lesbian, gay, and bisexual adults, there was no evidence of differential impact on access to primary care [59]. The Millennium Cohort Study has been used to understand the differential impact of the COVID-19 pandemic on sexual minority groups [57], as has Understanding Society [60].

Where to Next—Routine Data Analysis?

Routine data for LGBTQ+ health research are much better today, in 2024, than they were even 10 years ago. Sexual orientation has now been collected in many sources for over a decade and more diverse and inclusive gender measures are being introduced, and are established in some collections. Of course, measurement needs to continue and is continuing to improve, and there are limitations and barriers; no data set alone is perfect. However, across the spectrum of sources, there is a real depth of data now available and in terms of research, the data are good enough now to at least start thinking properly about how we can use these resources to improve LGBTQ+ health and tackle inequalities.

In terms of data development, of course linkage is 1 exciting potential future avenue, with the linked 2011 census and routine health care data in Scotland providing a possible model for future development. But in reality, using routine data for LGBTQ+ health research lies within the wider UK research landscape for using routine data overall. Here the Goldacre review probably shines some light on the direction of travel [61]. Access is becoming more cautious, and data are becoming more securely safeguarded, new frameworks and solutions are needed to ensure that access continues and barriers do not increase [62]. For sensitive fields such as sexual orientation, gender, and transgender status, this is particularly important, but it is likely that time, patience, and perseverance are going to continue to be required when working in this space. As a balance to concerns about the use of person-level data, tools sharing aggregate data such as the census resources from the United Kingdom's Office for National Statistics [63], and the analysis tool for the GP Patient Survey remain important resources and provide real insight.

So, the question remains, how are we going to use these data to improve LGBTQ+ health? Although the data are better, the

approaches have not changed and the methodological answers to the pathways from data to improved health remain the same. The four pathways are (1) descriptive epidemiology, (2) risk prediction, (3) informing innovation and improvement, and (4) impact evaluation.

Given the recentness of the data improvements and that data resources are still improving, there remains a real need for basic epidemiological descriptive work using these new data to answer questions and provide insight where simply the data have not been available before. More in-depth analyses, analyses considering longitudinal changes, and better measures of health and health outcomes, as well as sexual orientation and gender and transgender status, are all part of this. Frameworks for addressing health inequalities require researchers to go beyond simply describing known inequities [14], but for LGBTQ+ health there is still an evidence gap where descriptive epidemiology that focuses on areas where research could have an impact on policy has a place.

Maybe the results will be unsurprising, and research may show that inequalities have not disappeared as the data have improved, but the work is still important, and insight is still needed.

Risk prediction as a field has real challenges ahead to get to grips with equality, diversity, and inclusion, and this needs to include LGBTQ+ health. For transgender health specifically, there are some more questions to ask around risk model development; the exclusion of transgender adults from the development of some risk scores [47], and lack of clarity about how to implement scores based on binary gender or sex classifications are some specific issues to add to these [18]. Although methodological work is still needed to understand the best way to develop and implement risk scoring for transgender patients to avoid potentially both under- and overtreatment, the critical first step is to ensure that data used for model development do not exclude transgender populations before the research begins.

In terms of intervention development and audit, the improvement of data is important to ensure that evidence-based interventions are developed and part of wider thinking about how routine data can improve health and LGBTQ+ health in particular. Specific clinical data sets, such as cancer data collections or more in-depth surveys such as NATSAL will be particularly important in this domain. Much local evaluation of LGBTQ+ health interventions remains qualitative [64], and the evidence base for health equity audits to address inequalities remains poor [65].

The importance of including explicit inequality analyses in impact evaluations remains a key analysis strategy for improving health. Even when interventions are not LGBTQ+ specific, there may or may not be an inequitable impact. This kind of routine equalities impact work for LGBTQ+ and other groups is central to the drive the Equality Act has given to the improvement in data that we have seen, and needs to become a routine part of evaluative work.

Where to Next—LGBTQ+ Health Research?

The data are good enough now for routine data to play a substantive part in LGBTQ+ health research, and there are clear and realistic pathways for how this research can potentially improve health. This comes within the wider context of flourishing LGBTQ+ health research overall [66]. Health and health care are complex [67]. It is not a linear pathway from data to improved health outcomes; but good research can play a part.

There are particular challenges for health research with LGBTQ+ children and young people, where data are often less frequently collected and ethical and governance considerations are particularly important, and there is an identified need for more research [68,69].

The co-option of research findings into homophobic or transphobic narratives is a further difficult area, as are avoiding some of the blind spots around equality, diversity, and inclusion in routine data research that are beginning to be identified particularly in risk prediction work [15]. Good communication and cautious interpretations of findings are part of the solution, as are patient and public involvement, and the involvement of LGBTQ+ communities in identifying research priorities and in carrying out research [55]. Best practice guidance for LGBTQ+ health research [70], inclusive public involvement [71], and involvement in LGBTQ+ health research [72] provide some signposts for researchers.

Conclusions

Descriptive epidemiology, risk prediction, informing innovation and improvement, and impact evaluation are 4 practical pathways from data to improved health. Data for LGBTQ+ health research are now good enough and improving. We know that health inequalities exist, within both societal and biomedical frameworks. Research with strong public involvement, good clear communication, and stakeholder involvement is key, as in all research. Overall, this is a positive story for routine data. We are at the stage where the analysis of routine data can contribute to making real practical steps toward informing policy and practice, better targeting of interventions and understanding of population health needs, more rational health service developments, informing commissioning or funding decisions, and improving LGBTQ+ health.

Abstract

The COVID-19 pandemic led to behavioral exacerbations in people with dementia. Increased hospitalizations and lack of bed availability in specialized dementia wards at a tertiary psychiatric hospital in Singapore resulted in lodging people with dementia in the High Dependency Psychiatric Unit (HDPCU). Customizations to create a dementia-friendly environment at the HDPCU included: (1) environmental modifications to facilitate orientation and engender familiarity; (2) person-centered care to promote attachment, inclusion, identity, occupation, and comfort; (3) risk management for delirium; and (4) training core competencies. Such practical solutions can also be implemented elsewhere to help overcome resource constraints and repurpose services to accommodate increasing populations of people living with dementia.

Background

The spread of SARS-CoV-2 causing COVID-19 required significant reorganization of the Singapore health care system to support the rising number of COVID-19 cases and associated mental health issues [1,2]. Postponement of nonurgent clinic appointments due to reallocating hospital resources for pandemic control and patients' fear of contracting COVID-19 led to significant delays in treatment and further increased the risk of psychiatric relapses [3]. Reduced physical and cognitive activity from the cessation of dementia daycare programs and limited social engagements due to restricted visits with friends and family further increased social isolation and behavioral exacerbations in people with dementia [4]. On top of this, unemployment, work-from-home policies, quarantine orders, and home-based learning put family members in closer contact with people with dementia. This struggle to cope with the increasing care demands of people with dementia has resulted in greater caregiver burnout and hospitalizations for respite care [5,6].

Due to the shortage of beds in the dementia wards at the Institute of Mental Health (IMH), a tertiary psychiatric care facility in Singapore, people with dementia are occasionally lodged in the High Dependency Psychiatric Care Unit (HDPCU) of the IMH, which was not initially designed for dementia-friendly interventions. In this viewpoint, we provide insight into easily implementable and practical creative solutions that have been used to accommodate people with dementia in the HDPCU during the COVID-19 pandemic, overcoming resource constraints and repurposing services in the face of changing needs using a patient-centered approach (summarized in Table 1).

Table 1. Summarized framework for customizing a care environment for people with dementia.

Principles	Examples

Environmental modifications to facilitate orientation and engender familiarity	• Clear signs and signage
	• Sizable and readable calendars and clocks
	• Frequent reorientation by staff
	• Nurse in areas allowing natural sunlight and views of greenery
	• Simulate home-like surroundings, including
	  • partition areas to create "rooms" for different activities
	  • place photographs of friends/family close to the patient's bed
	  • arrange regular communication between the patient and their family/friends via video calls

Person-centered care to promote attachment, inclusion, identity, occupation, and comfort	• Obtain a detailed personal history from family/friends regarding the patient's preferences
	• Surround the patient with items that affirm their personhood, including
	  • playing songs that bring comfort or voice recordings of family/friends in the ward
	  • addressing patients by their usual/preferred nickname
	  • if possible, allow patients to wear/have sentimental items close by
	• Empower patients to exercise choice as much as possible, no matter how small the decisions may be
	• Encourage patients to join together for meals and games
	• Engage patients in meaningful and mentally stimulating activities
	• Express comforting interactions and validate patients' concerns
	• Patiently answer repeated questions and allow relatively more time to perform tasks

Risk management (delirium)	• Actively take measures to prevent delirium, including
	  • restrict physical restraints to only when necessary, and even then, for the shortest duration required
	  • minimize medications that risk iatrogenic delirium
	• Obtain a corroborative history regarding patients' expression of discomfort to recognize signs of distress and address agitated behavior promptly

Core competencies (training if required) of staff	• Understand core concepts of and practice person-centered care • Geriatric-specific care, including fall and choking risks, along with activities of daily living support • De-escalation skills for agitated geriatric patients

Environmental Modifications of the HDPCU

The HDPCU is a specialized inpatient unit devised for patients with an acute psychiatric disorder linked to severe agitation or aggression, placing them at significant risk to themselves or others, leading to the requirement of close monitoring. The nursing counter is sandwiched between two locked gender-specific cubicles with 4 and 6 beds, respectively, and single bathrooms. The nurse has a full view of both cubicles and there are various discreetly placed security cameras. Items that could fuel self-harming or suicidal behaviors, such as wires for electronics, plastic bags, detergents, sharp pencils, and utensils, are strictly prohibited in the ward. There is a 2:1 nurse-to-patient ratio. Staff are specially trained in swift de-escalation to ensure safety and prevent violence, including applying physical restraints and administering oral and intramuscular sedation if required. A psychiatrist, a junior doctor, and the nursing and allied health care team are on site to manage the patients.

People with dementia often experience disorientating situations due to separation from familiar settings, people, and routines. Dementia wards have specific modifications to orient people with dementia, such as legible signage; large clocks; brighter lighting; and contrasting-colored walls, furniture, and utensils [7]. Renovating the HDPCU to suit such requirements was not immediately feasible. Hence, modifying the environment to have clear signs indicating the bathrooms; a sizeable hand-drawn daily calendar facing the bed indicating the date, day, month, and year; and verbal reorientation 3 times a day were implemented to facilitate orientation. People with dementia were also nursed opposite a readable digital clock and beside big windows that offered a view of greenery and allowed in natural sunlight.

Dementia wards engender familiarity by creating homey surroundings, including paintings hung along corridors and divided kitchen, bedroom, and living room spaces. Since safety is of utmost priority in the HDPCU, rules are often strict, and cubicles are designed to be relatively smaller than found in other wards along with an open layout for easy monitoring. These restrictions may cause people with dementia, particularly those who like to wander, to feel trapped and anxious. Given the nature of patients admitted to the HDPCU, the noisy and disruptive atmosphere can destabilize and frighten people with dementia. To create a calm environment that minimizes overstimulation and distractions, people with dementia were nursed in a partitioned visitors' area accessed via a corridor

adjacent to the cubicles and nursing counter. Families of people with dementia were encouraged to bring photographs to place in front of patients' beds and participate in regular video calls from the ward smartphone to lessen the effects of visitor restrictions during the pandemic [8]. The sectioned area also reduced the risk of impaired sleep-wake cycles and sun-downing behaviors that are common among people with dementia and could provoke other patients. The improvised space simulated a private bedroom, while a wheel-in television and movable couches in the cubicles' shared living area imitated a makeshift living room.

Promoting Person-Centered Care

In person-centered care for people with dementia, personhood consists of attachment, inclusion, identity, occupation, and comfort. Emotional distress is usually triggered by unmet needs related to aspects of personhood. Obtaining a detailed personal history from the family regarding the preferences of people with dementia is essential to affirm personhood. For one such patient, playing Chinese songs from his childhood, hearing voice recordings of family, addressing him by his preferred nickname, and wearing a jacket gifted from his daughter in the ward provided a sense of comfort, identity, and continuation of self. Empowering the patient to exercise choice as much as possible, even for tasks as small as choosing a preferred snack, preserves autonomy and dignity. Encouraging people with dementia to join other patients during meals and games instills a sense of inclusion and occupation [9,10]. Engaging people with dementia in meaningful activities mentally stimulates and reduces the restlessness related to the tendency to worry about their situation. Expressing warmth through comforting interactions, patiently answering repeated questions, allowing them more time to perform tasks, and validating concerns can help to settle the wariness and diminished sense of attachment experienced by these patients. These efforts promote the therapeutic relationship and trust between staff and people with dementia, ultimately reducing aggression and distress.

Risk Management

Lastly, because people with dementia are prone to delirium during acute hospitalization, the HDPCU team actively took measures to prevent this risk. Physical restraints were only applied if verbal de-escalation repeatedly failed and the extreme agitation posed a safety risk to themselves or others; when required, patients were restrained for the shortest duration necessary. Wherever possible, medications that risk iatrogenic delirium in people with dementia were avoided, such as short-acting benzodiazepines for tranquilization, anticholinergic drugs, and opioid-containing analgesics. People with dementia often have issues communicating their needs and are likely to only respond to their present state due to verbal difficulties and memory problems. Obtaining a further history regarding the patients' typical behavioral patterns and expression of discomfort from pain, hunger, thirst, or constipation helped the team promptly recognize signs of distress and address agitated behaviors early without escalating to restraints.

Prospects

In conclusion, hospital care conditions can be difficult for people with dementia as they require familiarity, frequent orientation, and a high level of staff trained to handle their needs. The HDPCU adapted to rapid hospital protocol and health care policy changes during the COVID-19 pandemic and the resultant rise in the inpatient dementia population. Although the HDPCU staff were not geriatric-trained, the favorable staffing ratio and expertise in handling agitated and aggressive patients made it easier to implement person-centered care. Such conditions may not be available in nonspecialized wards, posing a challenge for catering to the increasing population of people with dementia admitted to hospitals in Singapore. Nonetheless, creative solutions could be established to customize the environment for such patients aptly. Hospitals could also consider bringing in key "experts" such as psychogeriatricians and geriatric nurses to advise on optimizing nonspecialized wards and provide training to care for people with dementia.

Abstract

Climate change, local epidemics, future pandemics, and forced displacements pose significant public health threats worldwide. To cope successfully, people and communities are faced with the challenging task of developing resilience to these stressors. Our viewpoint is that the powerful capabilities of modern informatics technologies including artificial intelligence, biomedical and environmental sensors, augmented or virtual reality, data science, and other digital hardware or software, have great potential to promote, sustain, and support resilience in people and communities. However, there is no "one size fits all" solution for resilience. Solutions must match the specific effects of the stressor, cultural dimensions, social determinants of health, technology infrastructure, and many other factors.

Introduction

In recent years, a series of stressful events has caused substantial economic, physical, and medical harm worldwide. As of June 2024, the COVID-19 pandemic that began in early 2020 has been estimated to be responsible for about 1,193,535 COVID-19–related deaths in the United States alone [1]. It was responsible for one of the worst global recessions in recent history in addition to causing great disruption to normal life due to lockdowns, closures of educational institutions, shutting down of tourism and travel, and a host of other adverse impacts [2-6].

In addition to pandemics, climate change has emerged as an economic and public health threat [7-10]. Climate change continues to intensify the emergence of pathogenic diseases and exacerbate pandemics and infectious disease outbreaks such as Ebola, COVID-19, and Mpox [11,12]. Mental health has been identified as a casualty of climate change worldwide [13-16].

Migrant and refugee populations are also subject to increased health risks [17,18].

Adverse events, whether disease outbreaks or climate-driven events, cause significant stress to people, communities, and organizations, threatening human health and animal health while exacerbating systemic inequities. These events highlight the importance of building resilience in communities to prepare for and mitigate the impact of these stressors on people and communities.

Resilience has been defined in several ways (see Multimedia Appendix 1 [19-22]). In this paper, we will use the comprehensive definition from the US Agency for International Development: "the ability of people, households, communities, systems, and countries to mitigate, adapt to, and recover from shocks and stresses in a manner that reduces age and chronic vulnerabilities and facilitates equitable health outcomes" [19]. The discipline of resilience research investigates and develops

evidence-based strategies, technologies, knowledge, and information to build preparedness and inform response and recovery across communities [23]. These stressors can include pandemics, floods, droughts, and displacement of populations due to conflicts, among others. It is noteworthy that these events can be recurrent [24]. While these stressors can affect all aspects of society and the environment, including agriculture, economics, industry, and infrastructure, in this paper, we will focus on resilience relating to public health threats. Thus, all references to resilience in the following should be understood as relating to health.

Informatics and communications technologies are essential infrastructures worldwide. Due to their increasingly powerful capabilities, these technologies have great potential to play important roles in supporting resilience. In this paper we propose Resilience Informatics (RI) as the application of informatics techniques to materially improve and promote the ability of people, communities, and organizations, to effectively cope with natural and man-made stressors [25]. We introduce RI as a people-centric field of study, research, and development.

Climate and Pandemic Resilience

Climate change threatens human health and well-being in myriad ways: warmer temperatures are expected to increase the risk of vector-borne diseases [26]; elevated temperatures are projected to result in deaths of millions by the year 2100 [27]. Of particular concern among certain island nations and coastal zone communities is the rise in sea levels which could result in the submergence of these locations. This could lead to large-scale displacement of people [28,29]. The impacts of a changing climate are already evident across the United States: in 2012 alone, the economic cost of climate change effects including wildfires, ozone pollution, heat waves, mosquito-borne disease was US $10 billion (in 2018 dollars) [30]. While direct impacts on health include morbidity and mortality associated with extreme weather events such as heatwaves and floods, indirect health impacts to adults and children are caused by changes in the dynamics of vector-borne and water-borne diseases, malnutrition due to decreased food security, and population displacement that may arise through alterations in our environmental and social systems [31-33].

Climate resilience refers to the ability to prepare for, recover from, and adapt to the threats associated with a changing climate, including but not limited to more frequent and severe extreme weather events and prolonged droughts. Climate resilience centers around societies and communities mobilizing resources and partners to anticipate these risks, reducing community vulnerability to those risks through infrastructure and other investments, preparing for, responding to, and recovering from these events.

Crisis Informatics and RI

Crisis informatics, also known as disaster informatics, is "a multidisciplinary field combining computing and social science knowledge of disasters" [34,35]. Crisis informatics has a major focus on the informatics needs of first responders such as firemen, construction workers, and health care workers including medics, nurses, and physicians. Crisis informatics tools have

been proposed to improve the efficiency of crisis response methods such as evacuations, provision of medical supplies, and disaster preparation. Mobile tools [36] have been used during crises to assist affected individuals and these can be viewed as examples of RI tools for, typically, short-term immediate responses to crises. By contrast, RI has its sole focus on improving the ability of people and communities to successfully cope not only with disasters but also to prepare for long-lasting and recurrent threats to health.

About Resilience Informatics

In the broad sense, RI encompasses (1) data science and artificial intelligence to aid the design, development, and evaluation of resilience strategies; and (2) hardware, software, and systems that translate resilience strategies into customized tools for people and communities. Well-designed RI tools can play an important role in strengthening local capacities in public health. Measurement of health resilience among people and communities is of particular importance. The recent COVID-19 pandemic saw the development and deployment of a host of informatics tools including contact tracing, disease surveillance, and messaging [37-41].

Classification of Stressors

The nature, design, requirements, and development processes of RI tools could vary across 2 types of stressor events as defined below. We identify drivers of resilience whose impact could be enhanced by RI tools and systems.

Type (1) Acute Events (eg, Floods or Wildfires)

Here, a major role of RI is to develop tools and systems that disseminate educational information on resources for resilience and recovery and gather data for computing and measuring resilience metrics. If a cellular data infrastructure is available, as in crises that do not affect basic infrastructures, the widespread availability of cell phones and the very high penetration rates of smartphones can provide very useful venues for this purpose [42]. Data gathered from cell phones can provide geo-coded and time-stamped information enabling dynamic identification of "hot spots" where resource allocation can be made to the most affected areas. These data can also be used to develop management dashboards for the benefit of public officials to monitor and inform decision-making. Typically, RI tools to promote resilience in type 1 events need to be developed rapidly, as soon as possible after the event has occurred to provide speedy assistance such as guidelines for recovery to affected persons.

Type (2) Long-Term "Chronic," Recurrent, and Persistent Stressors

Long-term and persistent effects of climate change, including hydrometeorological events such as droughts and warming temperatures, fall into this category. Another example is the transition of pandemics from an acute phase in which new infections occur at high rates, into a long-term phase in which new infections occur at greatly reduced rates while a percentage of persons who were previously infected have persistent consequences. The COVID-19 pandemic is an example [43]. Chronic stressors can cause acute stressors, for example,

excessive rainfall caused by changes in climate patterns. The major need for resilience to chronic stressors is to develop a culture of resilience. Here, data science and machine learning can identify data patterns that contribute to the long-term stressor as well as generate insights about efficacious responses and develop tools to reduce inequitable responses. Informatics tools developed for acute stressor response could be transitioned into systems to enhance resilience for chronic stressors. As noted previously, even in low- and middle-income countries (LMICs), cell phones have achieved very high penetration, providing a cost-effective and highly accessible means for providing targeted information and gathering data. As an example, in the last 10 years, mobile health tools in LMICs [44-47] have been intensively researched and could become common practice [36,46-50]. Notably, in LMICs the WhatsApp system is often used for videoconferencing between clinicians and remote patients [51].

Behavior Change in Resilience and the Role of Persuasive Technology in RI

Responding to stressors can require people and communities to change their behavior. A vivid illustration occurred during the COVID-19 pandemic. People worldwide needed to change their normal behavior both on individual and social levels. Frequent handwashing and the use of sanitizing wipes were recommended. Mask-wearing was mandatory when doing commonplace activities such as shopping and traveling on public transport.

Persuasive Technology (PT) [52] is concerned with the design of noncoercive tools and technologies to change human behavior. Following the original work of Fogg [52,53], Oinas-Kukkonen and Harjumaa [54] developed the Persuasive Systems Design (PSD) framework to guide the development of PT tools. Apart from Fogg 7 primary task support postulates, the PSD framework includes 3 major components in the design of PT tools: dialog support, system credibility support, and social support. A major focus in recent years has been the application of PT to support healthful behavior change [55-57]. Since, as noted above, behavior change can be an important comment on developing resilience, PT and PSD could help guide the design of effective RI tools and systems.

Drivers of Resilience and Informatics

Drivers of resilience include social contexts, community factors, economics, institutions, and infrastructure. An important area of future research is to identify the role of RI and the designs of RI systems to enhance the effectiveness of these drivers of resilience.

Social Contexts

Societal structures tend to be either individualistic or communal in nature and shape RI systems developed for the given level of structure (town, county, or state) [58-61]. In the example provided above, social media is highlighted as a communication

mechanism. The use of social media as an adaptive management tool has become increasingly prevalent which can be seen through the move of the news to social media sites [62] and the use of technology for this purpose has been seen through the development and use of messaging apps for flash flood warnings, silver alerts, and amber alerts [63,64]. These systems have proved effective in communities, and so the adaptive management approach and systems, which can easily change to include more information and updates about the status of the crisis, emergency, or disaster, can contribute substantially to developing a substantial resilience procedure.

Community Factors

Community factors that drive resilience include social groups, religious charitable organizations, and community food banks [61]. During the first part of the COVID-19 pandemic in 2020, communities in New York worked to form social groups through social media (Facebook or WhatsApp chats), which worked to establish a mutual aid system to provide resources such as groceries, masks, etc, as well as services such as child care, pet care, and running errands, for at-risk individuals in the community [65]. These mutual aid groups drove resilience within their communities through a demonstrated dedication to the well-being of the population.

Institutions and Infrastructure Factors

The measures that an institution may take in approaching a stressor, and the adaptability of those measures, are determining factors in the effectiveness of resilience-driven responses to crises. During the COVID-19 pandemic, governments had to quickly develop responses to the pandemic that would prevent the spread of the disease and reduce its prevalence [66]. Hong Kong, Singapore, and Japan maintained contact throughout the pandemic to implement systems restricting the travel of their citizens, which would in turn contain the spread of COVID-19. Additionally, each of these governments developed systems of communication between the health care providers and the government to ensure the practiced pandemic response was maximally effective at any given time [67]. These responses to the pandemic, as aforementioned, were developed at the time of the pandemic. Institutions establishing RI systems must be able to develop adaptive systems that can rapidly respond to changes in the conditions of the pandemic allowing for an effective resiliency response to be deployed.

Development of RI Systems

Systems development can be greatly aided by following a conceptual framework. Apart from systematic development and evaluation, the benefits of doing so can include flexibility, extensibility (the ability to add features easily), scalability (the ability of the system to be used by greater numbers of people without redevelopment), and others [68]. We propose the following 6-component framework (Textbox 1) [25] as a guide for efficient and effective development of RI systems.

XSL•FO
RenderX

Textbox 1. The 6-component development framework for Resilience Informatics (RI) tools and systems.

Component 1: Team

- The team should be multidisciplinary and multisectoral, including experts in the target population, the environment, the technologies, and the specific resilience context.

Component 2: Requirements

- Requirements may include system features that maximize system effectiveness, for example, multilanguage capability, consistent appearance, and functionality across operating systems (eg, Android and iOS); screen sizes; judicious use of multimedia.

Component 3: Information

- The system must provide the correct and most pertinent information at the right spatial and temporal scales.

Component 4: Design considerations

- Design of an RI system, including the user interface, must consider aspects including but not limited to the target population's characteristics, social determinants of health, and cultural factors.

Component 5: Implementation

- Efficient and rapid implementation strategies need to be developed. The project must have a process for responding to the changing needs in the targeted population.

Component 6: Evaluation

- The system should integrate an evaluation strategy to continuously assess the impact of the project on achieving its objectives.

Component 1: Team

It is important to recruit a multidisciplinary, multi-sectoral team that represents all aspects or factors that contribute to resilience.

Component 2: Requirements

Evolving project scope and changes in the operating environment as the effects of a stressor unfold suggest that RI systems requirements need to be flexible to accommodate these changes. An adaptive management approach including the Agile development model [69] would be most appropriate. Ideally, the development methodology can enable rapid changes to the system even doing implementation and during subsequent operations to accommodate changing requirements. Requirements gathering may take a lot of time but will likely have to be accelerated in the case of acute events to develop the system and make it available to the target users as soon as possible.

Component 3: Information

RI interventions are based on data that help to provide correct and relevant information. This information must be tailored to the target users and match the cultural, linguistic, literacy, educational, and economic status of the target population.

Component 4: Design Considerations

The design of an RI intervention must be tailored to the characteristics of the target population. These include the intended level of resilience, that is, the household, the community, and the health care system. The system must be designed to match the technological capabilities available in the target context. For example, the availability of clean and reliable electricity can be a constraint in some locations. In addition, the intervention must match the education, culture, language, and other characteristics of target users. To aid

engagement and sustained benefits, frameworks for technology adoption and principles of PT and PSD could be useful [70]. Integration of theory in the design of the RI project is another important consideration that would occur at this stage to support its effectiveness and impact.

Component 5: Implementation

The RI project or system must have an efficient and rapid implementation using an adaptive management approach and considering currently available resources (eg, availability of data and communications infrastructures). The process should provide maximum benefits while incorporating a feedback loop to respond to changes in the operating environment that may necessitate changing requirements.

Component 6: Evaluation

Finally, it is important to integrate a logic model or similar implementation-guiding tool into the design of the RI system or project to support continuous evaluation efforts that can inform needed changes and modifications.

RI Case Study: AZCOVIDTXT

As an illustration of the RI development framework, we present the following case study of a technology solution implemented to support the resilience of the people of the state of Arizona in the United States to the COVID-19 pandemic [71].

Context

Beginning in March 2020, the COVID-19 pandemic caused immense disruptions to normal life. These disruptions led to an atmosphere of fear in which uncertainty, rumors, and misinformation caused widespread public confusion preventing people from responding effectively.

XSL•FO

RenderX

Purpose

To help alleviate this situation and enhance resilience among Arizonans, faculty including some of the authors of this paper, at the University of Arizona identified the need for an informatics strategy to provide much-needed authoritative and timely COVID-19 information to the public, and to gather information on how the pandemic was impacting communities' health, well-being, and them financially.

Informatics Solution

We chose text messaging, also known as SMS, as the messaging modality because it is low-footprint, ubiquitous, and eliminates the time and expense of multi-language app development for iOS and Android. SMS text messaging is an established multi–operating system technology, shown to be effective in health care [72,73], usage of text messaging is universal, and no specific training is needed for individuals to read and respond to text messages. SMS text messaging is inexpensive, and unlimited text messaging is often included in many cell phone plans. Enrollment occurred by text messaging a toll-free number, and via the AZCOVIDTXT website during which enrollees indicate their preference for receiving messages or surveys in English or Spanish. Enrollment was limited to those providing Arizona zip codes. For data collection we developed a simple REDCap (Research Electronic Data Capture; Vanderbilt University)-based [74] mobile survey tool (Figure 1).

Figure 1. AZCOVIDTXT system. CDC: Centers for Disease Control and Prevention; REDCap: Research Electronic Data Capture.
System Design Considerations

Requirements identified included supporting individuals in both English and Spanish, ease of use and installation, and the capability to gather data on COVID-19–related challenges. A mobile health approach was identified as the optimal strategy since even among disadvantaged groups, cell phone access or ownership is at 100% and smartphone access is at least 85% [75]. The resulting system, called AZCOVIDTXT, was developed and deployed in 4 weeks beginning in April 2020 and operated until March 2022.

Messages and other content were developed and curated by specialists in public health, health behavior change, and health communications, assisted by graduate students and staff at the University of Arizona. The message content was derived from authoritative sources such as the Centers for Disease Control, and new messages were developed weekly to reflect the latest information, including countering misinformation, on the availability of vaccines, outbreaks of SARS-CoV-2 variants, and other evolving events.

By March 2022, a total of 3746 households from 225 Arizona zip codes were enrolled in AZCOVIDTXT, and more than 522,000 text messages providing COVID-19–related information had been sent. Except for a few outages, surveys were sent about every 10 days and messages 3 times a week. Curated content consisting of nearly 200 news updates, SMS text messages to enrollees, and social media posts (@AZCOVIDTXT on Instagram [Instagram from Meta], Facebook [Meta], and Twitter [X Corp]) had been developed.

AZCOVIDTXT applied the 6-components principles for RI (Textbox 2) and successfully developed and deployed the system.

Due to the waning of the COVID-19 pandemic in early 2023, this system was discontinued.

Textbox 2. Application of 6-component Resilience Informatics development framework in AZCOVIDTXT.

Component 1: Team

- A multidisciplinary team of experts in informatics, mobile health, infectious disease epidemiology, health promotions, health behavior change, programmers, and students was assembled rapidly.

Component 2: Requirements

- Simplicity and ease of use were primary requirements. Messaging should be in English and Spanish and received on cell phones due to their very widespread use and minimal cognitive demand on a user. These requirements precluded the use of apps because apps take time to develop, need maintenance, and can require the user to download them on their phones. SMS text messaging in English and Spanish was selected since it is available on all types of phones (not just smartphones); the user interface is understood universally.

Component 3: Information

- Messages and content were sourced from authoritative sources (Centers for Disease Control and Prevention, World Health Organization) and curated by an infectious disease epidemiologist and health promotions expert assisted by University of Arizona graduate students and staff [71]. Weekly messages reflected the latest information and conditions (ie, vaccine availability or SARS-CoV-2 variant outbreaks).

Component 4: Design

- The team applied the requirements of simplicity and ease of use to design the AZCOVIDTXT website.

Component 5: Implementation

- The system was developed and deployed in 4 weeks using public-domain software and systems such as REDCap (Research Electronic Data Capture). This included a web site (now discontinued), and toll-free numbers for enrollment.

Component 6: Evaluation

- The performance of the system was evaluated by the number of families enrolled and the reach of the system.

Discussion, Issues, and Limitations

Overview

The public health system comprised of a web of federal, state, and local agencies, hospitals, nonprofit agencies, and businesses is at the forefront of the health response to climate change. Building climate resilience for the public health system requires understanding the complexity of the climate, health, and human systems that have unique innate behaviors and structures that contribute to risks and vulnerabilities and need to be considered when informing any community resilience-building strategy. The development of resilience could benefit from a systems-wide informatics approach that engages partners and stakeholders in the processes involved in recognizing threats, determining capacity, informing solutions, recovering from a crisis, and adapting the process to enhance our capacity to deal with the next crisis. RI systems could also play an important supporting role in the US Agency for International Development's Program Cycle [76] for enhancing resilience.

Issues and Limitations

It is important to note that RI tools and systems are subject to operating limitations caused by the stressor event. For example, issues such as inaccessibility to sufficient cellular network connection, low health literacy, and fragility of cellular networks may interfere with the effectiveness of an RI project. Older adult populations, who often tend to be largely represented in rural areas, may not be able to access new technology easily due to the rapid development of new technologies. Additionally, cellular networks may be overused in the case of an emergency which may lead to issues with communication via technology.

Initiatives, such as FirstNet, are being put into place to try to address this issue, especially for first responders and others who need to react quickly and coordinate with their teams during an emergency, but the public at large may still be negatively impacted [77]. Additionally, it is important to recognize the limitations of informatics tools being able to support and enhance resiliency. Resilience is a very large issue that requires a multilevel and multifaceted response, and informatics is only one part of the larger response that would need to occur for a community to be able to cope effectively in the face of a disaster.

Equity and Inclusion

The current issues and limitations of RI data communication lie within already existing socioeconomic discrimination and access difficulty of the methods of communication. Yang et al [78] discuss how underserved communities, identified as minorities, older adults, and the poor, were not considered in deciding systems for spreading disaster informatics data. By effect, these groups experience sizable differences in the disaster relief provided to them. As RI systems continue to become more heavily technology-reliant, these gaps in treatment could be further emphasized. Virapongse et al [79] detail how these gaps are becoming ever more important to address, as communities become more reliant on the data provided to them. They argue that working directly with stakeholders in underserved communities would allow for their issues to be directly addressed and prevent further inequitable treatment of these groups.

Tailored tools, interventions, and programs are a critical aspect of informing resilience and RI allows for this strategic, locally relevant decision-making. No model for RI will be effective for

every community, as the conventions and resources of each area differ greatly. Therefore, RI system designs must allow decision makers to adapt the model to fit the needs of their area. For information distribution, this would mean that decision makers would adapt their RI systems to account for the technology available to the given community and the preferences of each group of people in how they desire to receive information.

Conclusions

RI has great potential to enable and support strategies, resources, and technologies that enhance the ability of individuals, populations, and the environment to respond successfully to natural and man-made stressors. The conditions under which RI systems function impose design and other constraints that make RI distinct from other informatics environments. There is a great need for research to establish the basic principles of RI leading to the efficient development of RI systems to support resilience in the United States and globally. The 6-component framework presented here could be a useful guide to the efficient development and effective deployment of informatics tools to promote resilience in public health.

Abstract

Telehealth presents both the potential to improve access to care and to widen the digital divide contributing to health care disparities and obliging health care systems to standardize approaches to measure and display telehealth disparities. Based on a literature review and the operational experience of clinicians, informaticists, and researchers in the Supporting Pediatric Research on Outcomes and Utilization of Telehealth (SPROUT)–Clinical and Translational Science Awards (CTSA) Network, we outline a strategic framework for health systems to develop and optimally use a telehealth equity dashboard through a 3-phased approach of (1) defining data sources and key equity-related metrics of interest; (2) designing a dynamic and user-friendly dashboard; and (3) deploying the dashboard to maximize engagement among clinical staff, investigators, and administrators.

(Interact J Med Res 2024;13:e57435)   doi:10.2196/57435

KEYWORDS

Telehealth Equity

The COVID-19 pandemic catalyzed a surge in telehealth adoption [1,2]. However, disparities in access to and adoption of digital health care persist among Black, Hispanic, public-insured, low-income, and rural populations [3,4]. This "digital divide" risks worsening health disparities in these populations [5]. As such, Crawford and Serhal [6] created the Digital Health Equity Framework (DHEF) to guide the equitable design and implementation of future digital health interventions.

The DHEF takes into consideration, how individuals' sociocultural and economic contexts influence intermediate factors, such as environmental stressors and health behaviors, which then drive the digital determinants of health (eg, acceptability of or access to digital health and digital health literacy) at the root of these disparities.

While health systems can use the DHEF to implement equity-minded telehealth strategies, understanding and bolstering the quality of the digital infrastructure within the communities

XSL•FO
RenderX

they care for are critical steps to ensuring equitable access to telehealth [7]. Unfortunately, digital analytics are still lacking in understanding patterns of use for those underserved by technology infrastructure. Dashboards that showcase key performance indicators in real-time have become valuable tools to track health care access, understand disparities, and apply interventions. Yet, there are no consensus guidelines for the creation of telehealth-specific equity dashboards, which can apply the nuanced considerations for telehealth equity outlined through the DHEF to existing standards for data monitoring.

To standardize such dashboards, the Supporting Pediatric Research on Outcomes and Utilization of Telehealth (SPROUT)–CTSA Network formed the Telehealth Equity Workgroup. Evidence on best practices for the collection and use of equity-related data continues to evolve. Based on the review of the existing literature and the operational experience of clinicians, informaticists, and researchers in this workgroup, we aim to describe a strategic framework for adult- and pediatrics-serving health systems to execute telehealth equity dashboards through 3 phases: define, design, and deploy (Figure 1). In addition, we offer a checklist for framework navigation (Figure 2) to motivate more critical monitoring and evaluation of health systems' current telehealth practices and ultimately identify service delivery gaps.

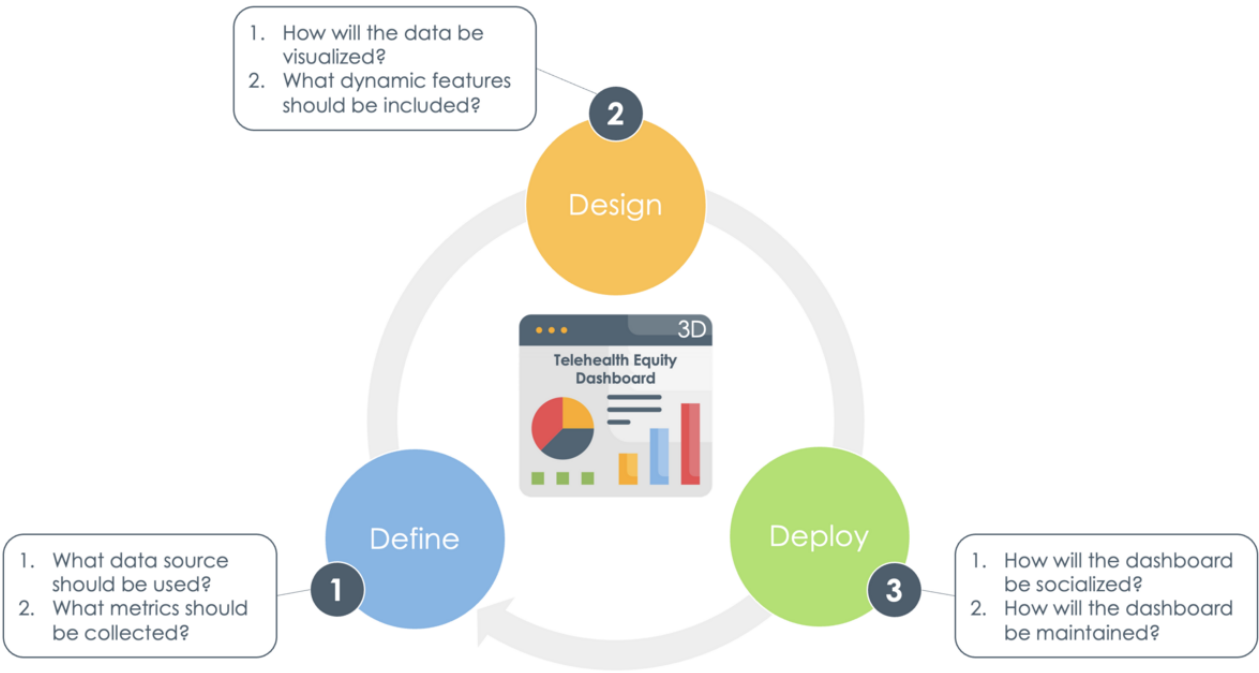
Figure 1. Telehealth equity dashboard framework.


Figure 2. Telehealth Equity Dashboard Checklist (aSTEM: SPROUT Telehealth Evaluation and Measurement).

Engaging Interested Parties

Before beginning to create a telehealth equity dashboard, health systems must identify all interested parties to balance diverse perspectives and priorities. This should include all potential dashboard users such as clinical staff, investigators, and administrators as well as dashboard experts and patient advocates. Early engagement facilitates institutional buy-in to both the development and use of a dashboard. In addition, as there is notable variation in data privacy regulations based on patient age, type of medical problem, local health system policy, and federal laws, early involvement of senior leadership can help ensure dashboards are implemented appropriately. Once identified, interested parties must be continuously engaged throughout all phases of the framework process to ensure these dashboards are developed with the intended users in mind.

Phase 1: Define

First, health systems should consider what data sources to leverage. Data source mapping is one useful technique to identify usable sources for dashboard development. This inventory process involves cataloging all available sources and describing potentially relevant data to allow teams to consider the feasibility, reliability, and quality of these sources [9].

Poor data quality can have negative downstream impacts, as inaccurate or incomplete data can mask disparities [10]. First, patient and caregiver demographics can often be conflated in pediatric and elderly care settings. In addition, previous research found that non-White patients were less likely to have the correct race in their health records and were often mislabeled as White, skewing disparities [11].

Several strategies can mitigate the limitations of missing or inaccurate data [12]. Imputation or Bayesian modeling techniques can help bolster existing data by addressing missingness with inferred values. For example, imputing race and ethnicity identified greater disparities in the COVID-19 pandemic compared with only excluding missing data [13]. Health systems can also enhance existing data by linking their databases to external sources to conduct area-based monitoring [14]. To illustrate, health systems could integrate regional-level population data from national datasets (eg, the National Survey of Children's Health or the American Community Survey for United States health systems) with internal patient data by census tract. Inequities can then be tracked between geographic regions to further support patients from medically underserved areas.

Unfortunately, these methods fail to address the root of data inaccuracy. Improvement of data collection processes is the best long-term solution. Staff training, patient education, and options for self-reporting outside of clinical encounters are the key to improved collection [10]. Greater transparency regarding the purpose of data collection and improved framing of questions to reduce discomfort in sharing sensitive data could also increase self-reporting [11].

Once data sources are established, health systems can select metrics from the domains of the SPROUT Telehealth Evaluation and Measurement Framework [8], including health outcomes (ie, disease-specific measures), health delivery (ie, quality and cost), individual experience (ie, patient experience data), and key performance indicators (ie, implementation measures), as well as equity stratifiers (ie, environmental and patient attributes). In addition, defining each metric's performance target is critical. Targets can be based on peer organizations' performance, past institutional achievements, national-, state-, or county-wide standards, and public policy goals.

Phase 2: Design

Next, health systems should carefully consider the design of their dashboards, as literature demonstrates how data aggregation and visualization influence the ability to detect disparities. Common broad racial or ethnic categories such as Black or Hispanic obscure within-group differences that can have significant clinical implications [15]. For example, when Asian is grouped with Native Hawaiian and Other Pacific Islanders, such aggregated statistics conceal meaningful differences between subpopulations [16]. Thus, it is important to present data as disaggregated by equity stratifiers as possible, acknowledging that some level of aggregation is necessary given data quality limitations. A recent proposal for revised federal government standards for race or ethnicity classification may guide new best practices [17].

We recommend, at a minimum, comparing data from medically underserved populations tailored to each health system with an aggregated "catch-all" category. Health systems may consider including a reference, which is often the total population, or the group with the largest population, the most favorable health outcomes, or the greatest socioeconomic advantage [18]. However, there are risks of identifying a "reference" group. Selecting White, for example, as the "reference" population may inherently imply "nonreference" populations require assimilation or acculturation or are generally "abnormal."

In addition, designing dashboards with filter functionality across multiple metrics can provide more robust analytics and displays. Irrespective of the population that a health system serves, intersectionality, or the connection between personal identities, is another key attribute to dashboard design, allowing for a more in-depth look at identified disparities. Race as a stratifier on its own could be a proxy for other variables underlying why these disparities exist. However, through filter functionality, users might consider assessing telehealth equity across races with another key attribute such as social determinants of health or internet access [18].

Designers should follow best practices for data visualization [19], including maximizing data-ink ratios and selecting the appropriate software for desired displays. Commercial visualization tools can be found in Figure 2. When choosing visualizations, it is essential to consider ease of interpretation and potential risks of misrepresentation. Tables explicitly lay out comprehensive information but can be difficult to digest. Interpretation can be supported through bolding or color-coding. Graphs can simplify data presentation and draw attention to specific insights, but this simplicity can be misleading [18]. It is essential to include missing data percentages to illustrate uncertainty and incorporate features to understand the context of the data for accurate interpretation. For instance, when interpreting a narrowed disparity, the availability of hover functionality to display numerators, denominators, and count breakdowns for each data point can help users understand the source of this change. In addition to reporting current statistics, the ability to view metrics over time permits the detection of trends and postintervention changes in disparities, which is an essential dashboard function.

Once a preliminary design has been determined, teams can develop a draft dashboard. From this point forward, design and development should proceed concurrently. The draft dashboard should undergo pretesting with sample end users, which can subsequently inform alterations to the design. Keep in mind, multiple designs are likely needed to accommodate different audiences, from frontline staff implementing care and

XSL·FO

RenderX

monitoring day-to-day activity to administrators interested in quarterly or annual trends.

Phase 3: Deploy

Finally, intentional deployment of a telehealth equity dashboard is critical to increase use, inform and monitor operational and clinical interventions, preserve institutional buy-in, and create a data-driven culture to improve health equity.

Socialization, the process of organizations adjusting to, learning about, and buying into a new initiative, is a key aspect of successful dashboard deployment. Socializing with leadership and clinical providers allows teams to create relationships for long-term reporting and inspires clinicians to use the dashboard in day-to-day operations. Normalizing the use of equity dashboards at all levels can stimulate maintained awareness and action to improve telehealth equity hence laying the foundation for a culture of accountability and quality data collection to address disparities in telehealth and beyond.

In this phase, it is also essential to identify a cadence of dashboard review and updates, given the likely differing preferences among users. For example, leadership may expect a quarterly update on high-level telehealth equity experience, while interpreter services may desire monthly check-ins to monitor progress on their practice changes. Socialization with regular review allows for opportunities for feedback, which studies have shown improve data quality [20]. By recognizing the appropriate set of interested parties, health systems can continue to enhance their dashboards with the right feedback from a broader and inclusive user group.

Once the dashboard has been deployed, data can be used and updated to advocate for new programs or workflows supporting medically underserved populations. The implementation of a dashboard is an ongoing, iterative process through each phase. For example, the telehealth equity dashboard may highlight a disparity that motivates the creation of a new intervention. The implementation of a new intervention may then require new metrics to be added to the existing dashboard or identify other ways to track performance. The dashboard development team may thus return to phase 1 to re-evaluate their sources and metrics. In addition, periodic usability testing by end users can allow for the identification of these key areas of improvement for subsequent iterations. This process, akin to the plan-do-study-act cycle in improvement science, can ensure the adaptability and continual advancement of a dashboard to meet the demands of a dynamic health system [21].

Call to Action

Dashboards offer an avenue to improve data transparency. Data sharing, especially as it relates to equity, may be limited due to lack of incentives, fear of public scrutiny, or perceived opportunity costs if data are used for research by external parties [22]. However, this creates silos between and even within health systems. Data sharing has the potential to establish shared standards and cross-institutional efforts to improve health on the population level. Therefore, as technology use in health care advances, we must pay close attention to what the data are telling us, be transparent with our progress and shortcomings, and push for change in our care models to ensure equitable quality of and access to care for all patients.

Conclusions

The COVID-19 pandemic laid bare the implications of the digital divide on health disparities. Nevertheless, telehealth continues to serve as a potential cost-effective care model and promising access point for patients with barriers to in-person services. As such, our strategic framework for developing a telehealth equity dashboard offers a valuable means to track patterns of use and outcomes to provide the evidence needed to support continued investment in an equitable telehealth offering. Telehealth equity dashboards present a promising means to build a culture of data transparency, equity-centered implementation, and continuous improvement to narrow the digital divide and improve access to care for all patients in this expanding world of digital health care.

Abstract

Various behavioral and mental health issues have been reported by space crews for decades, with the overall number of mental health complications expected to be higher than is publicly known. The broad range of mental health complications encountered in space is expected to grow as people venture deeper into space. Issues with privacy, dual relationships, and delayed communications make rendering effective psychological therapy difficult in a spaceflight environment and nearly impossible in deep space. Automated psychotherapy offers a way to provide psychotherapy to astronauts both in deep space and low Earth orbit. Although automated psychotherapy is growing in popularity on Earth, little is known about its efficacy in space. This viewpoint serves to highlight the knowns and unknowns regarding this treatment modality for future deep space missions, and places an emphasis on the need for further research into the applicability and practicality of automated psychotherapy for the spaceflight environment, especially as it relates to long-duration, deep space missions.

Introduction

The assumed importance of mental health in a spaceflight environment has changed over time, with earlier mission planners thinking that mental health complications would not be an issue for sufficiently qualified personnel [1]. This "right stuff" mentality was thought to indicate that astronaut candidates who were resilient to stress, capable of operating under extreme pressures, and able to draw on a reserve of inner strength to push through dangerous and anxiety-provoking circumstances would be the ideal astronaut in space [2]. However, these highly specific selection criteria do not appear to be capable of picking individuals who are impervious to mental health complications during spaceflight, with a number of notable examples being reported over the past 60 years.

In 1982, a Russian cosmonaut reported struggles with isolation and depressed mood while in space [3]. A 1985 Russian Soyuz mission ended 60% earlier than expected due to what is believed to be issues involving "mood and performance" for crew members [3]. In addition, over the course of 89 American space shuttle missions, there were 34 separate behavioral issues reported among the 208 different crew members [4]. The differing labels used for these instances—hostile and uncooperative, depressed mood, mood and performance, and behavioral issues—reflect the imprecise way in which mental health complications have been discussed in relation to astronaut activities. It is important to note that these instances do not

necessarily reflect something that would have threatened the safety of crew or the mission and were often transient.

Of the psychological and behavioral problems that have been reported and made public, recorded issues include anxiety, depression, irritability, sleep-wake disorders, asthenia, interpersonal tension, impaired judgement, inappropriate behavior, stress, exhaustion, euphoria, neurosis, accentuation of negative personality traits, and various cognitive impairments [4-7]. While these reported psychological and behavioral problems are broad, it should be noted that these have all been reported in missions to low Earth orbit; it is not yet determined what psychological issues could present during long-duration, deep space missions. A general consensus is that all of these previously reported problems could occur in deep space, in addition to serious psychiatric symptoms, psychotic disorders, delirium, and homesickness, among others [4,8-10]. Although these examples are noteworthy, they do not give a complete picture of the mental health incidences that have occurred during spaceflight. It is believed that the actual incidence rate is higher than previously reported and that a number of astronauts may be unwilling to divulge these details with ground personnel [11]. The purpose of this viewpoint is to summarize the current state of automated psychotherapy for the spaceflight environment, especially as it relates to the advantages that it offers, the drawbacks associated with this treatment modality, and the current unknowns.

Current Treatments for Mental Health Problems in Space

Mental health interventions in a spaceflight environment begin at the crew selection phase, where astronauts are screened for commonly known psychological risk factors [2], commonly referred to as "select-out" logic. In addition, in accordance with "select-in" logic, previous research has indicated that the ideal psychological profile for a crew member for a space mission, especially a long-duration, deep space mission, is an individual with high levels of adaptability, resistance to stress, psychological stability, and strong social skills [12]. It is believed that these highly specific psychological selection criteria may help reduce the rate of psychological issues experienced during the mission. In addition, the Human Behavior and Performance Support Program, a component of NASA comprised of highly trained psychologists, physicians, and other mental health professionals, is tasked with providing support to an astronaut at all phases of the mission—before, during, and afterward. The Human Behavior and Performance Support Program offers entertainment and activities to counteract the detrimental effects of boredom and isolation, regular private video conferences with psychologists on the ground, interactions with family and friends, and other supportive measures to prevent mental health complications from escalating to a degree that may present problems for mission success and could require further treatment.

When a mental health complication is reported during a spaceflight mission, ground personnel, medical personnel, and astronauts have a variety of methods available to them to treat the condition. The first step often focuses on reducing the levels of stress that the astronaut is feeling, as the very environment of a spaceflight mission may produce physical and psychic strain on the astronaut through a combination of microgravity, noise, isolation, reduced privacy, radiation, work-leisure balance, and other factors [1,7,10,11,13,14]. While stress reduction is commonly used as a preventative measure, it is also helpful after symptoms of psychopathology have been reported [8]. One research team has categorized the general stress reduction strategies for a spaceflight environment to show their focus on 4 main areas: ergonomic (factors associated with the design of the spacecraft), physiological (factors associated with nutrition, sleep, and hormonal balance), psychological (factors associated with known psychological stressors), and psychosocial (factors associated with relationships between the astronaut and other crew members as well as ground personnel) [14]. Recommended treatments for dealing with stress while in space often involve increased leisure time, increased time spent communicating with loved ones on Earth, and structured interventions. One such structured intervention is the Spaceflight-Induced Stress Management Plan, which involves a series of group training modules that prepare astronauts for stressors and equips them with the skills needed to form support groups while in space [14]. Given the strong connection between reduced coping with stress and subsequent psychopathology [15], it is evident that the ability to de-escalate the stress that an astronaut is feeling may reduce their likelihood of developing mental health complications, symptoms, and disorders while in space. However, it is important to note that while stress reduction initiatives can help improve the overall mental health of an astronaut, they are not likely to be a sufficient intervention to treat psychopathological responses, such as depression, psychosis, or severe anxiety disorders.

In the event that a mental health complication has been reported that cannot be remedied by noninvasive stress interventions alone, it is recommended that some sort of psychological therapy begin [6]. Regular scheduled interactions between astronauts and a psychologist on the ground may provide a normalized way for crew members to discuss their emotions, relieve tension, and receive feedback from trained specialists [16]. However, the usual version of psychological therapy used on Earth, where a provider and a client have roughly 1 hour of uninterrupted, private, structured discussions using a standardized treatment, is exceedingly difficult in space, and there are little available data on the practice or outcomes of psychological therapy in a spaceflight environment. This will be discussed in further detail in the *Difficulties of Therapy in Space* section. In addition, the use of monitoring tools that can be used to capture intraindividual variability across various behavioral and mental health markers, including real-time physiological measurements and medical monitoring, should be explored as a way to passively and actively gather data on the current functioning of astronauts as a way of detecting potential mental health concerns as early as possible. Often, these tools are used in psychological research to produce reliable data and can involve nonintrusive wearable devices to detect heart rate and skin conductance (such as a ring or a wristband), as well as passive environmental monitors for eye tracking and movement.

A commonly used treatment for mental health complications in space is medication, which is a separate treatment modality from psychotherapy and may be used independent of psychotherapy or in conjuncture with psychotherapy. The current psychiatric formulary onboard the International Space Station includes antidepressants, antipsychotics, anxiolytics, anticholinergics, sleep agents, and wake agents [4]. It is important to note that these medications are helpful for treating the expected psychological disorders that may be encountered in low Earth orbit and do not include medications for more severe psychopathologies, such as more powerful antipsychotics. Rather, this formulary was created with the assumption that severe psychological emergencies may be treated by a rapid return to Earth. Future deep space missions may need a more comprehensive formulary for a setting where a return to Earth is not feasible [4].

Taken together, it is apparent that most interventions for mental health complications in a spaceflight environment have focused on crew selection criteria and methods for coping with stress. While psychiatric medications are available in space and have been used by at least 24 crew members spread out among 20 different missions [17], the efficacy of the gold standard of psychological care, structured psychological therapy, is largely unknown for the spaceflight environment. The following section will focus on this topic.

Difficulties of Therapy in Space

It is recommended that physicians aboard the International Space Station be trained in psychological therapy in order to provide direct psychological care to crew members with a psychological disorder or symptom [18]. However, the American Psychological Association's Ethical Principles of Psychologists and Code of Conducts outline that a psychologist providing therapy to an individual, while at the same time already possessing another relationship with that person, is engaged in multiple relationships—a potentially dangerous state for a therapist and client to be in that represents real hazards to both individuals [19]. While dual relationships offer a potential pathway for harm to come to either the therapist or the client, they cannot always be avoided [20]. When one considers the perils associated with strained relationships in a spaceflight environment, including lack of cooperation between parties, interpersonal conflicts, reduced privacy and escape, and other hazards, it is apparent that any situation that could produce these hazards should be avoided wherever possible. For these reasons, it may be advisable to avoid providing psychological therapy to a crew member from another crew member on the same mission, if possible.

An alternative to intracrew psychological therapy may be ground-based psychological teletherapy. The proliferation of teletherapy during the COVID-19 pandemic has provided a way for more people to receive psychological care than was previously possible and has acted as an accelerator for this sort of technology [21], acting as a proving ground for the efficacy of teletherapy. However, the application of teletherapy to a spaceflight environment has not been fully explored. Astronauts in space commonly complain about a lack of privacy while onboard a spacecraft or space station [22,23], which may make teletherapy exceedingly difficult while in space. The lack of privacy during therapy, often referred to as a lack of a "safe therapeutic space," can seriously threaten the effectiveness of psychological therapy [24], as a therapy client may be unwilling or unable to divulge crucial details, express emotions fully, or fully participate in therapy in other crucial ways.

Although a lack of privacy in a spaceflight environment can conceivably be corrected through modified living quarters, one issue that cannot be corrected is delayed communications. Previous space simulation studies have revealed that delayed communication creates a host of problems for crews, including confusion and wasted crew time, decreased verbal encoding efficacy, increased stress and frustration, and general task and communication errors [25-28]. Surprisingly, difficulties were seen across the range of possible delayed voice communication times, with issues being found when messages were delayed by as brief as just fractions of a second [26] or as long as 5 minutes [25]. Currently, crews aboard the International Space Station experience communication delays between the crew and the mission support team on the ground measured in the millisecond range, although it is known that this will increase to upwards of 22 minutes for crewed missions to Mars [29], and even longer for more distant destinations. It is apparent that humans are sensitive to voice communications being delayed by any noticeable amount, with difficulties, errors, and stress quickly appearing under these conditions; during an emotionally charged psychotherapy session, these effects may be more pronounced.

Although psychological therapy is considered to be one of the most desirable psychological interventions and is empirically supported for both short-term and long-term outcomes, its use in a spaceflight environment may be difficult. Dual relationships between crew members create barriers to intercrew psychotherapy by introducing increased risk for other negative outcomes. In addition, a combination of a lack of privacy and delayed communications creates significant barriers for teletherapy between ground personnel and astronauts in low Earth orbit. As such, there are limited options available for psychotherapy in low Earth orbit.

Particular Issues Posed by a Deep Space Environment

A deep space mission may have particular stressors that create an increased risk for mental health complications; in addition to the known stressors of spaceflight (eg, monotony, microgravity, awareness of danger, interpersonal tension, and radiation), a deep space mission may encounter additional psychological stressors, including increased isolation, the psychological effects of distance from Earth, the knowledge of a lack of rescue, prolonged homesickness, and other related phenomena [10,30]. In addition, the very nature of deep space creates a certainty that delayed communications will become a facet of life for deep space astronauts; as the speed of light dictates the maximum speed at which information can travel, messages from Earth to Mars can take up to 22 minutes in 1 direction [29], with longer delays being a certainty for deeper space missions to asteroids, the moons of the gas giants, and

other destinations. As such, delayed communication is expected to be one of the most pressing issues with regard to future long-duration, deep space missions [25]. When combined with the known and expected stressors associated with deep space missions, it is clear that an option for psychological care is needed that does not rely on Earth-based interventions, while also avoiding the dual relationship hazards of intercrew psychotherapy.

Need for Automated Psychotherapy for Spaceflight

An increasingly common psychological treatment modality, automated psychotherapy, sometimes called computer-mediated psychotherapy, cybertherapy, or computer-created virtual reality for therapy [31,32], is often seen as a method of delivering psychological therapy (psychotherapy) to various groups of people, especially populations that are underserved or otherwise unreachable through traditional therapeutic routes [33]. Automated psychotherapy generally takes the form of a series of computer-delivered modules that explain applicable psychological terms to the therapy client, provides a degree of psychoeducation necessary to progress through the module, delivers homework tasks and the necessary training required for those tasks, and assesses the symptoms and progress of the client using standardized empirically supported measures. Automated psychotherapy is not to be confused with self-help books, which, although found to be effective for temporary amelioration of depressive symptoms (among other disorders), have not been found to produce lasting effects past 6 months [33]. Rather, automated psychotherapy has been shown to be highly effective in treating various psychopathologies with lasting and reliable results [34].

Automated psychotherapy provides a way for astronauts to receive empirically supported psychological therapy while in space and distant from the Earth. Notably, as will be outlined in greater detail below, automated psychotherapy is able to mitigate the issues that confound traditional therapy or teletherapy in a spaceflight environment. There are research projects currently underway to investigate the efficacy of, and design a treatment for, automated psychotherapy in a spaceflight environment [35]; these findings will be explored in greater detail below. Notably, future deep space missions will likely require an automated psychotherapy option that can function independent of ground-based personnel, although automated psychotherapy options in the foreseeable future will likely involve a trained human therapist to some extent or another. Discussions of automated psychotherapy below are generally in reference to the more automated end of this treatment modality.

Advantages of Automated Psychotherapy for Spaceflight

Automated psychotherapy has been widely discussed as a potentially popular method of delivering psychotherapy on Earth, as it allows treatments to be tailored to the client in a way that reduces the workload on experienced clinicians [36].

Cognitive behavioral therapy (CBT) is a common psychological treatment modality that is often modified into an automated psychotherapy course, usually referred to as internet CBT (iCBT). Here, it should be noted that the CBT umbrella is broad; many different components of other treatment modalities (eg, mindfulness-based treatments for anxiety disorders and exposure-based treatments for anxiety and trauma disorders) can fit under this umbrella, which is why CBT is often considered to be the gold standard of frontline psychological care [37]. A recent review has found that iCBT has been an effective treatment for a variety of psychopathologies, including depression, generalized anxiety disorder, panic disorder, obsessive compulsive disorder, posttraumatic stress disorder, adjustment disorder, bipolar disorder, and phobias, among others [38]. Recently, research has indicated that mindfulness-based interventions for stress, anxiety, depression, and other psychological disorders may be particularly useful in the spaceflight environment [39]. Given that automated psychotherapy has already been tested for mindfulness training, this may be a particularly useful function of this treatment modality [40]. In future spaceflight environments, automated psychotherapy may be the only form of treatment available to astronauts, especially during deep space missions [14]. Based on the empirical support for the use of automated psychotherapy for a wide range of psychopathologies, it is evident that automated psychotherapy has broad applicability and can be tailored to the individual in a flexible and supportive way [36]. In addition, the instantaneous nature of automated psychotherapy, and the lack of a need for a second party (the trained clinician), means that this treatment modality can easily be integrated into the astronaut's schedule in a way that is convenient and accessible to them, reducing the barriers to treatment. Given that a lack of convenience is a commonly cited factor for not pursuing psychotherapy on Earth [36], reducing this barrier in a spaceflight environment is of the utmost importance.

In addition, automated psychotherapy provides a way for therapy to be conducted that does not require individuals to enter dual relationships (eg, both as professional colleagues and as therapist or client) [41]. In a spaceflight environment, the importance of this cannot be overstated. Given the known history of intracrew social tensions to quickly devolve the general morale and effectiveness of crews in space, any steps that can reduce the risk of social strain on space crews are steps worth taking. Similarly, the increased privacy of automated psychotherapy treatments can also protect the social reputation of crew members and reduce the likelihood of conflict. Given that some forms of automated psychotherapy allow for a client to undergo therapy without having to verbally speak, the opportunity for inadvertent or intentional eavesdropping from other crew members is significantly reduced. Accordingly, automated psychotherapy clients may feel more comfortable divulging their thoughts, feelings, and emotions in a therapeutic context without fear of their reports being overheard by other crew members. Notably, astronauts have previously cited a lack of privacy as a barrier to participating in psychosocial research while onboard the International Space Station [42], and these concerns can be expected to persist in a therapeutic environment.

Automated psychotherapy also creates the only pathway for therapy to occur between the client and another party not on the spacecraft that does not result in delayed communications. Given that an accumulation of stressors can threaten the therapeutic relationship and the overall effectiveness of psychotherapy [43], any steps that may reduce these stressors are worth pursuing. Automated psychotherapy offers a way to reduce the strain caused by delayed communications, protects the privacy of the client, reduces the risk of dual relationships, offers a tailored and customizable course of treatment, and has broad applicability for a wide range of psychopathologies. Accordingly, this treatment modality appears to be useful for future long-duration, deep space missions and may even offer advantages to crew members in low Earth orbit. As such, the usefulness of automated psychotherapy in a spaceflight environment should be further investigated.

Drawbacks of Automated Psychotherapy for Spaceflight

However, automated psychotherapy is not impervious to all criticisms, and there are noteworthy concerns about this treatment modality. One potential detractor for automated psychotherapy is its apparently low treatment adherence rate compared with other psychotherapies; a meta-analysis of iCBT and face-to-face CBT adherence rates found that 84.7% of individuals receiving face-to-face CBT would complete their treatment, compared with 65.1% of individuals receiving iCBT [44]. Little data have been found regarding generalized predictors of treatment nonadherence for automated psychotherapy [45]. However, incorporating knowledge from the medical field more broadly may provide some insight to treatment nonadherence for automated psychotherapy. For example, the Medication Adherence Model provides a framework for understanding nonadherence to medication recommendations and treatments [46]. Within this model, it is thought that 2 different types of nonadherence may be seen: the intentional decision to miss a medication dose and the unintentional interruptions that can cause a medication dose to be missed. A core concept related to nonadherence is whether the patient shows purposeful actions to increase adherence, can demonstrate patterned behaviors to increase adherence, and are receptive to feedback to increase adherence. The Medication Adherence Model incorporates concepts from various cognitive and self-regulatory models of behavior to explain the processes involved in medication adherence [46]. Considering the framework provided by the Medication Adherence Model, it is possible that adherence to psychological therapies, and therefore, automated psychotherapies, may be impacted by similar factors. With regard to adherence to automated psychotherapy, it is possible that individuals who show purposeful actions to adhere to their treatment, can implement patterned behaviors to help adhere to their treatment, and are receptive to feedback regarding their treatment adherence may be able to complete automated psychotherapy modules at a higher rate than was previously found. The proposed ideal psychological profile for future deep space astronauts includes traits similar to these [12], which may indicate that future deep space astronauts will have a higher adherence rate to automated psychotherapies than the general population. However, an inclination to adhere to therapy provided by an automated psychotherapy system may be moderated by the astronaut's belief that the information received from the system is accurate and helpful; if a client does not believe this to be the case, treatment adherence may be low. Accordingly, it is important to investigate how future deep space astronauts feel about the usefulness of these therapy solutions, and effort should be made to provide education surrounding the use of, and outcomes associated with, automated psychotherapy.

Automated psychotherapy may also be unsuitable for severe psychopathologies. Given that automated psychotherapy requires that an individual be able to self-monitor, adhere to their own treatment, and provide accurate assessments of their own thoughts and feelings, certain types of delirium, psychosis, or other severe psychopathologies may render an individual unable to use automated psychotherapy treatments. However, ruling out a treatment modality based on the severity of a diagnosis is common practice in therapeutic settings [47]. In the case that a crew member is experiencing a severe psychopathology, it is possible automated psychotherapies could be modified to incorporate another crew member to help provide the treatment. This, combined with the psychiatric formulary available to the crew, may offer a way to treat an individual who is far from Earth and is experiencing severe psychological symptoms.

It is also possible that while automated psychotherapy is intended to alleviate some of the uneasiness that an astronaut may feel about divulging sensitive mental health concerns to another person, this treatment modality may be unable to fully address this concern. For example, an astronaut may think that informing an automated psychotherapy program about their thoughts of depression, their anxiety surrounding a mission objective, or their feelings of isolation and loneliness will somehow be stored in an accessible personnel file or be relayed to mission planners on the ground. These concerns may prevent some astronauts from seeking help, and addressing these concerns will take deliberate education and planning to ensure that astronauts understand the full limits of confidentiality between themselves and the automated psychotherapist.

First Examples of Automated Psychotherapy Options for Spaceflight

Numerous early, simplified examples of automated psychotherapy have been designed and tested for future long-duration, deep space missions. One such project aims to create a digital tool that allows astronauts to monitor their behavior, performance, and feelings; make small changes to their routines as recommended; and reduce stress in key areas to help reduce the risk of developing a psychopathology [48]. Similarly, an interactive media program is being developed to help astronauts cope with interpersonal conflict and depression while engaged in deep space missions [49]. This program was tested by a crew of 6 individuals who spent 8 months in group isolation in a space analog environment [50]. Overall, the space analog crew found the conflict and stress modules of the treatment to be particularly helpful, with one of the most cited areas of improvement being a desire to learn how to use these modules to help other crew members. In addition, there are

various virtual and augmented reality methods for mitigating psychological demands under development and in various stages of testing. One such option is the Crew Interactive Mobile Companion, developed by IBM and Airbus Group and already tested on the International Space Station [51]. Crew Interactive Mobile Companion is designed as an artificial intelligence assistant for astronauts that is designed to offer them guidance on certain tasks and supply answers to technical questions. Overall, the development of automated psychotherapy for a spaceflight environment is still in its early stages. In addition, it should be noted that there is not public-facing information about what, if any, automated psychotherapy tools are currently available to astronauts in space. NASA and other space agencies should make a concerted effort to publish this information if it is available; if no automated psychotherapy tools are currently being used or tested in an actual spaceflight environment, efforts should be made to begin incorporating these as soon as possible.

Variables Still to be Determined About Automated Psychotherapy for Spaceflight

Although much progress is being made with regard to developing automated psychotherapy treatments for long-duration, deep space missions, there are still key variables that have yet to be fully explored. More information is needed regarding adherence to automated psychotherapy, especially as it relates to the common personality profiles of astronaut crews. While the Medication Adherence Model offers general principles for treatment adherence [46], the applicability of this model to automated psychotherapy for astronauts has yet to be explored. There is also a need to investigate whether the usefulness of automated psychotherapy could expand the astronaut selection criteria. Currently, some of the astronaut selection criteria operate on a "rule-out" procedure, where certain medical, occupational, sociological, and psychological factors are searched for in order to disqualify a particular astronaut candidate [52]. Identifying the cognitive components most associated with treatment adherence to automated psychotherapy courses could help add to the existing "rule-in" procedures for astronaut selection (involving required skills or attributes for a given mission), wherein certain cognitive factors that would indicate that an astronaut candidate is more likely to respond to automated psychotherapy courses in the future are used when creating astronaut crew rosters. Given that it is almost expected that an astronaut will experience some level of psychological distress, discomfort, or disorder during future long-duration, deep space missions [53], perhaps it is worth searching for

astronauts who best respond to psychological treatments, rather than restricting astronaut classes to only those who we believe are the most resilient against psychological disorders.

Fitting Automated Psychotherapy Into Mental Health for Spaceflight More Broadly

Recent publications involving the mental health of the spaceflight environment more broadly have provided an excellent framework for understanding what our current knowledgebase is for space psychology and what research is still needed [41]. Notably, automated digital therapeutics has been recognized as a potentially useful psychological support tool for long-duration, deep space missions [54], indicating that multiple research teams have identified this as a helpful tool that should be developed. As research into digital therapeutics, a line of medical interventions that allow patients to interact with digital health technology in lieu of or in addition to medical professionals, accelerates, it is hoped that these technologies will continue to proliferate [55]. Automated psychotherapy can be conceptualized as an arm of digital therapeutics that has been proven to be particularly effective on Earth [34] and may drastically improve psychological outcomes for future astronauts that experience mental health difficulties.

Conclusion

Automated psychotherapy offers a way for astronauts engaged in long-duration, deep space missions to receive empirically supported psychotherapy in a way that protects their privacy, reduces the risk of interpersonally straining dual relationships between crew members, and removes the difficulties presented by delayed communications. Although there are little data available regarding predictors of adherence to automated psychotherapy treatments, knowledge incorporated from the Medication Adherence Model suggests that the cognitive factors associated with reduced adherence to medical treatments may be less of a risk for astronauts due to the psychological selection criteria used by space agencies. The usefulness of automated psychotherapies for severe psychopathologies and unwilling participants has yet to be fully explored, but its overall efficacy for a broad range of psychopathologies that could be encountered during a long-duration, deep space mission indicates that automated psychotherapy could be a useful tool for safeguarding the mental health of future astronauts.

Abstract

Government policies in the United States and the European Union promote standardization and value creation in the use of FAIR (findability, accessibility, interoperability, and reusability) data, which can enhance trust in digital health systems and is crucial for their success. Trust is built through elements such as FAIR data access, interoperability, and improved communication, which are essential for fostering innovation in digital health technologies. This Viewpoint aims to report on exploratory research demonstrating the feasibility of testing a patient-centric data flow model facilitating semantic interoperability on precision medical information. In this global trend, the interoperable interface called Sync for Science-J (S4S-J) for linking electronic medical records (EMRs) and personal health records was launched as part of the Basic Policy for Economic and Fiscal Management and Reform in Japan. S4S-J controls data distribution consisting of EMR and patient-generated health data and converts this information into QR codes that can be scanned by mobile apps. This system facilitates data sharing based on personal information beliefs and unlocks siloed Internet of Things systems with a privacy preference manager. In line with Japanese information handling practices, the development of a mobile cloud network will lower barriers to entry and enable accelerated data sharing. To ensure cross-compatibility and compliance with future international data standardization, S4S-J conforms to the Health Level 7 Fast Health Care Interoperability Resources standard and uses the international standardized logical observation identifiers names and codes (LOINC) to redefine medical terms used in different terminology standards in different medical fields. It is developed as an applied standard in medical information intended for industry, health care services, and research through secondary use of data. A multicenter collaborative study was initiated to investigate the effectiveness of this system; this was a registered, multicenter, randomized controlled clinical trial, the EMBRACE study of the mobile health app M♡Link for hyperglycemic disorders in pregnancy, which implements an EMR–personal health record interoperable interface via S4S-J. Nevertheless, the aforementioned new challenges, the pivotal Health Level 7 Fast Health Care Interoperability Resources system, and LOINC data mapping were successfully implemented. Moreover, the preliminary input of EMR-integrated patient-generated health data was successfully

shared between authorized medical facilities and health care providers in accordance with the patients' preferences. The patient-centric data flow of the S4S-J in Japan is expected to guarantee the right to data portability, which promotes the maximum benefit of use by patients themselves, which in turn contributes to the promotion of open science.

Introduction

Global Convergence in Digital Health Infrastructure

The standardized medical information network in Europe and the United States not only provides high-quality medical care in individual practice but also serves as a development research infrastructure that enables effective epidemiological research. When digital health care is provided with appropriate infrastructure, training, and engagement, it has the potential to improve population health by using artificial intelligence, big data, and precision medicine [1]. FAIR (findability, accessibility, interoperability, and reusability) data practices can enhance trust in digital health systems, which is crucial for their success. Trust is built through elements such as FAIR data access, interoperability, and improved communication, which are essential for fostering innovation in digital health technologies [2]. The ELIXIR Hub of the European Committee (EC) integrates Beacon to connect geographically distributed data centers and unify their data access methodologies [3,4]. The cloud-based analysis platform enables ready sharing and reproduction of research results through workspaces in the National Institutes of Health All of Us research program's Researcher Workbench [5,6]. With continued adoption, these systems are creating a large network of globally searchable data sets that have the potential to unlock new data-driven discoveries and applications in medicine. Meanwhile, in the policy making of medical information, the European Commission initiated policies on cross-country data sharing of individual-level data, specifically through initiatives like the European Health Data Space in March 2022 [7], and the Data Governance Act, a new EC legal system, came into effect in September 2023, promoting standardization by the EC, as well as the creation of value in the use of FAIR data in anticipation of improved computational technology [8]. The legal system is being developed to promote data-driven innovation, as well as to develop low-cost medical technology. The US Department of Health and Human Services, through the Office of the National Coordinator for Health IT, released the draft 2024-2030 Federal Health IT Strategic Plan which places an emphasis on addressing the policy and technology components essential for securely catering to the diverse data requirements of all health IT users [9]. In response to this global trend, the Basic Policies for Economic and Fiscal Management and Reform 2022, approved by the Japan cabinet office on June 7, 2022, set forth a policy of linking health and medical data obtained within and outside medical institutions. Consequently, the Japan cabinet office devised a national medical information platform to encompass a broad range of data, including medical and long-term care information, medical receipts, data on specific medical examinations, vaccination information, electronic prescription data, and data on municipality clinical examinations, as well as electronic medical records (EMRs). The objective of this initiative is to facilitate the adoption of online medical care and to promote the implementation of artificial intelligence hospitals with a view to advancing medical digital transformation. Furthermore, the platform will examine standard EMRs and use EMR data in a manner that optimizes treatments, facilitates the development of new artificial intelligence–based or other medical technologies, and supports drug discovery [10].

Economic and Clinical Impact of Mobile Health Technologies

In line with this policy, this research group was commissioned by the Japan Agency for Medical Research and Development to develop a mobile health (mHealth) app M♡Link. It designed and implemented the Sync for Science-J (S4S-J) interface to realize EMR-personal health record (PHR) interoperability using a QR code. In this research project, we implemented this system to construct a mobile cloud network designed for Japan's medical situation that enables information sharing centered on individuals and enables data sharing based on personal free choice with a privacy preference manager (PPM) [11] for siloed Internet of Things (IoT) systems. Putting everything in perspective to cover all steps in a FAIR data management plan when conducting health research efforts, 56.57% of the time could be saved when using the FAIR4Health solution. This translated into economic savings of €16,800 (€1=US $1.0821 in 2023) per month, representing 17.11% of the cost per person per month of the institution [12].

Recently, the widespread use of internet technologies and mHealth tools for public health and medical purposes has changed human life [13,14]. SMS text messages sent from cell phones using reminder systems had a positive effect on medication adherence among patients with chronic diseases and those in need of medical services [15,16]. mHealth apps have been widely applied in the medical management of patients with cancer [17], diabetes [18,19], cardiovascular disease [20,21], and other chronic conditions [22]. Obstetric and gynecologic practices are also increasingly equipped with telemedicine to improve patient access to health care services. Previous studies have demonstrated the effectiveness of telemedicine services in obstetrics and gynecology, including improved health behaviors [23,24], weight management [25], mental health problems [26], and postpartum depression [27] in pregnant women. The effects of telemedicine as another applied medical infrastructure have also been reported to be

XSL·FO

RenderX

associated with improved health outcomes for high-risk obstetric patients, including hypertensive disorders, diabetes, fetal abnormalities, and pregnancy in underserved areas [28].

Evolution of FAIR-Compliant Interoperability Standards Through HL7-FHIR and SMART Technologies

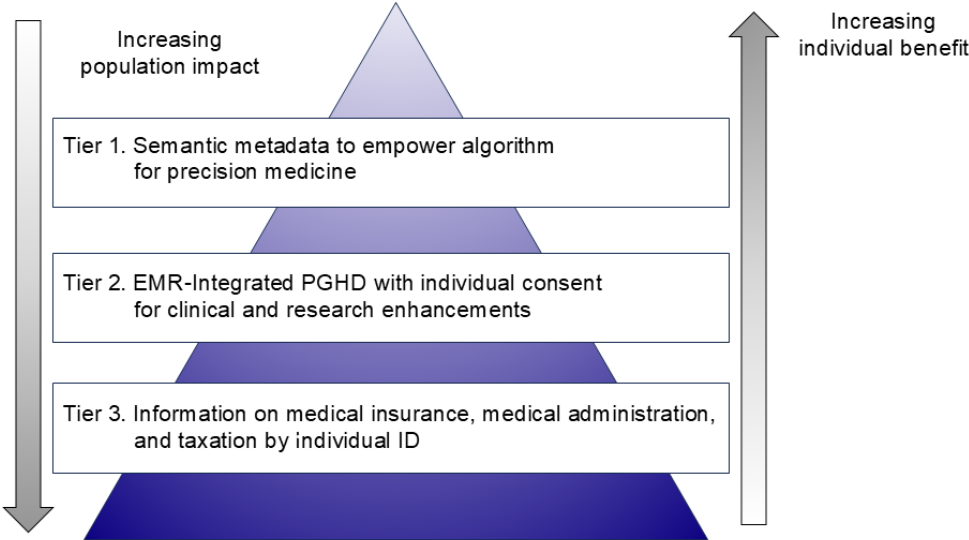
The critical challenge of health care data interoperability, a key issue in modern health care systems, the increasing volume of health data necessitates efficient data-driven approaches to improve various aspects of health care, including disease detection, prognosis, clinical research, and patient management. However, the current landscape is characterized by data silos and incompatible systems, hindering the seamless exchange of information. Amid this current of events, the components of FAIR digital objects can be represented in Health Level 7 Fast Health Care Interoperability Resources (HL7-FHIR), thus increasing their interoperability and reusability. Appropriate FHIR profiles can further facilitate advanced search capabilities based on extensive metadata, and easier access to the health data capitalizing on the data model of HL7-FHIR [29]. Consequently, interoperability develops a communication framework between noncommunicable systems, which can be achieved by transforming health care data into ontologies. Thus, an effective solution is the development of methods for finding matches among the various components of ontologies in health care, in order to facilitate semantic interoperability [30]. The SMART (Substitutable Medical Applications and Reusable Technologies) team initially selected platform components that suited our mission, emphasizing web standards (eg, HTML, JavaScript, OAuth, and resource description framework) and widely adopted terminologies for coded data (eg, RxNorm [31], logical observation identifiers names and codes [LOINC] [32], and Systematized Nomenclature of Medicine—Clinical Terms) [33]. The remaining need was a standard for sharing granular clinical data (eg, a prescription, lab result, or blood pressure measurement) with a developer-friendly, semantically consistent, on-demand (vs server-initiated messaging) approach. To expose patient-level data according to these models [34], they built a corresponding representational state transfer application programming interface (API) offering data access through a fixed URL structure and HTTP verbs (eg, GET and POST) [35]. We added and refined our set of clinical statements and API calls over time to enable richer payloads with more expressive queries, which was achieved by transforming health care data into ontologies. An effective solution to this problem is the development of methods for finding matches among the various components of ontologies in health care, in order to facilitate semantic interoperability [36]. The patient-centric approach through the S4S-J in Japan is expected to guarantee the right to data portability, which is a patient right, and at the same time promote the maximum benefit of the utilization by the patients themselves. Therefore, we have started clinical studies of the mHealth app M♡Link for hyperglycemic disorders in pregnancy, which implements this EMR-PHR interoperable interface S4S-J on the data model of HL7-FHIR. This viewpoint aims to report on exploratory research demonstrating the feasibility of testing a patient-centric data flow model facilitating semantic interoperability on precision medical information.

Architecting Japan's Digital Health Evolution

Stratified Health Data in Japan

In the health care industry, large standards-developing organizations have defined numerous standards, data formats, terminologies, etc, in order to support the design and building of interoperable IT systems. Perhaps the most well-known and most important standards are the ones introduced by HL7, which can be used as a foundation for the development of data exchange standards among eHealth systems [37]. In 2022, the Ministry of Health, Labor, and Welfare established HL7-FHIR as a medical data standard regulation with the objective of promoting the interoperability of medical data and implementing the use of FAIR data [38]. In accordance with this Japanese government policy, we developed an API with the objective of achieving interoperability between EMR and PHR data. This was based on the HL7-FHIR standard, with the use of the LOINC terminology. This interface is distinguished by two key features: a patient-centric data flow enabled by dynamic e-consent named PPM, which facilitates personal data use permissions, and the use of QR codes, which are specifications readily implementable in the Japanese information environment for data transport. Moreover, metadata uses LOINC, a terminology focused on laboratory observations [36], in response to the functional requirements of M♡Link-app embedded S4S-J. Additionally, a data library has been implemented, converted from the Japan Laboratory Analysis Code standard to LOINC, which enhances the functionality of semantic interoperability. Consequently, in this study, we have developed an M♡Link using S4S-J and verified the effectiveness of the system. S4S-J is an interface for linking the warehouse data consisting of EMR and patient-generated health data (PGHD) and converting it into a QR code that can be scanned into a mobile app. S4S-J complies with the HL7-FHIR standard and unifies medical language with globally standardized terminology using LOINC. Developed as an applied standard in the medical information business, S4S-J is intended for medical applications in cooperation with Mynaportal, Japan's Public Individual Number Card Service, and development research and health care services leveraging clinical information through secondary use of data. Japanese medical information is stratified as follows (Figure 1 and Textbox 1). Tier 3 provides public information on taxation, public medical insurance, and public health checkup systems through the Individual Number Card Service; Tier 2 provides FAIR data based on EMR-integrated PGHD with individual consent for the enhancement of research; and Tier 1 provides semantic metadata empowers algorithm for precision medicine. In the context of the rich metadata objects proposed by Haslhofer and Klas [39], it has been suggested that metadata instances may be extended using annotated semantic descriptors drawn from various sources, including different ontologies, terms, and coding systems. Meanwhile, in this study, the priority was on implementation and an approach was selected based on an outline and classification of metadata interoperability technology that would be optimal for the specific metadata integration scenario. S4S-J controls data distribution mainly for Tier 1 through Tier 2, making it facilitating the provision of

purpose-built medical services to users, and at the same time promoting the industrial secondary use of data for drug discovery research. S4S-J and structured metadata will be used to provide precise telemedicine to pregnant women with hyperglycemic disorders in pregnancy using the mHealth app M♡Link, and a clinical registry study will be conducted to evaluate the usefulness of the system.

Figure 1. Stratified health data in Japan. Decreasing tiers represent information that has a stronger impact on the public, whereas increasing tiers represent information that offers higher individual benefit. Further digitization is currently underway with the objective of semantics, and efforts are being made to address issues of data collection and traceability in a way that is easily understandable. DPC: diagnosis procedure combination; EMR: electronic medical record; HL7-FHIR: Health Level 7 Fast Health care Interoperability Resources; ICD: International Classification of Disease; LOINC: Logical Observation Identifiers Names and Codes; NDB: national database; PGHD: patient-generated health data; PRO: patient-reported outcome; SNOMED-CT: Systematized Nomenclature of Medicine-Clinical Terms.


Textbox 1. Three tiers of stratified health data in Japan.

Tier 1

Semantic technologies provide a layer of metadata to content that allows computers to understand and make connections to it. The implementation of semantic metadata facilitates the enhancement of algorithms used for the computation of medical solutions, thereby advancing the field of precision medicine. In research and some commercial applications, the following data elements are being used to expand the metadata vocabulary with natural definitions: (1) standardized medical terms and ontologies such as Systematized Nomenclature of Medicine—Clinical Term, International Classification of Diseases, and Logical Observation Identifiers Names and Codes; (2) omics analysis, including genome, transcriptome, proteome, metabolome, and metagenomics; (3) amino acid composition, fatty acid composition, vitamins, trace metals, etc, as dietary nutrients; and (4) external environmental factors.

Tier 2

Electronic medical record (EMR)–integrated patient-generated health data (PGHD) is in accordance with the Health Level 7 Fast Health care Interoperability Resources standard, and upon obtaining electronic consent for the use of personal information, it is accessible for utilization of primary data for telemedicine and mHealth. Furthermore, it will serve as a valuable source of secondary data for the development of new health care services and research initiatives in academic and industrial settings. The data set includes medical data, such as patient interviews, blood biochemistry, and images (x-rays, computed tomography, magnetic resonance imaging, endoscopes, and ultrasound sonography), as well as PGHD (biological sensor data such as number of steps, sleep, oxygen saturation, blood pressure, body temperature and electrocardiogram, nutritional intake data, patient-reported outcomes (PROs), and electrograms). Additionally, the data set incorporates nutritional intake and PROs.

Tier 3

Information on medical insurance, health administration, and taxation, based on Mynaportal, the government's individual number in Japan. The Mynaportal is only active for specified purposes as defined by legislation: (1) social security, including pensions, medical insurance, and welfare services; (2) taxation, including income tax returns and withholding certificates; and (3) disaster policy, including support for disaster survivors. The preliminary set of medical data serves as a reference point for the standardization of data exchange between EMRs. It encompasses the medical information provision form, discharge summary, health checkup result report, disease or injury name, allergy, infectious disease, contraindicated drugs, chemical examinations, and prescription information. The data comprising Tier 3 is stored in the NDB, and the statistical data are accessible to the public. These include (1) diagnosis procedure combination data, (2) information on specific health checkups, and (3) health guidance.

An EMR-PHR Medical Information Interoperable Interface: S4S-J

S4S-J is an interface that has three main functions tailored to the actual situation of medical information sharing in Japan.

The system information structure and design of S4S-J are shown in Figure 2. The simple QR code system was specifically designed to interoperate the EMR among major obstetric medical record systems with the S4S-J cloud data warehouse. It covers the requirements of third-party organizations for the

primary use of medical information by medical providers and medical services (eg, online medical care and interhospital sharing of medical information) and secondary use in research and development (eg, drug discovery research and development of new diagnostic equipment): (1) medical information sharing within QR-coded EMR, (2) conversion to LOINC as a global standard terminology, and (3) privacy data provision based on the consent of using personal information by PPM [11]. S4S-J exports the EMR of various EMR vendors in the form of QR codes by converting them into JSON bundles in compliance with the HL7-FHIR and SMART health cards standards. SMART health cards are verified versions of your clinical information, such as vaccination history or test results. They allow you to keep a copy of your important health records on hand and easily share this information with others if you choose. SMART health cards contain a secure QR code and may be saved digitally or printed on paper, which is encoded as compact serialization JSON web signatures (Figure 3) [40]. For enhanced security of personal information and to prevent accidental exposure, S4S-J implements SMART health cards compliant with RFC7515 (JSON web signatures) in a format enhanced

with encryption based on RFC7516 (JWE) to prevent QR codes from being read by anyone other than the person in the QR code. The QR code, which is the key for personal identification, is output at the same time and can be scanned via mobile app to read the EMR when the personal code is authenticated and the verification is confirmed. (Figures 4 and 5). This eliminates unintended and dishonest access. Japan Laboratory Analysis Code, a clinical laboratory code established by the Japanese Society for Laboratory Medicine, and medical information and others are converted to the international standard terminology LOINC. The user can choose to share the data with health care providers, government health agencies, private services, and research and development organizations according to the preferences of the patient's information use and contact various services. In this process, we have designed an easy-to-use interface to obtain informed consent electronically, using videos to provide clear explanations and aid in understanding. Consent can be withheld completely or temporarily for privacy with the ability for dynamic consent to adjust to changes in patient intent over time (Figures 6 and 7).

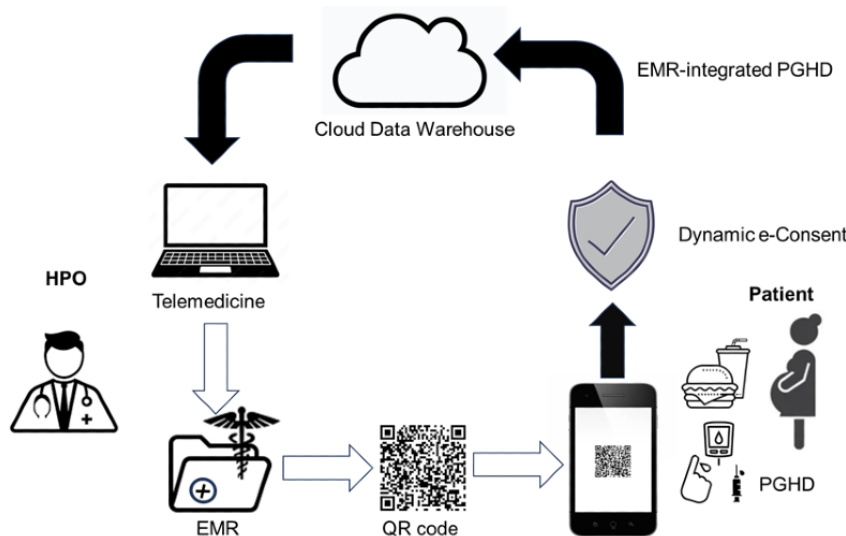
Figure 2. The information circulation on S4S-J interface EMR standardized in the HL7-FHIR, SMART health cards and oneM2M aligned LOINC terminology is converted to a QR codes. The QR coded EMR is captured by the patient's mobile app and processed with PGHD into a JSON bundle according to the Smart health cards standard to output structured EMR-integrated PGHD, which is stored in a cloud data warehouse. Healthcare providers download the metadata and EMR-integrated PGHD via the cloud data warehouse and access highly detailed and rich clinical data to provide precise telemedicine. In the aspect of research promotion, data distribution with the consent of personal information use is available through S4S-J, and it is easy to analyze aggregated EMR-integrated PGHD as a resource for research and development.


Figure 3. The FHIR bundle consists of EMR-integrated PGHD. EMR-integrated PGHD are converted into JSON bundles in compliance with the HL7-FHIR and SMART health cards standards. The medical information contained in the payload portion of the Smart Health Cards, such as "hospital," "patient," and "infectious disease test," are described as an array in the "entry" field of the "bundle" resource in HL7-FHIR. The entire data is bundled as a "bundle" resource, and the resource type is "document" according to the Medical Information Form HL7FHIR Description Specification (Version 1). The "composition" resource at the beginning of the "entry" in the "bundle" serves as the table of contents contained in the bundle. Behind it, medical information expressed as resources are lined up. Medical and laboratory data such as "blood pressure" and "blood sugar" are represented as "observation" resources. EMR: electronic medical record; HL7-FHIR: Health Level 7 Fast Health care Interoperability Resources; PGHD: patient-generated health data; SMART: Substitutable Medical Applications and Reusable Technologies.
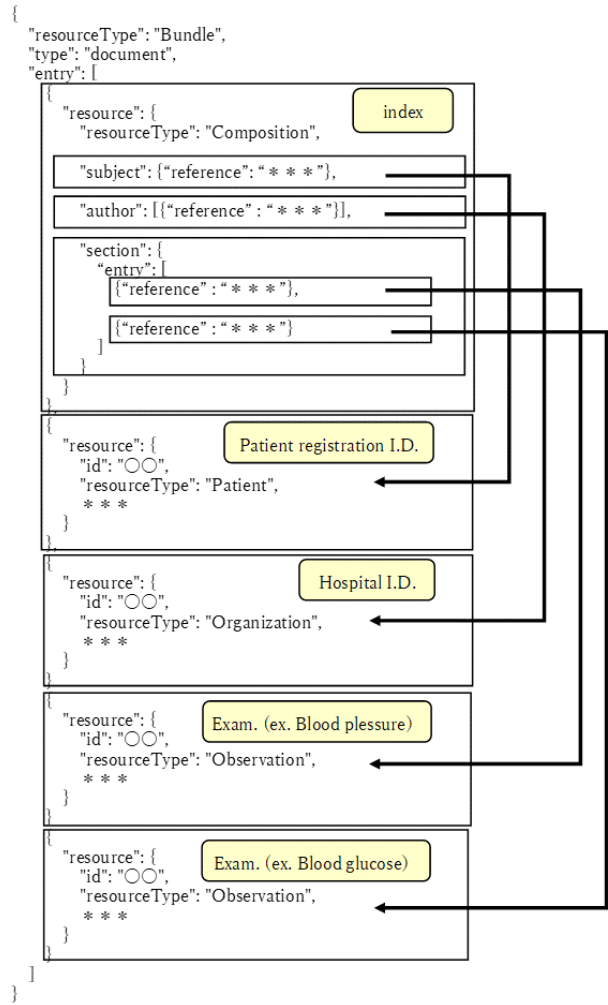

Figure 4. UI/UX of the mHealth web app system M♡Link. User interface for data sharing indicating the number of patient consent forms obtained and HPs authorized to share their data. HP: health care provider; UI: user interface; UX: user experience.
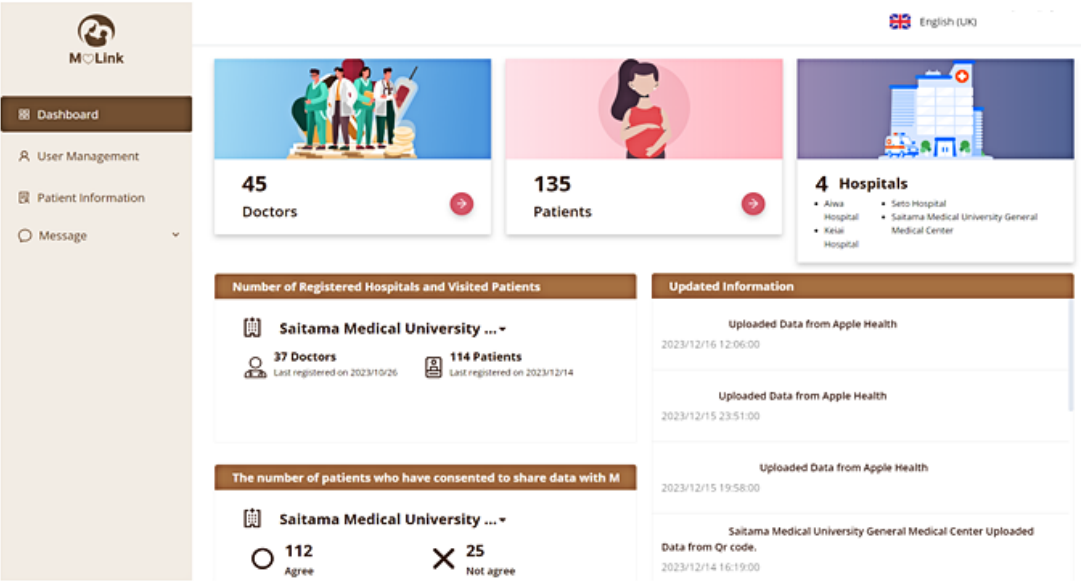

Figure 5. Upload of EMR-integrated PGHD to the cloud data warehouse via QR codes and the M♡Link app. The process is as follows: EMR-integrated PGHD are captured in the app through QR codes, displayed in the user interface or user experience, and stored in the cloud data warehouse. Encryption key to identify the individuals (left) and QR coded EMR-integrated PGHD (right). EMR: electronic medical record; PGHD: patient-generated health data.
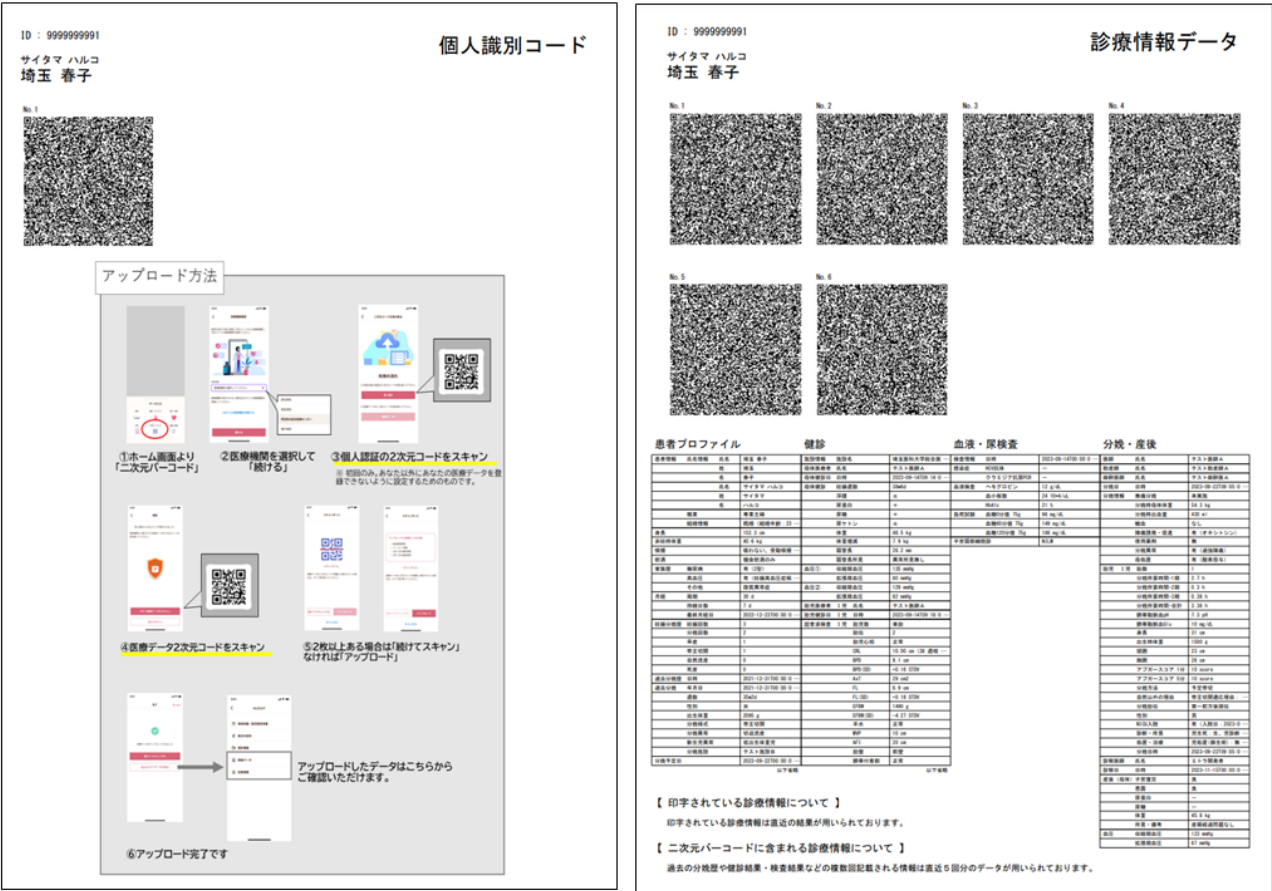

Figure 6. Uploading the EMR-integrated PGHD to the cloud data warehouse via QR codes. EMR-integrated PGHD are captured in the app through QR codes, displayed in the UI/UX, and stored in the cloud data warehouse. EMR: electronic medical record; PGHD: patient-generated health data; UI: user interface; UX: user experience.
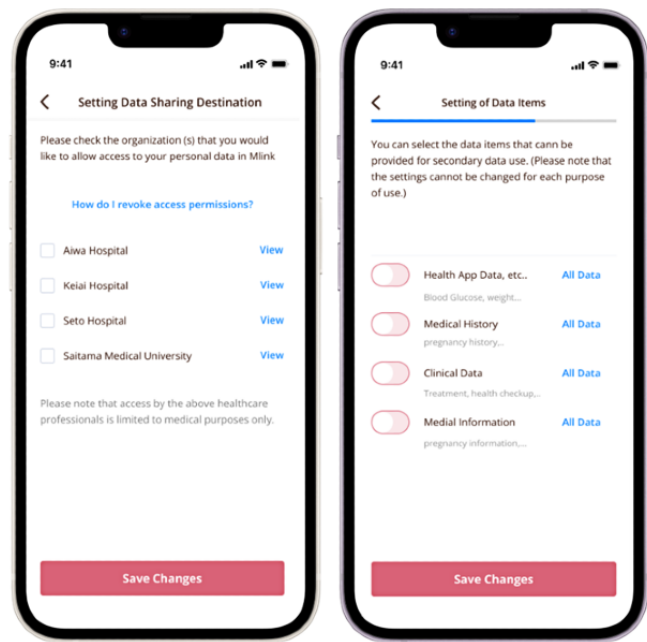
Figure 7. Displaying acquired dynamic e-consent. Explanatory movie for patients embedded in the mobile app explains how the data will be used, what users can access the wider medical service, and how data sharing will contribute to research and drug discovery through dynamic e-consent.

A System Design and Information Framework for mHealth Solutions: The M♡Link App

The system was developed in a robust working environment with a well-detailed specification. During the development, we have used various tools and software to ensure security and efficiency in the system. The development environment consisted of a cloud data warehouse built on Amazon Web Services. Other software tools such as Firebase (Google) for push notification services and Twilio [41] for messaging have been used to enhance the system's capabilities. The hosting repository being used is GitHub, and to enable automated testing and deployment continuous integration and continuous

deployment pipelines were implemented using Kubernetes (Google). The backend of the system was built using Hasura [42] which provides a ready-to-use GraphQL API on top of the PostgreSQL database [43]. PostgreSQL served as the primary database, chosen for its reliability and powerful querying capabilities. The web application frontend was developed using React.js and the ant-design library (Figure 8). We also have developed the Android and iOS versions using React Native, a well-known JavaScript library for building hybrid mobile apps. The system integrated various third-party APIs and services to enhance its functionality. This included the use of "Calomeal API" [44] which is a food image analysis and which incorporated an API. The system also used the React Native

Healthkit package to enable synchronization with Google Fit and Apple Health. We have been performing regular security audits including cloud application security assessments and network vulnerability assessments to identify potential threats. In terms of use, the system collects various types of PGHD, such as blood glucose levels, insulin dosage, and nutrient and calorie intake. It also includes medical records like ultrasound fetal predicted weight and maternal weight, and the medical information is mapped using HL7-FHIR format and converted into QR codes. This allows for easy capturing and incorporation of data into the cloud via the mobile app. Users can scan QR codes to register their medical information. With user permission, this information can be shared with health care providers through the web application. All data, including symptoms, nutrient intake, and medication-related behaviors, are stored in a cloud data warehouse.

Figure 8. Setting up data sharing based on individual decisions through dynamic e-consent. Left: checkboxes allow selecting HPs with which to share data. Right: dynamic e-consent for secondary use of data; the UI/UX facilitates the secondary use of data by showing the attributes to be used, including PGHD, medical history, clinical biochemical values, ultrasound values, and clinical physical values, and the attributes of the recipients, such as HPOs, government health agencies, academia, industry, and other organizations. HP: health care provider; HPO: health care provider organization; PGHD: patient-generated health data; UI: user interface; UX: user experience.


Patient-Centric Digital Health Implementation in Maternal Care

End-to-End Quality Evaluation for Patient-Centric Data Flow in the S4S-J and M♡Link App Architectures

An end-to-end evaluation was conducted from the user's perspective to ascertain the quality control of each system component as an integrated ecosystem demonstrating the functionality of the patient-centric data flow. In particular, the patient-centric data flow was implemented in accordance with the following customer journey. First, health care providers enter the patient's medical data into the EMR and upload data such as ultrasound measurement findings and biochemical test results. Medical information from EMRs is converted into QR codes compliant with S4S-J and generated in the EMR systems of four major EMR vendors for obstetrics and gynecology in Japan (MITLA Co, Ltd, NEWWAVE Co Ltd, TAK Co, Ltd, and TOITU Co, Ltd) at multiple medical facilities. Second, the QR codes were scanned on the M♡Link app, and the PGHD, comprising nutritional intake, blood glucose levels, insulin administration information, and patient-reported outcomes, were entered. Third, at multiple medical institutions, health care providers who had obtained consent for the primary use of patient data entered this data into the M♡Link web app screen and proceeded to provide medical care based on the large volumes of precise data.

In consequence, the end-to-end evaluation revealed issues that had not been identified during the system test. These issues are: (1) the attributes for standardized data in the data libraries used by each EMR vendor differed, resulting in discrepancies between companies and varying definitions of the details of medical information in some cases. (2) The presence of multiple QR codes within the same field of view when scanning a single QR code resulted in the interference of the recognition process, whereby the individual codes were not recognized as a single piece of information. Accordingly, the configuration of the QR code required refinement, and the precision of the reading functionality also necessitated enhancement. (3) In some instances, the reliability of certain entries, specifically "measurement time" and "before or after meal," in the PGHD was not optimal. This led to the modification of the user interface and user experience to a function that automatically determined the label based on the time. The patient-centered data flow was confirmed to be functioning while maintaining consistency with the functions of the S4S-J API, following the overcoming of the obstacles. Moreover, it was demonstrated that this API optimizes the functions of the M♡Link app and aligns with the functional requirements of various obstetrics

and gynecology EMR vendors, facilitating an effective and streamlined information flow.

Implementation of the Pilot Study

Since 2022, a multicenter collaborative registry study (jRCT1030220452) and since 2023, a multicenter randomized controlled trial, the Efficacy of M♡Link based telemedicine on GDM in a randomized controlled trial (EMBRACE jRCT1032230258), have been conducted after receiving research ethics approval of Saitama Medical University, Saitama Medical Center, Clinical Research Review Committee (SOU2023-014). A mobile cloud network was established between three obstetrics and gynecology hospitals and a core university hospital to facilitate data collection and analysis. The participants are women with hyperglycemic disorders in pregnancy, and we have established a treatment style in which the pregnant women receive concurrent medical outpatient treatment via web-based medical service while attending obstetrics and gynecology departments. Using this app, online medical care in the form of mHealth, real-time blood glucose levels, nutrient and calorie intake, and medical information from the EMR-derived OB/GYN, such as estimated fetal and maternal weight, are displayed for diagnosis and decision-making by health care providers, as well as medical instructions for insulin dose adjustment and nutrient intake. Text-style messages were exposed via the app 1-2 times per week, sometimes as needed. In order to facilitate in-depth counseling, health care providers have implemented the use of the app through SMS text messages, with the objective of achieving high app retention rates. These strategies are designed to enhance pregnant women's motivation for treatment and adherence to app use. The data disclosed and provided by patients as PGHD and the number of steps taken, as well as QR code-generated EMR and the hierarchical metadata could be generated.

The first feature is that the participants were pregnant women, a homogeneous target population, which tends to minimize variation in information and communication technology (ICT) literacy and makes the study design less susceptible to individual differences in app use skills. Even in the differences between genders, it has been shown in previous studies examining gender differences in ICT literacy that this is a significant difference in favor of women scoring higher on cognitive measures of computer use frequency, perceived ICT skills, and attitudes toward computers [45]. Compliance was also high, despite a limited understanding of gestational diabetes mellitus and dietary requirements and why changes were necessary [46]. Moreover, almost without exception, patients negatively recalled the process of measuring blood glucose multiple times a day and taking medications during pregnancy but recognized and showed resilience in making this work for the baby's health. Women reported that health care providers could recognize that maternal health increases motivation for lifestyle changes during pregnancy that directly affect the baby [47]. As in previous reports, pregnant women actively participated in telemedicine using the app and then received mHealth on a patient-centric data flow infrastructure.

Discussion, Issues, and Limitations

Patient-Centric Approach to EMR-PHR Integration Within Social and Technical Constraints

In Japan, standardization of data distribution was adopted in 2022 as a standard by the Ministry of Health, Labor and Welfare, and is integrated in the HL7-FHIR standard, aiming to spread standardized electronic medical information and exchange systems. As a pilot operation, 3 documents and 6 pieces of information are provided: medical information including the name of injury or disease, allergy information, information on infectious diseases, and information on contraindications to drugs; examination information (tests useful in emergency situations, tests related to lifestyle-related diseases); and prescription information. For example, documentary information includes the following forms: medical information form, discharge summary with key images, and health examination results report. Nevertheless, the regulation of interoperable common API in Japan, defined as Sync for Science (S4S) in the United States, has yet to be officially released by the relevant bureau or enterprise organizations. Consequently, each tier of siloed data remains underused for research in academia and industry.

S4S-J is endorsed by the Japan Agency for Medical Research and Development and distributed by the Life Course Design Consortium, a multistakeholder consortium consisting of telecom, pharmaceutical companies, medical devices, academic organizations, and academia. This common interface that provides interoperability for EMR-PHR is compliant with HL7-FHIR and SMART health cards as standardization and enables the distribution of EMR and PGHD in a patient-centered manner. Because of avoiding subordinated to proprietary systems or applications defined by exclusive standards, S4S-J is characterized by converting EMRs to QR codes for patient-centered mobile circulation, which takes into account the tendency of notions that medical information stakeholders intend in Japan. Health care providers in Japan are hesitant to actively connect medical information to the IoT, preferring isolated networks due to concerns about cybersecurity and information disclosure [48]. Mobile and wearable devices are increasingly being developed for health care purposes. mHealth data includes personal health data collected from sensors and mobile apps. mHealth data and metadata standardization improves the ease of data aggregation and location accuracy (semantic interoperability) and reduces the cost of using this data for biomedical discovery, health improvement, and disease management [49]. Standardization of data along the entire PGHD integration pipeline is critical to ensure that it is device-independent, modular, flexible, versatile, and therefore, low-cost to integrate into clinical workflows [50]. For health care provider organizations, standardization will make it simpler to integrate data into workflows and write easily to EMRs for billing purposes. EMRs in the United States are currently required by law to support HL7-FHIR data and protocol standards [51]. As a schema to promote research and development. S4S has collaborated with Harvard Medical School, various EMR vendors, and the US Federal government (National Institutes of Health and the Office of the National

Coordinator for Health IT). S4S is a technology that allows individuals to donate electronic clinical and health data to biomedical research studies, which provides the ability for participants to share their electronic health record–based clinical health data with selected research programs via an open, read-only API. The S4S API is based on the HL7-FHIR and OAuth 2.0 standards. The S4S API is being developed to allow applications to use OAuth 2.0 to provide read-only access to all or a portion of electronic personal health information about a patient available through the health care provider organization patient portal via the patient's authentication credentials [52]. PGHD aggregation services that provide standards-based PGHD integration have a critical role to play in the transition from today's siloed and friction-prone data ecosystem to a frictionless, interoperable system appropriate for patients. Health care leaders responsible for telemonitoring and other PGHD programs should explore and adopt a pipeline-based approach to standardize the integration of PGHD into clinical care [50]. Likewise, in Japan, data mapping with HL7-FHIR enables the integration of EMR-integrated PGHD, and data portability using QR codes provides the option of building a data flow that is adapted to Japanese usability. Moreover, the value sets are standardized using LOINC terminology. Meanwhile, since digital distribution in S4S-J is a patient-centric data flow, the amount of data distribution is limited by patient refusal to provide data and the frequency of data provision. The decline in adherence leads to loss of data provision opportunities and poor data quality. This means that health care providers need to encourage users to provide accurate data, record high-quality data in a text-based manner, and control the quality of data flow through frequent communication. Agreement and trust in data handling between patients and health care providers will enable the generation of well-structured, highly useful EMR-integrated PGHD and enable health care providers to provide precise health services based on a patient-centric data flow system. In that context, a key factor is for health care service providers to offer services that are attractive enough for patients to willingly provide their data, and to promote services that are mutually beneficial to both patients and health care providers in order to strengthen patient-centric data provision.

Gender-Specific Advantages and Clinical Safety of Telemedicine Interventions

In considering application differences arising from gender differences in this study, the results indicated that young women outperformed men in the overall higher ICT literacy test score in a study that was administered to Norwegian students [53]. According to the results of multigroup confirmatory factor analysis, the test had sufficient measurement invariance across genders to allow the researchers to make meaningful comparisons. The comparison revealed that girls were more ICT literate than boys. The impact of gender differences in the use of ICT applications (annotated multimedia electronic readers) was also tested in pre- and postclassroom learning. The results show that women use learning tools more frequently than men [54]. These also suggest that the use of ICT applications for pregnant women may be a good indication and an effective treatment target.

As an intervention effect of the one-directional messages through a mobile phone, it significantly improved physical activity, healthy eating, and medication adherence in chronic heart disease patients. In addition, more people may also control cardiovascular disease risk factors by following the recommendations via messages. The intervention group was 62% more likely to control all five risk factors according to recommendations [55]. Likewise, in perinatal care, Text-4-Baby, another telemedicine service for pregnant women and its SMS text message service, was also associated with improvements in women's health behaviors and attitudes toward parenting [56,57]. Thus, health outcomes in telemedicine could prove to be noninferior to traditional face-to-face care in the perinatal period. For example, the prenatal and newborn guidelines, education, and learning system of one of the largest telemedicine obstetric care programs providing telephone consultation services to pregnant women in the United States was as effective as traditional face-to-face services [58,59]. In the safety issue of telemedicine, programs involving synchronous videoconferencing were not associated with an increased risk of health complications or medical adherence compared to traditional outreach programs [56,60]. In a online obstetrics and gynecology consultation service in Japan, telemedicine services using multiple communication tools, such as chat messages and voice calls, have also been shown to be clinically safe [60]. The interim analysis of the registry using M♡Link suggests that it may improve postprandial blood glucose and improve target range (data not shown), however, there are limitations due to the small number of cases and the retrospective nature of the study and also suggests that further research is needed to evaluate the effect of telemedicine using EMR-integrated PGHD on the incidence of perinatal complications such as preterm birth or cesarean section.

Limitations and Future Directions in Patient-Centric Health Data Systems

In S4S-J, metadata is mapped in accordance with HL7-FHIR standards, and instances are executed as part of the process. In this study, an objective evaluation was not conducted using statistical measures typically used to assess the reliability of agreement between multiple raters, such as Fleiss κ statistics [61]. This limits the ability to validate the appropriateness of metadata harmonization. The patient-centric data flow commences with the acquisition of consent to access personal data, which is contingent upon the appeal and consistency of the services provided as use cases. The study did not use statistical methods to verify the dropout rate or the reliability of the services provided, necessitating further analysis. In the implementation of data distribution adapted to usability in each country, it is important to introduce a system that ensures data security and reliability according to habitual backgrounds in digitalization. Over the future, a patient-centric approach will enable mHealth to effectively provide advanced health care services with EMR-integrated PGHD and metadata, both for the patients themselves and for health care providers and researchers.

Conclusions

A QR code–based EMR-PGHD interoperable interface, S4S-J, was launched in the medical field in Japan. S4S-J constructs a mobile cloud network designed for Japan's medical situation that enables data sharing based on personal choices with a PPM for siloed IoT systems. In accordance with Japanese information handling practices, the development of a mobile cloud network through S4S-J is expected to lower barriers to entry and accelerate information sharing. To ensure cross-compatibility and compliance with future international data standardization, S4S-J complies with the HL7-FHIR standard and unifies medical language using globally standardized terminology via LOINC. The patient-centric data flow of the S4S-J in Japan is expected to guarantee the right to data portability and promote a maximum benefit for patients themselves, which in turn will develop as an applied standard in health care services and contribute to open science through the secondary use of data in Japan. In the near future, a metadata integration scenario will be selected that allows for a generic metamodel approach to be used, with the objective of creating an information infrastructure that enables deep semantic understanding. In order to achieve this objective, it would be prudent to adopt a metamodel approach that is based on 5 key characteristics: extensibility, modularity, refinement, multilingualism, and machine processability [62]. Concurrently, efforts should be made to develop a sustainable information society through the implementation of green computing practices, in response to the growing concern over energy consumption and global warming [63].

Authors' Contributions

Y Izumida and TO contributed to the conceptualization and study ideas. Y Ishihara, TO, SB, MF, AY, MH, S Nakayama, and S Nukaya contributed technical development of systems and the creation of the mobile app. Y Izumida, TO, SY, RN, WM, YO, SM, Y Ishihara, YM, RO, JA, and YT contributed to data collection. KT and YY contributed to the ethical study design and statistical analysis. Y Izumida was the principal investigator and wrote the first draft of the manuscript.

Conflicts of Interest

The study was supported by Life Course Design, a general incorporated association, which provided the database free of charge.

Abstract

Background: There is considerable evidence of the burden of care encountered by informal caregivers of persons with severe and enduring mental health conditions in low- and middle-income countries. Previous studies have highlighted the need to support these informal caregivers as key players in the care of these patients. To date, limited evidence exists on the extent and types of strategies for supporting these informal caregivers in low- and middle-income countries.

Objective: This scoping review aims to identify and describe the extent and type of evidence on the existing strategies for alleviating the burden of care among informal caregivers of persons with severe and enduring mental health conditions in low- and middle-income countries.

Methods: A systematic literature search was completed following the Joanna Briggs Institute methodology for scoping reviews. The participants, concept, and context framework was used to guide the search for literature sources across 5 databases: PubMed, MEDLINE, CINAHL, and PsycINFO for published literature and ProQuest for unpublished literature. This review included studies that reported on strategies for alleviating the burden of care among informal caregivers of persons with severe and enduring mental health conditions, with a focus on studies that evaluated or recommended caregiver interventions and support strategies in low- and middle-income countries. The search was limited to studies conducted between 2001 and 2021, and only papers written in English were considered for inclusion. Using the Covidence software (Veritas Health Innovation), 2 reviewers independently screened the papers, applied the inclusion and exclusion criteria, and met biweekly to discuss and resolve conflicts. The relevant studies and reported outcomes were summarized, organized, and analyzed descriptively using numeric summary analysis and deductive content analysis.

Results: Of the 18,342 studies identified, 44 (0.24%) met the inclusion criteria. The included studies were from 16 low- and middle-income countries in Asia, Africa, Europe, and South and North America. Most studies (21/44, 48%) were randomized controlled trials conducted in Asian countries. The identified strategies were grouped into 2 categories: implemented and recommended intervention strategies. Identified strategies included community-based interventions, psychoeducation interventions, support groups, cognitive behavioral therapy, spirituality-based interventions, and smartphone-based interventions. In addition, mindfulness and empowerment, collaborative interventions, standard care, financial and social support, counseling, occupation-based interventions, policy and legislature, and access to mental health care were identified. Psychoeducation and support group interventions were identified as common strategies for alleviating the burden of care among informal caregivers of persons with severe and enduring mental health conditions.

XSL•FO
RenderX

Conclusions: This review provides evidence on the types of implemented and recommended strategies for alleviating the burden of care among informal caregivers in low- and middle-income countries. Although psychoeducational interventions were the most preferred strategy for alleviating burden, their benefits were short-lived when compared with peer-led support groups.

International Registered Report Identifier (IRRID): RR2-10.2196/44268

Introduction

Background Functional Implications of Severe and Enduring Mental Health Conditions

People with severe and enduring mental health conditions are unable to cope with the demands of everyday life and need care after being discharged from a health facility. Serious functional limitations frequently interfere with the ability of people with severe and enduring mental health conditions to perform essential roles such as being a worker, family member, or friend [1]. The lack of independence among people with severe and enduring mental health conditions in daily living activities and, in some cases, behavioral problems result in poor quality of life. Psychosis, bipolar mood, major depressive, anxiety, eating, and personality disorders are often classified as severe and enduring mental health conditions [2]. The amount of care needed varies greatly depending on the diagnosis, severity of symptoms, and level of independent functioning. As such, assistance is needed in areas of basic self-care, healthy eating, following daily routines, medication management and compliance, engagement in meaningful activities, and community integration. Therefore, informal caregivers are essential to fulfill the care needs of people with severe and enduring mental health conditions. This task becomes draining, and the caregiver burden should not be underestimated [3,4].

Informal Caregivers in Mental Health

Informal caregivers are people who deliver care without remuneration to persons with a chronic condition. The caregivers of persons with severe and enduring mental health conditions are most often family members or neighbors who assist with the care of the person with a mental health condition [5]. Dixon et al [6] noted that, often, the caregiver of a person with a severe and enduring mental health condition does not have a choice in being the caregiver, which is an additional burden of care for the carer. Informal caregivers' roles include monitoring medication, being the contact person between the health provider and family, early identification of signs of relapse, taking care of daily tasks such as self-care, providing meals, and ensuring the safety of the person [7,8]. Informal caregivers provide emotional support when needed and deal with the challenging behavior of the person with a severe and enduring mental health condition, which may lead to police involvement [9]. Involving informal caregivers in the routine care and management of persons with severe and enduring mental health conditions has shown a positive influence on the course of the illness but only if the caregivers' needs are addressed and they are supported in one way or another [5,6,10].

Caregiver Burden and Need for Support

The burden of care experienced by caregivers is classified into objective and subjective burden. Objective burden refers to the tangible impact of the demands of caring tasks and encompasses the practical and concrete aspects of caregiving that can be quantified or assessed externally [11,12]. Subjective burden refers to the emotional and psychological experiences, feelings, and perceptions of caregivers related to their caregiving role [8,13]. It focuses on how caregivers perceive the impact of their responsibilities on their well-being and mental health.

In low- and middle-income countries, objective burden can easily overshadow subjective burden, such as a lack of community mental health care services and clinics that are out of stock of medication for people with severe and enduring mental health conditions, causing relapse and often readmission [11]. Other concrete aspects of objective burden, such as long hours of being available to the care recipient, time lost from daily activities, and not being able to earn an income, have serious consequences for caregivers as they are unable to pursue their own goals in life and, accordingly, experience a lower quality of life [9,12]. Cultural beliefs about being cursed by ancestors [14] and stigma from health care professionals [15] further aggravate the caring duties of caregivers, precipitating objective burden. The objective burden of care is less reported in the literature than subjective feelings of burden. Many studies have reported the subjective burden of care, which highlights emotional distress and feelings of anxiety, depression, and sadness related to the challenges of caregiving and witnessing the struggles of their family member. Loss of freedom and autonomy has also been reported owing to the demand of caregiving [16]. Feelings of shame and social isolation stem from the stigma of mental illness and cultural beliefs about being cursed by ancestors. Caregivers can also experience role strain as they have to juggle responsibilities at home, which can cause fatigue and overall dissatisfaction in life [17]. Both dimensions of burden are crucial for understanding the challenges faced by family caregivers of individuals with severe and enduring mental health conditions and play a vital role in informing support strategies and interventions.

There is overwhelming evidence in the literature for the need to support caregivers, and several studies from high-income and low- and middle-income countries have indicated successful strategies for alleviating caregiver burden. Studies on informal caregivers of people with severe and enduring mental health conditions in low- and middle-income countries have also increased over the past 10 years, and the burden of caregivers has been well described [18-21]. Yerriah et al [16] reported on the extent of the burden of caregivers of persons with

XSL•FO

RenderX

schizophrenia in rural South Africa and found that this sample has a higher burden of care. A recommendation from this study was to develop strategies to support caregivers with the aim of improving their quality of life.

Support Strategies for Caregivers

To date, a number of strategies to support caregivers have been investigated with varying results. In Turkey, family-to-family support programs have shown a positive impact on the burden of care [22]. A meta-analysis by Chen et al [23] showed some support for nonpharmacological interventions (mostly psychoeducation) for caregivers of persons with schizophrenia, but the authors reported a potential bias in the results because of the small sample size. In contrast, the systematic review and meta-analysis by Sin et al [24] did not support psychoeducation to improve compliance with treatment and prevent relapse in persons with psychosis, and they reported a lack of available data; thus, no meta-regressions could be conducted. Ewertzon and Hanson [18] conducted a narrative review and identified provision of knowledge, problem-solving, stress management, mutual support groups, and individual-support interventions as successful support interventions for caregivers. Finally, a systematic review by Napa et al [25] revealed that there is insufficient evidence of interventions for psychological distress and expressed emotions in families of persons who experienced first-episode psychosis.

There is limited evidence of web-based health care services and digital health technologies for supporting informal caregivers of individuals with severe and enduring mental health conditions [26]. Sin et al [27] developed an eHealth intervention called Carers for People with Psychosis e-support, but its effectiveness has not yet been investigated. Ploeg et al [28] conducted a rapid review of web-based interventions to improve general caregiver outcomes. More than half of the 17 included studies showed a positive outcome for decreased depressive symptoms, stress, and anxiety among caregivers. If virtual strategies can support caregivers in rural areas, they may be a feasible method to reach people in remote areas who have poor access to health care.

Informal caregivers in rural or remote areas face additional objective burdens such as poor access to services, lack of integration of mental health into community health services [29], and poor intersectoral collaboration. They often have to wait long hours before any support arrives, and in many cases, they have to deal with challenges with the limited resources they have available.

If the types of intervention strategies that could be relevant for low- and middle-income countries, how they were implemented, and the outcome that was achieved were mapped, it could guide health care workers to support informal caregivers on various levels and with various strategies. The availability of virtual support strategies could add another dimension of support to caregivers, which may lead to additional positive outcomes such as immediate support, available information, and contact with support groups. People with severe and enduring mental health conditions benefit as they are most likely to receive optimal care, and their relapse rate may decrease, which means less need for readmission in overextended mental health care wards or hospitals. In addition, people with severe and enduring mental

health conditions may also experience a better quality of life if their carers are supported. Thus, it is essential to understand the strategies to alleviate informal caregiver burden and how these strategies should be implemented.

This scoping review aimed to map the strategies to alleviate the objective and subjective burden of informal caregivers of persons with severe and enduring mental health conditions in low- and middle-income countries. The objectives of this scoping review were to (1) identify the types of existing strategies (virtual and face-to-face) for alleviating the objective or subjective burden of care, (2) describe the characteristics of the identified strategies, and (3) list the positive outcomes that were achieved using the identified strategies.

Methods

Review Methodology

This scoping review followed the Joanna Briggs Institute methodology specific to scoping reviews [30]. An a priori protocol for this review has been published [31].

Review Question

The scoping review addressed two research questions related to the strategies for alleviating the burden of care among informal caregivers of persons with severe and enduring mental health conditions:

1. Which existing strategies are reported in the literature for alleviating the burden of informal caregivers of persons with severe and enduring mental health conditions in low- and middle-income countries?
2. What are the outcomes reported by the authors of the strategies for alleviating burden among informal caregivers?

Eligibility Criteria

Participants

Studies were included if participants were informal caregivers of persons with severe and enduring mental health conditions in low- and middle-income countries. Studies that focused on informal caregivers of patients diagnosed with Alzheimer disease and dementia were excluded. This included family, friends, neighbors, and community members who voluntarily provided care without any remuneration. Studies that included both informal caregivers and patients as participants were considered for inclusion, whereas those that reported only on patients were excluded.

Concept

Caregiver burden was defined as the physical, psychological, emotional, social, and financial stresses of providing care to a person with severe and enduring mental health conditions [32]. Severe and enduring mental health conditions in this scoping review included the schizophrenia spectrum and other psychotic disorders, bipolar and related disorders, mood or depressive disorders, and personality disorders. Studies that investigated strategies for alleviating caregiver burden were considered for inclusion. This also included studies that investigated the synonyms used to describe the burden of care among informal caregivers, such as *caregiver strain*, *stress*, and *role fatigue*.

Studies that reported on the burden of care without suggesting strategies for alleviating it were excluded.

Context

Studies from low- and middle-income countries, including countries in Africa, Asia, Latin America, and the Caribbean, were considered for inclusion. In addition, the inclusion criteria comprised studies from lower-middle-income countries using the World Bank classification of the economic status of a country at the time the study was conducted. The term *developing country* was included as it is similar to *lower-middle-income country*, and thus, countries in Africa, Asia, and Latin America (including the Caribbean) were eligible for inclusion.

Types of Sources

This review included published qualitative, quantitative, and mixed methods studies with all types of designs as well as unpublished studies, including dissertations and theses. Over the last decade, there has been a growing body of knowledge from studies outlining strategies for alleviating burden among informal caregivers in low- and middle-income countries. As a result, this review was only restricted to studies conducted between 2011 and 2021. Only papers written in English were included in this review.

Search Strategy

A 3-step search strategy process was used to identify relevant studies. The search strategy commenced with an initial limited search of PubMed, MEDLINE, CINAHL, and PsycINFO for published studies between 2011 and 2021. The keywords were as follows: "[informal caregiver/s OR caregiver/s] AND [caregiver burden OR caregiver stress] AND [support strategy/ies OR intervention/s] AND [severe mental disorder/s OR mental illness] AND [developing country/ies]."

The second search was refined with the assistance of the librarian at the University of the Witwatersrand, and additional terms were added: "[Carers or 'Informal Carers' or 'Male Caregiver' or Women Caregiver' or 'Family Caregivers'] AND [Caregiver* strain' or 'Caregiver *Exhaustion' or 'Caregiver* burnout' or 'Carer* burden'] AND ['underserved' or 'deprived' or 'middle-income' or low income country]." On advice from the librarian, gray literature such as conference presentations and unpublished studies was searched on ProQuest Dissertations and Theses Global and public health and conference databases. Finally, 2 reviewers (OS and DC) screened the reference lists of the included articles for additional studies. Textbox 1 presents the final list of search terms used to search published and unpublished studies across all the selected databases in this review. The identified references were imported into the Mendeley reference manager (Elsevier) for screening.

Source of Evidence Selection

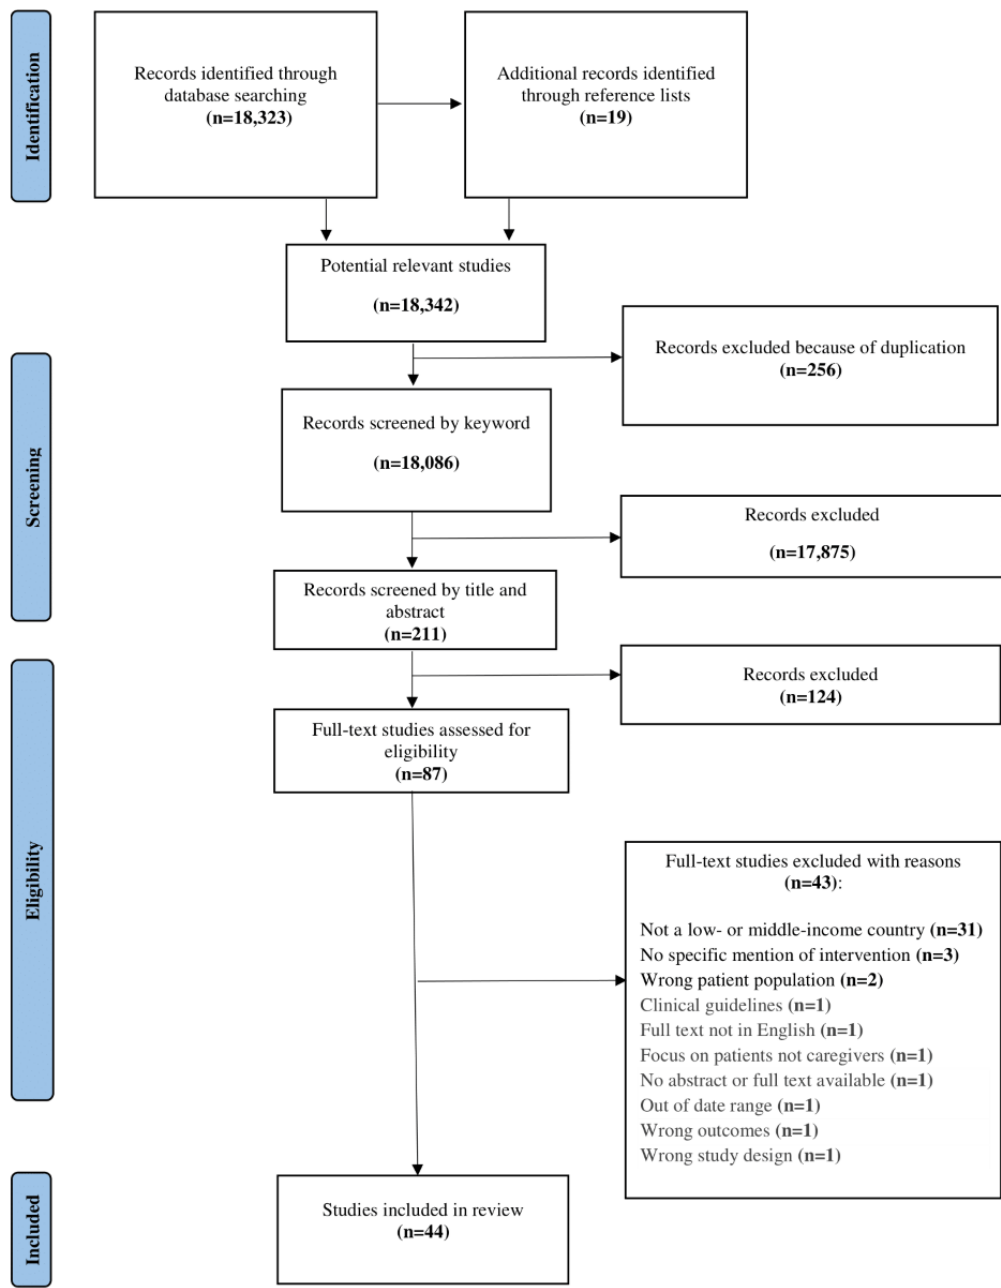
Following the search, all identified citations were exported to the Mendeley reference manager and thereafter to a web-based software, Covidence (Veritas Health Innovation), for primary screening and data extraction from the selected articles. Duplicates were removed, and 2 reviewers (OS and DC) independently conducted the screening for titles, abstracts, and full texts using the inclusion and exclusion criteria. To enhance the reliability of the review results, the first 5 abstracts were screened, and the 2 reviewers compared the screening results and clarified conflicts. Following this, the criteria were revised

to ensure a detailed description of the various types of burden. The remaining abstracts were screened, and comparisons were made after 10 screenings to manage conflicts. The 2 reviewers (OS and DC) proceeded to screen texts and extract data from the selected articles. Any disagreements regarding the inclusion of the studies were resolved through discussion between the 2 reviewers.

Data Extraction

The Covidence software has templates for data extraction. These templates were modified using the data extraction tables proposed by Peters et al [30]. To ensure the extraction of

relevant data to answer the review question, these templates were piloted by the reviewers before use. In total, 2 separate data extraction templates (Multimedia Appendix 1) were used to extract data from studies that implemented an intervention and from studies that recommended interventions and strategies for alleviating caregiver burden. Data related to the characteristics of the studies were extracted, including study title; study aims; citation details; population of interest; concept of interest; context of the study, including the country and type of setting; type of evidence sources; study approach and designs; and participant characteristics, such as age, gender, and diagnosis of the care recipients. In addition, information on the characteristics of the interventions was extracted. This included the intervention content (ie, type of intervention, intervention developer and deliverer, and type of burden targeted by the intervention). The intervention description included the duration of the intervention, number of sessions, and location for the intervention. The templates for extracting the data are available in Multimedia Appendix 1. The reviewers extracted the data independently. Web-based meetings were held biweekly to discuss and resolve any discrepancies in the extracted data. Regular comparisons were easy and quick to conduct and improved the consistency of the extracted data. After completing the data extraction, the 2 reviewers scanned the references of the included articles to ensure that no articles were missed. Included and excluded studies were reported in a PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) flow diagram (Figure 1).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.


Data Analysis and Presentation

To increase consistency in the data, this review followed a 3-step analysis process as proposed by Levac et al [33]. This included analyzing the data, reporting the results, and applying meaning to the results [33]. The first step was reviewing the extracted data and identifying the type of data to be analyzed, which were then grouped according to the objectives of the review. This was followed by identifying the type of analysis appropriate for the specific type of data and then analyzing the extracted data. A descriptive quantitative analysis was conducted in a Microsoft Excel (Microsoft Corp) spreadsheet to describe the characteristics of the studies. This included the overall number of studies, types of study design, years of publication, characteristics of the study populations, countries where the studies were conducted, and types of interventions. In addition, descriptive content analysis was conducted deductively using the NVivo software (Lumivero) to code the characteristics of the extracted data into overall categories [34]. Data were categorized into types of strategies—implemented and recommended intervention strategies—and the outcomes of the strategies aimed at alleviating the burden of informal caregivers as reported by the authors. To enhance the clarity of the emerging findings, the data were summarized and presented in graphs and tables.

Results

Study Inclusion

A total of 18,323 studies were identified from the databases using the keywords. In total, 19 additional studies were identified from the reference lists of the included studies, thereby bringing the total number of potentially relevant studies to 18,342. Subsequently, of the 18,342 studies, 256 (1.4%) duplicates were removed, thereby leaving 18,086 (98.6%) studies deemed relevant to the review based on the keywords. A total of 98.83% (17,875/18,086) of these studies were then excluded; this exclusion of numerous studies occurred because of their incongruence with the predefined inclusion criteria, such as instances in which the study did not pertain to a low- or middle-income country context or in which the primary emphasis lay on the patient rather than the caregiver. Therefore, 1.17% (211/18,086) of the studies were screened by title and abstract based on set inclusion and exclusion criteria. This led to the exclusion of 58.8% (124/211) of these studies from the review. A total of 41.2% (87/211) of the studies were then retrieved as full texts based on eligibility by screening their titles and abstracts. Of these 87 studies, 43 (49%) were excluded for various reasons: 31 (72%) were not from low- or middle-income countries; 3 (7%) did not specify the intervention strategy; 2 (5%) focused on the wrong patient population; and another 7 (16%) were excluded for being a clinical guideline, focusing on patients rather than caregivers, having misaligned outcomes and a study design within the exclusion criteria (eg, review articles), being out of the date range of this review, the full text being in a language other than English, and a lack of an abstract and full text. Finally, 44 studies were included in this scoping review. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram was used to present the selection of the studies (Figure 1). It took approximately 8 months, from September 2021 to June 2022, to carry out the study from conception to completion of the project.

Characteristics of the Eligible Studies

Summary of Studies and Evidence Type

The included studies were published between 2011 and 2021. Most studies (31/44, 70%) were published between 2016 and 2021, and 30% (13/44) were published between 2011 and 2016. The types of studies included peer-reviewed journal articles (40/44, 91%), research reports or theses (2/44, 5%), and opinion pieces (2/44, 5%). Of the 44 included studies, 29 (66%) reported on a specific implemented intervention strategy, and 15 (34%) outlined recommended intervention strategies aimed at alleviating the burden of informal caregivers of people with severe and enduring mental health conditions in low- and middle-income countries. The study designs included randomized controlled trials (21/44, 48%), quantitative studies (15/44, 34%), qualitative studies (3/44, 7%), mixed methods studies (3/44, 7%), and gray literature (2/44, 5%; Table 1).

Table 1. Characteristics of the included studies (N=44).

Characteristic	Studies, n (%)
Summary of studies	
Implemented strategy studies	29 (66)
Recommended strategy studies	15 (34)
Type of evidence	
Journal articles	40 (91)
Research reports or theses	2 (5)
Opinion pieces	2 (5)
Year of publication	
2011-2015	13 (30)
2016-2021	31 (70)
Study design	
Randomized controlled trial	21 (48)
Quantitative design	15 (34)
Qualitative design	3 (7)
Mixed methods	3 (7)
Gray literature	2 (5)

Context of the Studies

A total of 44 studies identified from 16 low- and middle-income countries in Asia, Africa, Europe, and South and North America (Mexico) were included. The countries included China (12/44, 27%); Iran (10/44, 23%); India (5/44, 11%); Brazil (3/44, 7%); Greece (2/44, 5%); Ghana (2/44, 5%); and Thailand, Nepal, South Korea, Indonesia, Jordan, Mexico, Ethiopia, Turkey, Botswana, and mixed countries (including Brazil, Iran, Colombia and Mexico 1/44, 2% of the studies each). As shown in Table 2, majority of the studies with implemented strategies (24/29, 83%) and those with recommended strategies (9/15, 60%) were from Asian countries. Overall, 7% (2/29) of the studies each from Europe, South America, and North America implemented the strategies for alleviating burden and 13% (2/15) of the studies from South and North America recommended the strategies. Only 3% (1/29) of the studies conducted in Africa implemented the strategies and 20% (3/15) of the studies recommended the strategies. A study (1/15, 7%) from mixed countries recommended the strategies for alleviating burden.

Table 2. Continents of the recommended and implemented strategies (N=44).

Continent	Implemented strategies, n (%)	Recommended strategies, n (%)
Asia	24 (83)	9 (60)
Africa	1 (3)	3 (20)
Europe	2 (7)	0 (0)
South and North America	2 (7)	2 (13)
Mixed countries	0 (0)	1 (7)

Characteristics of the Study Populations

The targeted populations in the included studies were mainly family caregivers (38/44, 86%), 7% (3/44) of the studies targeted informal carers, and some studies (3/44, 7%) did not specify their targeted population but rather identified them as caregivers. Most studies (33/44, 75%) included both male and female caregivers, and 25% (11/44) did not specify the sex of their sample. Similarly, most studies (24/44, 55%) included both male and female care recipients, only 2% (1/44) of the studies focused only on male care recipients, and 43% (19/44) did not specify the gender of the care recipients included in the studies. The diagnoses of the care recipients in the included studies were grouped into 6 categories: schizophrenia (17/44, 39%), mood disorders (4/44, 9%), multiple diagnoses including schizophrenia and mood disorders (5/44, 11%), mixed severe and enduring mental health conditions (5/44, 11%), other psychotic and chronic conditions (6/44, 14%), and unspecified mental disorders (7/44, 16%; Table 3).

Table 3. Characteristics of the study populations in the included studies (N=44).

Characteristic	Studies, n (%)
Population of interest	
Family caregiver or caregivers	38 (86)
Informal carer or carers	3 (7)
Caregiver or caregivers	2 (5)
Carer or carers	1 (2)
Concept of interest	
Caregiver burden	18 (41)
Family burden	16 (36)
Caregiver stress	9 (20)
Caregiver strain	1 (2)
Sex of caregivers	
Mixed-gender groups (male and female)	33 (75)
Not specified	11 (25)
Gender of care recipients	
Mixed-gender groups (male and female)	24 (55)
Male	1 (2)
Not specified	19 (43)
Diagnosis of care recipients	
Schizophrenia	17 (39)
Mood disorders	4 (9)
Schizophrenia and mood disorders	5 (11)
Mixed diagnoses of severe mental disorders	5 (11)
Unspecified mental disorders	7 (16)
Other (drug dependency, psychotic disorders, and chronic conditions)	6 (14)

Concept of Interest

The concepts of interest reported in the studies included caregiver burden (18/44, 41%), family burden (16/44, 36%), caregiver stress (9/44, 20%), and caregiver strain (1/44, 2%; Table 3).

Review Findings

This section outlines the findings of the scoping review and includes the types of intervention strategies, characteristics of the intervention strategies, and author-reported outcomes from the included studies.

Types of Intervention Strategies

The various strategies for alleviating caregiver burden were grouped into 2 categories: implemented and recommended intervention strategies. The implemented intervention strategies emerged from studies that investigated the effects of a specific intervention to alleviate the burden of informal caregivers. The recommended interventions were identified from studies that investigated caregiver burden and outlined recommended intervention strategies to be used to alleviate the burden of informal caregivers of persons with severe and enduring mental

health conditions. Most studies (29/44, 66%) reported on an implemented intervention strategy, and 34% (15/44) of the studies recommended strategies to alleviate caregiver burden.

Most of the studies and articles (33/44, 75%) originated in Asia, with 55% (24/44) implemented and 20% (9/44) recommended intervention strategies reported on, followed by Africa with 2% (1/44) implemented and 7% (3/44) recommended intervention strategies, South and North America with 5% (2/44) implemented and 5% (2/44) recommended intervention strategies, and Europe with 5% (2/44) implemented intervention strategies (Table 2). A study from mixed countries only reported recommended intervention strategies. The identified strategies were grouped into the following categories: community-based interventions, psychoeducation interventions, support groups, cognitive behavioral therapy (CBT), spirituality-based interventions, smartphone-based interventions, mindfulness and empowerment, collaborative interventions, standard care, financial and social support, counseling, occupation-based interventions, policy and legislature, and access to mental health care (Table 4 and Textbox 2). These categories are discussed in the following subsections.

Table 4. Description of the identified evaluated strategies for alleviating informal caregiver burden.

Type of strategy	Evaluated interventions	Author-reported outcomes
Community-based interventions	• CoMHIP[a] • RESHAPE[b]	• Positive outcomes (positive effects on family caregivers)
Psychoeducation interventions	• Psychoeducation program • Group psychoeducation • FLEP[c] • Peer-assisted education	• Improved coping skills • Enhanced recovery • Improved QoL[d] • Knowledge and skill acquisition • Reduced burden of care • Reduced anxiety and stress • Reduced psychological strain • Enhanced family functioning • Relapse prevention • Reduced prolonged admissions • Negative outcomes (no efficacy on burden of care, QoL, or self-esteem among BMD[e] caregivers)
Support groups	• FPGP[f] • Family-led mutual support program	• Knowledge and skill acquisition • Enhance help seeking • Alleviation of guilt • Improved family and patient functioning • Decreased demand on mental health services • Improved psychosocial health • Improved QoL
Cognitive behavioral therapy	• Emotional regulation training	• Reduced burden of care • Reduced anxiety and stress • Increased resilience
Spirituality-based intervention	• Spirituality-based program	• Reduced anxiety and stress
Guided self-help interventions	• Manual-guided PBSP[g] • The Good Mood Guide	• Strengthened positive caregiving experience • Reduced negative caregiving experience • Increased access to support
Smartphone-based interventions	• MHapps[h]	• None
Mindfulness and empowerment interventions	• IEP[i] • MBSR[j] program	• Caregiver empowerment • Improved QoL • Decreased depressive symptoms • Increased self-efficacy
Collaborative interventions	• Participatory care model	• Reduced burden of care • Increased resilience
Standard care	• Multimodal intervention (general medicine, psychiatry, psychology, family therapy, neuropsychological rehabilitation, and occupational therapy)	• Reduced burden of care • Increased social support

[a]CoMHIP: community mental health early intervention project.

[b]RESHAPE: Reducing Stigma Among Healthcare Providers.

[c]FLEP: Family Link Education Programme.

[d]QoL: quality of life.

[e]BMD: bipolar mood disorder.

[f]FPGP: Family-led Peer Support Group Program.

[g]PBSP: problem-solving–based self-learning program.

[h]MHapps: mental health apps.

[i]IEP: integrated empowerment program.

[j]MBSR: mindfulness-based stress reduction.

RenderX

Textbox 2. Description of the identified recommended strategies for alleviating informal caregiver burden.

Community-based interventions

- Strengthening existing primary health care system
- Establishment of day nursing or care
- Respite care
- Vocational training for patients
- Single-family caregiver organization
- Supported employment for patients
- Home visits

Psychoeducation interventions

- Group psychoeducation
- Family education
- Continuing education programs for effective practice
- Educational lectures
- Psychoeducation program

Support groups

- Nongovernmental mental health–related support groups
- Family caregiver assistance programs

Cognitive behavioral therapy

- Family therapy groups

Spirituality-based intervention

- Turning to traditional healers and spiritual leaders

Smartphone-based interventions

- Mental health apps

Mindfulness and empowerment interventions

- Stress management training

Collaborative interventions

- Caregiver involvement in all program elements
- Pluralistic and ecological approach to service delivery

Standard care

- Telepsychiatry
- Availability of emergency teams

Financial support

- Disability grant
- Fee-free mental health services
- Medical insurance and free medication

Social support

- Medical care social security
- Social resources

Counseling

- Basic counseling

- Supportive psychotherapy

Occupation-based interventions

- Physical and leisure activities

Policy and legislature

- National health insurance schemes

- Advocacy for a strong mental health policy

- Integration of caregiver actions and interventions into national mental health care plans

- Fee-free mental health services

Access to mental health care

- Caregiver care inclusion in daily treatment facilities

- Access to therapeutic tools

- Availability of mental health units or departments

- Periodic health checks for caregivers (every 6 months on average)

- Improvement in institutional mental health care

Psychoeducational Interventions

The first strategy was psychoeducational interventions, which was identified as the most common strategy implemented and recommended to alleviate caregiver burden. A total of 27% (12/44) of the studies implemented 4 different psychoeducational interventions, including 58% (7/12) of these studies using a psychoeducation program [35-40], 17% (2/12) using group psychoeducation [41,42], 17% (2/12) using the Family Link Education Programme [43,44], and 8% (1/12) of the studies implementing peer-assisted education [45] (Table 4). Similarly to the implemented intervention strategies, the recommended psychoeducational interventions identified included psychoeducational programs, group psychoeducation, family psychoeducation, continuing education programs for effective practice, and educational lectures [7,46] (Textbox 2).

Support Group Interventions

The second strategy was support groups. In total, 7% (3/44) of the studies implemented support group strategies, including the Family-led Peer Support Group Program, family-led mutual support programs, and nongovernmental mental health–related support groups [47-49] (Table 4). The recommended support group strategies identified in this review included nongovernmental mental health–related support groups and family caregiver support programs [50-54] (Textbox 2).

Community-Based Interventions

Community-based interventions were identified as a third strategy to alleviate caregiver burden, and 5% (2/44) of the included studies reported on implementing a community mental health early intervention project and Reducing Stigma Among Healthcare Providers [55,56] as community-based interventions (Table 4). The recommended community-based interventions included strengthening existing primary health care systems, establishing day nursing or care for the care recipients, respite

care, vocational rehabilitation training for patients, single-family caregiver organizations, supported employment for patients, and home visits [46,52,53,57] (Textbox 2).

Guided Self-Help Interventions

A total of 5% (2/44) of the studies implemented guided self-help interventions, namely, a manual-guided problem-solving–based self-learning program [58] and the Good Mood Guide [59] (Table 4). No recommended guided self-help interventions were identified in this review.

Mindfulness and Empowerment Interventions

Mindfulness and empowerment interventions were implemented in 5% (2/44) of the studies, and the programs implemented were a mindfulness-based stress reduction program and an integrated empowerment program [60,61] (Table 4). Stress management training was identified as a recommended mindfulness and empowerment intervention strategy in this review [7] (Textbox 2).

CBT Interventions

Emotional regulation training was the only implemented CBT strategy identified in 5% (2/44) of the included studies [62,63] (Table 4). The recommended cognitive behavioral strategy identified in this review was family therapy groups [64] (Textbox 2).

Spirituality-Based Interventions

In total, 2% (1/44) of the studies implemented a spirituality-based program for informal caregivers in which the comparison intervention was 2 standard group training sessions related to general mental disorders [65] (Table 4). Turning to traditional healers and spiritual leaders was identified as a recommended spirituality-based intervention for alleviating informal caregiver burden [52] (Textbox 2).

Participatory Care Model

In total, 2% (1/44) of the studies implemented a participatory care model as a collaborative intervention strategy [66] (Table 4). The recommended collaborative interventions were caregiver involvement in all program elements and a pluralistic and ecological approach to service delivery [56,67] (Textbox 2).

Standard Care

The implemented standard care interventions were multimodal interventions that encompassed general medicine, psychiatry, psychology, family therapy, neuropsychological rehabilitation, and occupational therapy with no comparison intervention [68] (Table 4). The recommended standard care interventions were telepsychiatry and ensuring the availability of emergency teams [53] (Textbox 2).

Smartphone-Based Interventions

Only 2% (1/44) of the studies implemented smartphone-based interventions using mental health apps to alleviate the burden of informal caregivers with no comparison intervention [67] (Table 4). Although the study indicated the use of the mental health apps with care recipients and their caregivers, the specific intervention offered was not described. No recommended smartphone-based interventions were identified in this review.

Additional Strategies Recommended for Alleviating Caregiver Burden

The additional recommended intervention strategies were financial support, including the provision of a disability grant, fee-free mental health services, medical insurance, and free medication for care recipients [7,57,68]. The recommended social support comprised medical care social security and social resources [52,54,56,57,69]. Recommended counseling interventions comprised basic counseling and supportive psychotherapy [64,69]. Occupation-based interventions included participation in physical and leisure activities [64]. Policy and legislature recommended interventions comprised the implementation of national health insurance schemes, advocacy for a strong mental health policy, integration of caregiver actions and interventions into national mental health care plans, and

fee-free mental health services [53,62,68]. Finally, other recommended interventions were access to mental health care, which considers caregiver care inclusion in daily treatment facilities; access to therapeutic tools; availability of mental health units or departments; periodic health checks for caregivers (every 6 months on average); and improved institutional mental health care [35,52,54,67] (Textbox 2).

Characteristics of the Implemented Intervention Strategies

Most of the implemented intervention strategies (18/29, 62%) were targeted at alleviating both objective and subjective burden, and 38% (11/29) were exclusively aimed at alleviating subjective burden. The intervention developers were reported as being researchers based on evidence (13/29, 45%) and researchers with expert input (5/29, 17%). In total, 28% (8/29) were existing interventions implemented without any adaptations, and 10% (3/29) of the interventions did not specify the intervention developer. The intervention deliverers identified in the studies included trained peer facilitators (7/29, 24%), researchers (7/29, 24%), psychiatrists and nurses (5/29, 17%), multiple health care professionals (4/29, 14%), and psychologists (3/29, 10%), and 10% (3/29) of the interventions did not specify who delivered them.

The number of sessions offered in the implemented intervention strategies was between 6 and 8 sessions (13/29, 45%), ≤5 sessions (8/29, 28%), and ≥11 sessions (5/29, 17%), and 10% (3/44) of the interventions did not specify the number of sessions. The duration of the implemented interventions in the studies was 6 to 15 weeks (10/29, 34%), ≤5 weeks (7/29, 24%), and ≥16 weeks (4/29, 14%), and 28% (8/29) of the interventions did not specify the duration. Most interventions (9/29, 31%) were delivered once per week, some were offered twice a week (8/29, 28%), and some of the interventions (12/29, 41%) did not specify the frequency of their sessions. The length of the sessions in the implemented interventions ranged between 2 and 2.5 hours (8/29, 28%), 1 to 1.5 hours (6/29, 21%), and ≤1 hour (1/29, 3%), and 48% (14/29) of the interventions did not specify the length of their sessions (Table 5).

Table 5. Characteristics of the implemented strategies for alleviating informal caregiver burden (N=29).

Study	Year of publication	Type of intervention	Type of burden targeted by the intervention	Intervention developer	Intervention deliverer	Number of sessions	Duration of intervention	Frequency of sessions per week	Length of the sessions
Ng et al [56]	2018	CoMHIP[a]	Subjective and objective	Not specified	The Integrated Community Centre for Mental Wellness	Not specified	Not specified	Not specified	Not specified
Rai et al [55]	2018	RESHAPE[b]	Subjective and objective burden	Developed as part of WHO[c] mhGAP[d] and PRIME[e]	TPO[f] Nepal, a Nepali non-governmental organization	5 sessions	4 days	Not specified	Not specified
Rajai et al [45]	2021	Peer- assisted education	Subjective and objective burden	Researchers and approved by 3 faculty members of the Army College of Medical Sciences	Trained peer facilitators	6 sessions	3 weeks	Twice weekly	1 hour
Zhou et al [44]	2020	FLEP[g]	Subjective and objective burden	FLEP: peer-led psychoeducation program developed from the stress and coping model by Pearlin et al [70]	Group facilitators who were peer specialists of experienced caregivers	8 sessions	8 weeks	Once weekly	2 hours
Dewi et al [37]	2019	Family psychoeducation and care decision without pasung	Subjective and objective burden	Researchers	Researchers	3 sessions	3 weeks	Not specified	35-40 minutes
Tabeleão et al [36]	2018	Psychoeducation	Subjective and objective burden	Not specified	10 psychologists	6 sessions	Not specified	Not specified	Not specified
Ntsayagae [40]	2017	Psychoeducation	Subjective and objective burden	Researcher based on existing literature	Researcher	2 sessions	Not specified	Not specified	Not specified
De Souza et al [39]	2016	Psychoeducation	Subjective and objective burden	Psychoeducational intervention for patients with BD[h] by Colom et al [71] translated and adapted by Dell-Aglio et al [72]	Psychiatrist responsible for specific case	6 sessions	6 to 8 weeks	Twice weekly	Not specified
Kolostoumpis et al [38]	2015	Psychoeducation	Subjective burden	Adapted from the treatment protocol developed by Reinares et al [73] in the Barcelona Bipolar Disorders Program in Spain	Psychiatrist and psychologist	7 sessions	Not specified	Not specified	Not specified
Jessy and Kalaimathy [35]	2014	Psychoeducation	Subjective and objective burden	Researcher based on WHO guidelines for educational interventions and existing literature. Manual translated into Tamil.	Researcher	5 modules	10 weeks	Twice weekly	1 hour

Study	Year of publication	Type of intervention	Type of burden targeted by the intervention	Intervention developer	Intervention deliverer	Number of sessions	Duration of intervention	Frequency of sessions per week	Length of the sessions
Fallahi Khoshknab et al [41]	2014	Group psychoeducation	Subjective and objective burden	Researchers based on educational program of psychiatric nursing and psychiatric textbooks	Organized based on educational program of psychiatric nursing and psychiatric textbooks (Campbell [74]) and converted to understandable text for patients and families	4 sessions	4 weeks	Once weekly	2 hours
Navidian et al [42]	2012	Psychoeducation	Subjective burden	Researchers based on the families' needs and the existing literature	Psychiatrist and mental health nurse	4 sessions	4 weeks	Once weekly	2 hours
Sharif et al [75]	2012	Psychoeducation	Subjective and objective burden	Psychiatrist and psychiatric nurse based on the literature and needs of the families	Psychiatrist, nurse, and guest speakers	10 sessions	5 weeks	Not specified	1.5 hours
Chiu et al [43]	2011	FLEP	Subjective burden	Task force consisting of a mental health social worker, a recovered patient with editorial experience, and a caregiver based on available related local educational materials and the NAMI[i] Family-to-Family program	Trainers who were themselves family members of people with SMF[j]. They received training and a trainer manual.	8 sessions	Not specified	Once weekly	Not specified
Chien et al [48]	2018	Family-led support program	Subjective and objective burden	Family-led mutual support group—contents were based on similar program protocols and the researcher-developed family mutual support groups for psychotic disorders	Family-led mutual support group—co-led by 2 peer family caregivers along with a researcher and rehabilitation nurse	16 sessions	36 weeks	Twice weekly	2 hours
Mentis et al [49]	2015	Support group intervention	Subjective burden	Nongovernmental mental health organization (NGOMH[k])	Not mentioned	Not specified	Not specified	Not specified	Not specified
Chien et al [48]	2018	Family-led mutual support program	Subjective burden	6 experts on psychiatric rehabilitation (including psychiatrists, clinical psychologists, and nurse specialists)	Peer leader who received training from the researchers and worked closely with a group leader who was a trained psychiatric nurse	14 sessions	39 weeks	Twice weekly	2 hours

Study	Year of publication	Type of intervention	Type of burden targeted by the intervention	Intervention developer	Intervention deliverer	Number of sessions	Duration of intervention	Frequency of sessions per week	Length of the sessions
Chien and Chan [47]	2013	FPGP[l]	Subjective and objective burden	Content and format were based on previous programs conducted by Li and Arthur [76] in mainland China. Appropriateness of the content was rated by 7 experts, including psychiatrists, psychologists, and nursing specialists.	Peer support—peer leader supported by principal researcher	14 group sessions	39 weeks	Twice weekly	2 hours
Behrouian et al [62]	2021	Emotional regulation	Subjective burden	On the basis of the Dialectical Behavior Therapy Skills Workbook and CBT[m] principles	Clinical psychologist	8 sessions	8 weeks	Once weekly	Not specified
Behrouian et al [63]	2020	Emotion regulation training	Subjective and objective burden	Sessions were based on previous studies (Gratz and Gunderson [77]). Trainings were based on the Dialectical Behavior Therapy Skills Workbook (McKay et al [78]).	Clinical psychologist	8 sessions	Not specified	Not specified	Not specified

Perceived Effectiveness of the Implemented Intervention Strategies

This review outlines the effectiveness of the implemented intervention strategies as reported by the authors who conducted the studies (Table 4). It should be noted that this scoping review included both published and gray literature, and therefore, no critical appraisal of the studies or meta-analyses were conducted. Therefore, care should be taken as these interpretations may be clouded by author bias [84].

The authors expressed the effectiveness of the implemented intervention strategies by highlighting whether the strategy resulted in a positive or negative outcome for the informal caregivers or their care recipients. Overall, the implemented strategies were reported to be effective in reducing the burden of care and improving the quality of life of informal caregivers. Psychoeducation intervention strategy outcomes included improved coping skills, improved quality of life, reduced anxiety and stress, reduced burden of care, reduced psychological strain, improved knowledge and skills in caregiving, enhanced family functioning, enhanced recovery, relapse prevention, and reduced prolonged admissions. Support group outcomes included alleviation of guilt, enhanced help-seeking behavior, improved quality of life, improved knowledge and skills in caregiving, improved psychosocial health, improved family and patient functioning, and decreased demand for mental health services. CBT outcomes included reduction in burden of care, anxiety, and stress and increased resilience of informal caregivers. Guided self-help outcomes included strengthened positive caregiving experiences, reduced negative caregiving experiences, and increased access to support. The reported outcomes for mindfulness and empowerment interventions included empowerment of caregivers, increased self-efficacy, improved quality of life, and decreased depressive symptoms. Collaborative intervention outcomes included reduced burden of care and increased resilience. The standard care outcomes reported included positive outcomes in caregiving, reduction in the burden of care, and increase in social support for caregivers.

Negative outcomes were only reported for the psychoeducation and mindfulness and empowerment intervention strategies. The reported negative outcomes of psychoeducation interventions were no improvement in the burden of care, quality of life, or self-esteem. The reported negative outcomes of mindfulness and empowerment interventions included short-lived improvement in anxiety, and the authors highlighted no improvement after 3 months of follow-up with the participants and no effect on perceived stress, quality of life, and self-compassion, indicating that the effects of the interventions were not sustainable.

Discussion

Principal Findings

This scoping review set out to map the literature on strategies for alleviating the burden of informal caregivers of persons with severe and enduring mental health conditions in low- and middle-income countries. The review identified types of strategies, strategy characteristics, and outcomes of the strategies as reported by the authors. The types of strategies identified were categorized as implemented and recommended intervention strategies and included community-based interventions, psychoeducational interventions, support groups, CBT, spirituality-based interventions, guided self-help, smartphone-based interventions, mindfulness and empowerment, collaborative interventions, standard care, financial and social support, counseling, occupation-based interventions, policy and legislature, and access to mental health.

Most of the implemented and recommended intervention studies (33/44, 75%) were conducted in Asian countries and targeted both subjective and objective burdens, and some studies (18/29, 62%) focused exclusively on subjective burden. This shows an increasing research interest in caregiver interventions in mental health research in Asian countries over the last decade. In contrast, the small number of studies from other low- and middle-income countries possibly confirms the limited research on support strategies for alleviating caregiver burden in mental health. Despite consensus on the high levels of burden of informal caregivers of persons with severe and enduring mental health conditions in these countries [56,85-87] and the importance of supporting caregivers, few studies (44/18,086, 0.24%) implemented and recommended intervention strategies for alleviating caregiver burden. This evidence gap raises significant concerns considering the scarcity of mental health care professionals and limited access to quality mental health services in many low- and middle-income countries. As a result, informal caregivers assume a vital role in the support and care of persons with severe and enduring mental health conditions in these regions [88,89]. Having limited strategies for alleviating the burden of informal caregivers may have dire consequences for the management of persons with severe and enduring mental health conditions in these countries.

The implemented and recommended intervention strategies were mainly focused on both male and female family caregivers. These findings are consistent with the literature as families have long been acknowledged as key stakeholders in the care and management of mental disorders [90-93]. Therefore, it is important to ensure that the strategies for alleviating caregiver burden are targeted specifically to this population, particularly in low- and middle-income countries, where occupying this role is often obligatory [94]. The fact that most implemented intervention strategies were aimed at both male and female caregivers is important to note. Although caregiving is identified as a female-oriented role, there is evidence that men also occupy the primary caregiver role and are also likely to experience high levels of caregiver burden [20,94]. This emphasizes the need to ensure that, where strategies for alleviating caregiver burden are implemented, they focus on all caregivers irrespective of their gender. The care recipients in these studies were mostly diagnosed with schizophrenia and mood disorders. This is consistent with the literature highlighting that depressive disorders, schizophrenia, and bipolar disorders are among the top 10 leading causes of disability in low- and middle-income countries [95].

The findings of this scoping review emphasize the need for evidence-based intervention strategies aimed at alleviating the

burden of informal caregivers in low- and middle-income countries. Most implemented intervention strategies were informed by evidence, in which researchers consulted existing literature and sought expert input to develop their interventions. Trained peer facilitators delivered most of the implemented interventions and were informal caregivers themselves. This is important to note as it aligns with task shifting, which is focused on transferring skills and responsibilities to local people with the aim of increasing access to mental health services in low- and middle-income countries where there is a shortage of human resources [96,97]. In addition, the findings of this review reveal that researchers, nurses, and psychiatrists offered some of the interventions, which may not be sustainable in low- and middle-income countries given the shortage of mental health professionals [95]. Most studies (13/29, 45%) offered 6 to 8 sessions over 6 to 8 weeks, and the sessions were facilitated once or twice a week for 1 to 2 and a half hours. Given the number and frequency of sessions, it may be useful to use peer facilitators to offer these interventions as most are already in the community, which will ensure sustainability in resource-constrained contexts in low- and middle-income countries.

Overall, the implemented intervention strategies were reported to have a positive effect on alleviating the burden of informal caregivers of people with severe and enduring mental health conditions in low- and middle-income countries. In some studies, these effects were reported for both informal caregivers and their care recipients. The authors reported the effectiveness of the strategies in their studies in terms of the help, benefit, and effect that a specific implemented intervention strategy had on the informal caregivers. Some compared their interventions mainly with standard psychiatric care and psychoeducation, which focused on providing caregivers with information on specific or general mental disorders. Psychoeducational interventions were frequently implemented intervention strategies and were identified as helpful, beneficial, and effective in reducing caregiver burden [35,38,42,75]. This type of intervention was reported to improve caregiver knowledge and skills to enable them to cope with the demands of caregiving. In addition, psychoeducational interventions were linked with positive patient outcomes as they were reported to enhance patient recovery, which subsequently reduced relapses and prolonged admissions. These interventions were commended for being simple, feasible, and cost-effective, making them the most preferred form of intervention strategy to address the burden of informal caregivers.

Similarly, implemented intervention strategies such as support groups, community-based interventions, guided self-help, mindfulness and empowerment, and CBT were reported to have a positive effect on the burden of informal caregivers in low- and middle-income countries. It is important to note that the family-led mutual support program, a peer-facilitated intervention, was reported to have long-term desirable benefits on the psychosocial health of both caregivers and their care recipients compared with the psychoeducational program and standard care offered by psychiatrists, clinical psychologists, and nursing specialists. Similarly, the manual-guided problem-solving–based self-learning program, a guided self-help

intervention, was reported to have a superior treatment effect on caregiver burden, care recipients' symptom severity, and the duration of rehospitalizations at the 6-month follow-up compared with a well-accepted family psychoeducation group program. This implies that support groups and guided self-help, although not frequently implemented, should be considered beneficial strategies for alleviating caregiver burden. In addition, as self-directed and peer-evaluated interventions, these intervention strategies may be considered cost-effective in extending the services to informal caregivers, especially in low- and middle-income countries where a shortage of human resources affects the delivery and quality of mental health services.

Although not frequently implemented, intervention strategies such as spirituality-based, collaborative, and standard care interventions were also reported to reduce caregiver burden. Spirituality-based interventions were identified as an inexpensive and readily available resource for alleviating the burden of informal caregivers. Similarly, the participatory care model was reported to be an efficient and low-cost method for reducing caregiver burden and increasing caregiver resilience. Therefore, it is necessary to further explore the use of these interventions with informal caregivers of people with severe and enduring mental health conditions in low- and middle-income countries.

Despite their potential, the use of virtual interventions or telehealth strategies for informal caregivers remains underrepresented in the literature. This may be attributed to the relatively slow adoption of telehealth among informal caregivers. Notably, only 1 smartphone app was identified in this scoping review. However, telehealth holds promise as a viable approach for disseminating psychoeducational information, providing real-time support, and facilitating participation in virtual caregiver support groups, particularly in remote areas. The increasing proliferation of smartphones and internet access in Africa further emphasizes opportunities for the development of telehealth programs tailored to caregivers of individuals with severe and enduring mental health conditions. Although most of the implemented intervention strategies reported positive effects on caregiver burden, there were negative outcomes reported for some interventions. Hou et al [60] reported that the mindfulness-based stress reduction program led to a short-lived improvement in the stress and anxiety of the informal caregivers but that no improvement was noted after the 3-month follow-up. In addition, this intervention did not demonstrate a sustained effect on health-related quality of life, perceived stress, or self-compassion. These outcomes were attributed to the loss to follow-up and the fact that the measurement instruments could have been less sensitive to changes in quality of life and stress. Similarly, the 6-session individual psychoeducation intervention for informal caregivers of persons with bipolar mood disorder showed no effect on burden, quality of life, or self-esteem. This was attributed to the reduction in the number of sessions from 21 in the original instruction [71] to 6 in this study [35]. Another reason was that the sessions were conducted individually, whereas the literature highlights that multifamily intervention groups are effective [71,73,98].

Implications for Practice and Policy

The findings of this review provide evidence for the reported evaluated and recommended interventions having benefits in reducing the burden of care among informal caregivers in low- and middle-income countries. Previous studies conducted in low- and middle-income countries have since emphasized the urgent need to strengthen informal caregiver support regarding mental health. The need for information and skills in handling mental health care users, as well as the need for emotional and tangible support, has been highlighted in previous studies [42,99]. The findings of this review revealed that psychoeducation and support groups were highly used strategies for improving knowledge and skills as well as building support for informal caregivers in low- and middle-income countries. Furthermore, these strategies were reported to be beneficial and cost-effective, thereby making them a viable option for implementation in low- and middle-income countries, where limited access to mental health resources prevails [100]. The need to ensure that these strategies are offered on a continuous basis was highlighted in many studies, indicating the need for 6 to 10 sessions over a period of 6 to 10 weeks [7]. To ensure sustainability, training of peer facilitators to deliver these interventions may be realistic as this aligns with a task-shifting approach, which has long been advocated for as a cost-effective strategy for increasing access to mental health services in low- and middle-income countries [101]. It is interesting to note that peer support groups and guided self-help were reported to have long-term benefits on caregiver burden compared with psychoeducation; this highlights that using self-directed interventions is considered a practical option for alleviating informal caregiver burden. In low- and middle-income countries where a shortage of human resources prevails, it is important to consider such interventions as they empower informal caregivers to build support and take ownership of their health and well-being [35]. Spiritual-based interventions, although not frequently implemented, are important to note in the context of low- and middle-income countries as most informal caregivers have been identified as relying on spiritual and religious coping [102,103]. Recommended strategies such as the provision of financial and social support as well as policy and legislature strategies call for an urgent need for policies in mental health to shift focus toward integrating caregiver-oriented services into practice. In addition, these findings highlight the need to adopt an intersectoral approach [104] in which various sectors such as religious and spiritual organizations provide mental health services to extend their accessibility to informal caregivers.

Limitations

In alignment with Arksey and O'Malley, this review did not include a critical appraisal to ascertain the quality of the studies as the purpose of this scoping review was to map existing strategies for alleviating caregiver burden and report on the outcomes as stated by the authors. In their study, Woo et al [105] cautioned that the exclusion of critical appraisals in scoping reviews means that the review cannot ascertain the research gaps that it aims to address if the included studies are of poor methodological quality. Although this scoping review provides evidence on the existing strategies for alleviating caregiver burden, it is important that the suggested strategies be evaluated in the specific context to ensure their effectiveness before implementation in clinical practice. This step was omitted as the purpose of this review was to map the available intervention strategies and the outcomes reported by the authors in alleviating burden among informal caregivers in low- and middle-income countries. This review only included studies conducted in low- and middle-income countries, and only papers written in English were considered, thus reducing the extent and scope of the evidence on the strategies for alleviating burden among informal caregivers regarding mental health.

Conclusions

The findings of this scoping review provided the authors with categories they can use to develop semistructured interview guides to use when exploring the existing formal and informal community mental health services to alleviate the burden of informal caregivers in rural South Africa. The categories outline the different types of strategies that can be used to alleviate caregiver burden, in particular the types of strategies offered to informal caregivers and the intervention developers and deliverers in and outside the mental health care system. Although most of the included studies (29/44, 66%) implemented these strategies, a few studies conducted in other low- and middle-income countries (15/44, 34%) recommended the use of these interventions to alleviate caregiver burden. Future studies from low- and middle-income countries in other continents, including Africa and South and North America, should address this gap in the research by evaluating these intervention strategies to alleviate the burden of informal caregivers.

Critical appraisal, which is used to ascertain the quality of the studies, was omitted as the purpose of this scoping review was to map existing strategies for alleviating caregiver burden and report on the outcomes as stated by the authors. Future studies should conduct quality appraisals to establish the effectiveness of these strategies in alleviating the burden of informal caregivers. Peer-facilitated support group interventions, although not frequently implemented, were identified as having long-term benefits compared with frequently implemented interventions such as psychoeducation. It is recommended that future research be directed at implementing and evaluating these interventions to alleviate burden in low- and middle-income countries.

Data Availability

All data generated or analyzed during this study are included in this published paper.

Authors' Contributions

OS completed the literature search. OS and DC completed the screening of titles, abstracts, and full texts of the identified studies. In addition, they extracted data from all the included studies and completed the draft of the manuscript. FA and NGN reviewed the manuscript draft. OS incorporated the feedback from the authors for publication.

Conflicts of Interest

None declared.

Abstract

Background: Generation Z (Gen Z) includes individuals born between 1995 and 2012. These individuals experience high rates of anxiety and depression. Most Gen Z individuals identify with being spiritual, and aspects from religion and spirituality can be integrated into mental health treatment and care as both are related to lower levels of depression. However, research on the spiritual and mental health of Gen Z is sparse. To date, there are no systematic or scoping reviews on digital methods to address the spiritual and mental health of Gen Z.

Objective: This scoping review aimed to describe the current state of digital methods to address spiritual and mental health among Gen Z, identify the knowledge gaps, and make suggestions for how to leverage digital spiritual and mental health interventions for Gen Z.

Methods: A comprehensive literature search was conducted in PubMed, Scopus, PsycInfo, CINAHL, Education Full Text, Google Scholar, SocIndex, and Sociological Abstracts. The inclusion criteria were as follows: (1) study population born between 1995 and 2012 (ie, Gen Z); (2) reporting on spiritual health or well-being, spirituality or religion, and mental health or well-being; (3) reporting on using digital methods; (4) publication in 1996 or beyond; (5) human subject research; (6) full text availability in English; (7) primary research study design; and (8) peer-reviewed article. Two authors screened articles and subsequently extracted data from the included articles to describe the available evidence.

Results: A total of 413 articles were screened at the title and abstract levels, of which 27 were further assessed with full text for eligibility. Five studies met the inclusion criteria, and data were extracted to summarize study characteristics and findings. The studies were performed across 4 different countries. There were 2 mixed-methods studies (South Africa and Canada), 2 cross-sectional studies (China and United States), and 1 randomized controlled trial (United States). Of these studies, only 2 discussed digital interventions (a text messaging–based intervention to improve spiritual and mental health, and a feasibility study for a mental health app). Other studies had a digital component with minor or unclear spiritual and mental health measures. Overall, there was a lack of consistency in how spiritual and mental health were measured.

Conclusions: Few studies have focused on assessing the spiritual and mental health of Gen Z in the digital context, and no research to date has examined a digital spiritual and mental health application among Gen Z. Research is needed to inform the development and evaluation of approaches to address the spiritual and mental health of Gen Z via digital means (eg, mobile apps).

Introduction

The digital age is marked by widespread internet use and the ability to quickly communicate and find information online. Individuals born from 1995 to 2012 are considered "digital natives," as they are the first generation to live in an age where technology and the internet are accessible at all times [1]. The Pew Research Center considers these individuals as part of Generation Z ("Gen Z") and identifies the beginning of this generation to be in 1997 [1]. For the purpose of our research, we used the definition of Gen Z by Katz et al [2], who defined Gen Z as individuals born from 1995 to 2012, to account for those born when the World Wide Web made its public debut in 1995.

As a generation that grew up with technology, digital devices are familiar and seamlessly woven into the daily routines of Gen Z. It has been reported that 95% of Gen Z individuals have access to a smartphone [3]. In a study of 1000 Gen Z individuals aged 13 to 25 years, more than half spent 4 or more hours online compared with just 28% of all US adults who spent 4 or more hours online [4]. In a world where it is nearly impossible to socialize, work, and get an education without technology, Gen Z individuals are "always on," and this is associated with higher rates of depression, attention deficit disorder or attention deficit hyperactivity disorder, and technology addiction [5]. Compared with other generations, Gen Z individuals spend more time alone or on digital communication platforms than engaging in in-person interactions. Between 2000 and 2015, Gen Z high school seniors spent an hour less on in-person social interactions compared with early millennials [6]. Adolescents who spend more time on social media than in in-person interactions are the loneliest compared with those who spend less time on social media. Moreover, between 2007 and 2018, there were great increases in the relative percentage rates for self-injury (47%), seriously considering suicide (76%), and suicide attempts (58%) among Gen Z [7].

The American Psychological Association (APA) states that Gen Z individuals are more likely to report mental health concerns (eg, depression and anxiety) than previous generations [8]. In a 2022 survey of 1055 Gen Z adults, 1 out of 4 reported having more bad days than good within a 1-month time frame. More than 2 out of 5 (42%) had a diagnosed mental health condition, with more than a quarter of those being diagnosed during the COVID-19 pandemic (March 2020) or later. Anxiety and depression are the 2 largest mental health issues among Gen Z, with 9 out of 10 individuals diagnosed with a mental health condition having anxiety and 8 out of 10 having depression [3]. Notably, Gen Z individuals are the most comfortable discussing their mental health [3,8]. One third of Gen Z individuals report posting about their mental health on social media. They also attend therapy and are willing to pay out of pocket for mental health care and services [3]. Despite the comfort of Gen Z in talking about their mental health, there is a crucial need to address the high rates of anxiety, depression, and other health issues that they experience [8].

Spirituality may be an untapped resource to address the mental health crisis experienced by Gen Z today. While spirituality can serve as a component within organized religion, the 2 aspects are distinct. Religion is an organized belief or specific set of practices focusing on a higher power (ie, Christian, Muslim, Buddhist, etc) [9]. Spirituality is a broader concept in which individuals seek connection to self, others, nature, and a sacred or higher being [10]. Individuals may identify with being either religious or spiritual, or both. Gen Z individuals do not necessarily identify with a particular religion or belief but instead practice spirituality. Only half of Gen Z individuals report turning to their faith for support in times of uncertainty [11], and they are more likely to engage in spiritual practices than religious practices [12]. In a study of 10,000 Gen Z individuals aged 13 to 25 years, 68% considered themselves religious and 77% considered themselves spiritual [13]. Gen Z individuals define spirituality as autonomous and faith unbundled, and it is inclusive of all faiths and practices [11,13].

Spirituality is related to several positive health and psychosocial outcomes, namely greater mental health [14]. A recently updated review of the literature on the relationship between spirituality and mental health found that greater spirituality was associated with lower depressive symptoms, lower suicidality, and lower substance abuse [14]. Gen Z individuals face some of the highest rates of mental health conditions (eg, depression) [15,16]; thus, spirituality should be considered in addressing youth mental health today. In the aforementioned report by Singer [13], the majority of Gen Z individuals attributed their spiritual connection to their positive mental health state. Another aspect of mental health that is influenced by spirituality is quality of life among chronically and terminally ill patients. Palliative care patients who struggle with spirituality report poorer quality of life compared with those who feel stable with their spirituality [17]. Additionally, teens and young adults with cancer mention searching for meaning, hope, and life perspectives, even though they may not consider themselves as spiritual [18]. Interventions that promote spiritual well-being (one's sense of purpose, meaning in life, and connection to something greater [19]) may be a powerful resource for improving mental health in Gen Z.

Research on digital mental health interventions and spirituality exist separately. Little is known about digital methods (eg, mobile apps, text messaging, etc) that incorporate both spiritual and mental health among Gen Z. Scoping or systematic reviews on this topic are nonexistent, and research on this topic is very limited. Given that technology is woven into the daily lives of Gen Z, digital mobile apps that promote spirituality may offer a novel approach to supporting the mental health of Gen Z adolescents and young adults. Therefore, the purpose of this scoping review was to describe the current state of digital methods to address spiritual and mental health among Gen Z, identify the knowledge gaps, and make suggestions for how to leverage digital spiritual and mental health interventions for Gen Z.

Methods

Eligibility Criteria

The inclusion criteria for targeted articles were as follows: (1) study population born between 1995 and 2012 (ie, Gen Z); (2) reporting on spiritual health or well-being, spirituality or religion, and mental health or well-being; (3) reporting on using digital methods; (4) publication in 1996 or beyond; (5) human subject research; (6) full text availability in English; (7) primary research study design; and (8) peer-reviewed article.

Information Sources

Guided by the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) extension for scoping reviews (PRISMA-ScR) [20], searches were conducted in PubMed, Scopus, PsycInfo (EBSCO), CINAHL Plus with Full Text (ProQuest), Education Full Text (H.W. Wilson), Google Scholar, SocIndex with Full Text, and Sociological Abstracts (ProQuest) on May 2 and 3, 2023, by a health sciences librarian (J Hermer) at Arizona State University. The same information sources were searched on September 21-26, 2023, and again on November 7-8, 2023, and were also included in the results. ERIC and Atla Religion Database were also searched, but they returned no results.

Search Strategy

The searches were optimized for each individual database but included a combination of keywords and subject headings for the following 4 categories: Generation Z or Gen Z; spirituality or religion; mental well-being; and mobile health, mHealth, and eHealth (Multimedia Appendix 1). Owing to the very limited nature of the results, only language filters were applied to ensure that all relevant literature was available to be screened. All records were imported into Zotero to check if any articles were retracted and then into Covidence systematic review software for deduplication and screening [21]. Apart from the initial search, 2 additional searches were conducted to ensure that all relevant literature was found and to add any recent literature from the following 6 months. A search of all databases was performed on September 21-26, 2023, using the additional keywords of "faith," "transcenden*," and "life purpose" or "existential needs," and a final search was performed on November 7, 2023, using the additional keywords of "spiritu*" and "relig*." The scoping review protocol was registered online in Open Science Framework (OSF) on May 16, 2023.

Selection Process

The selection process was completed entirely on Covidence. Prior to reviewing titles and abstracts, duplicate titles were eliminated by Covidence. Two authors (SYP and BD) screened all titles and abstracts independently and were blinded to each other's decisions. Any disagreements were discussed between the authors SYP and BD, and agreed upon before full-text review. Agreement scores for article selection between the 2 authors were not logged in Covidence for the initial search; however, the agreement scores were 85% (81/95) and 90% (80/87) for reviewing titles and abstracts between the 2 authors

for the September and November searches, respectively. For full-text article review, the author SYP independently reviewed half of the articles, and the author BD independently reviewed the remaining articles. The authors SYP and BD deliberated with each other, and with J Huberty and JY if there were any questions regarding inclusion based on the article eligibility criteria. Articles were excluded if the study population included Gen Z but did not explicitly distinguish Gen Z in the population sample and the results were not disaggregated by age. The final articles included in the review were agreed upon by all 4 authors.

Data Collection Process and Synthesis Methods

Prior to the search, all authors agreed on the following characteristics for data extraction and synthesis: title; authors; study country; study objectives; study design; data collection timeframe; recruitment methods; sample size; participant characteristics; description of digital methods; constructs related to religion, spirituality, or spiritual well-being; assessment or measure for religion, spirituality, or spiritual well-being; constructs related to mental health; assessment or measure for mental health; main findings; and study limitations. These characteristics were selected to ensure a detailed understanding of available literature as it relates to the goal of the scoping review. For articles included in the scoping review, the author SYP independently extracted data based on the a priori characteristics for half of the articles and the author BD independently extracted data from the remaining articles. Given that each article had data extracted by a single author, there were no agreement scores. After evaluating the included articles, study characteristics and main findings were summarized in a descriptive manner.

Some studies that initially appeared eligible for this review were ultimately excluded because they did not meet specific criteria. For instance, a cross-sectional study on the perceptions of 475 Gen Z individuals and young millennials and their use of a spiritual self-care app [22] was originally included when reviewing titles and abstracts. However, upon full-text review, we found that the study results did not distinguish between Gen Z individuals and young millennials, thus failing to meet our review's criteria (ie, Gen Z only).

Results

Study Characteristics

Details on article selection are illustrated in a PRISMA diagram (Figure 1). Our search identified 824 articles from 8 databases based on the search terms. After removing 411 duplicates in Covidence, 413 articles were screened by title and abstract. After the initial screening based on the inclusion criteria, the full texts of the remaining 27 articles were screened. Review articles were not included in the final review, but references were screened to see if any additional literature was admissible. Ultimately, the scoping review included 5 articles. Of these 5 articles, 1 [23] was included in the review from the updated search conducted in September 2023 and 1 [24] was included from the updated search in November 2023. Characteristics and results of the studies are summarized in Table 1.

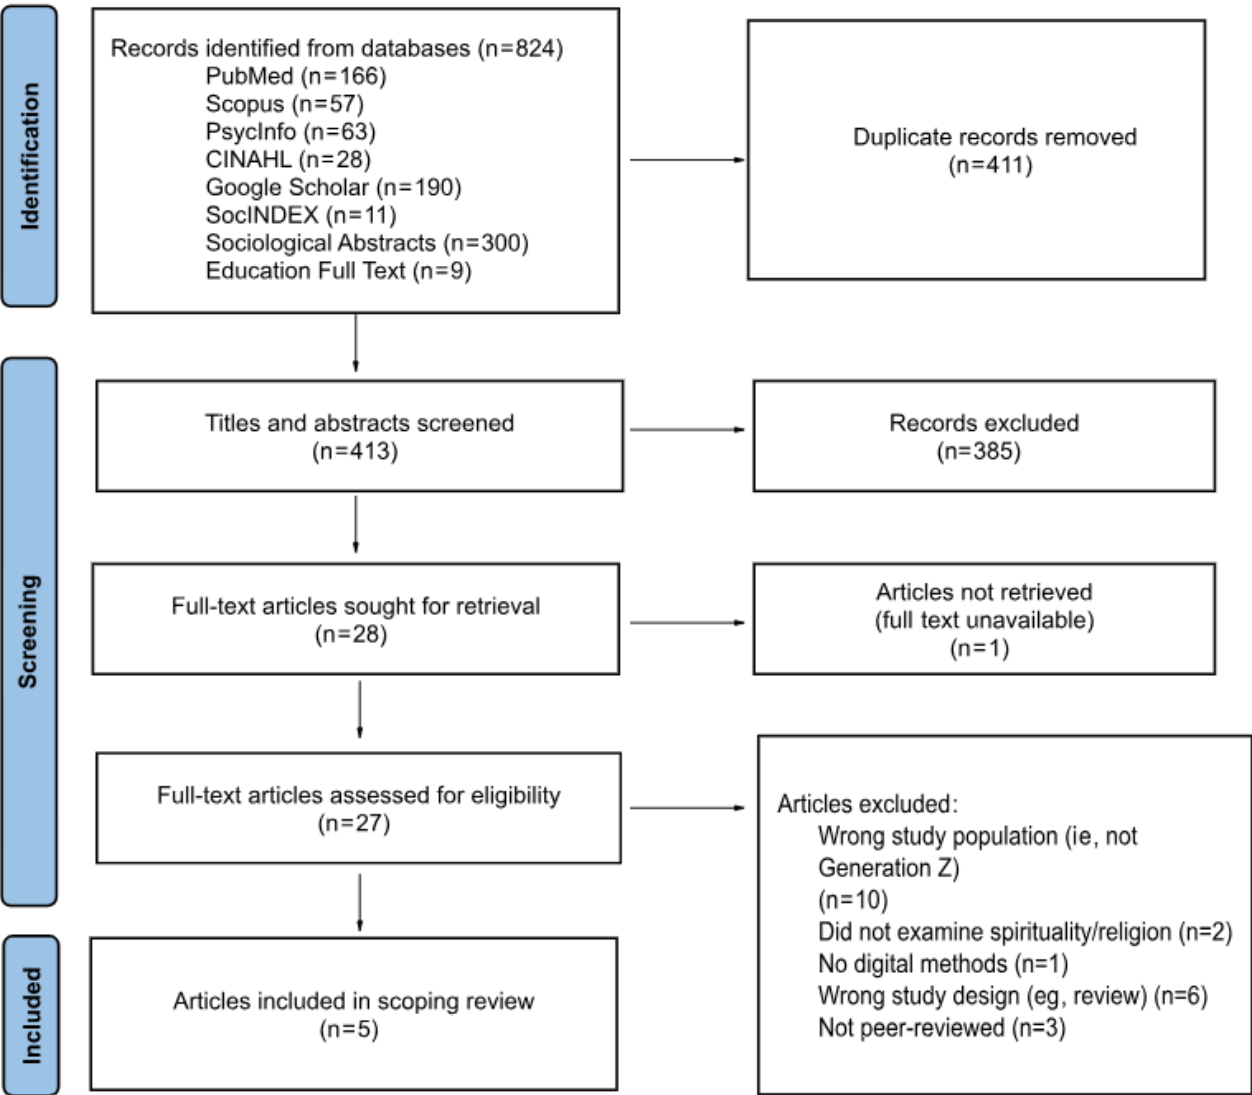
Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of article selection.


Table 1. Characteristics and main findings of the included studies.

Reference and study country	Study design	Sample characteristics	Digital aspect[a]	Religion/spirituality measures[b]	Mental health measures[b]	Main findings
Mindu et al [25], 2023 (South Africa)	Mixed-methods study	93 youth and young adults aged 16-24 years; 44% female	Assessed participants' knowledge and preferences for a digital mental health app	Where do youth seek treatment or assistance when they have mental health problems (Response options: Visit a spiritual healer; Go to a church for prayers; Traditional medicine; Clinic/hospital; Visit a health care worker)	Mental health awareness (eg, taught about mental health and no prior education on mental health) Mental health conditions affecting youth in the community (eg, substance abuse or misuse, posttraumatic stress disorder, depression, and anger)	• No participants had experience using a mental health app, but 99% indicated mental apps are important and can benefit youth. • Religious and cultural beliefs were a barrier to using digital platforms (eg, social media).
Gao et al [26], 2021 (China)	Cross-sectional study	1017 first-year college students (mean age 19 years); 77.8% female	Participants were recruited through an eHealth application to complete a survey	Religion (Response options: No religion; Buddhism; Christian; Others)	Generalized Anxiety Disorder-7 (GAD-7) and depression; Patient Health Questionnaire-9 (PHQ-9) [27,28]	• 95.3% indicated having no religion. • Belief in Christianity and in Buddhism were associated with greater anxiety.
Craig Rushing et al [29], 2021 (United States)	Randomized controlled trial	833 American Indian or Alaska Native teenagers and young adults aged 15-24 years; 66.3% female	The 2 intervention arms included 3 SMS text messages per week for 8 weeks with information, role model videos, images, and engagement opportunities (eg, reply for more information, resource links, etc)	Rate your spiritual health (Response options: Excellent; Very good; Good; Fair) [30]	Rate your mental health (Response options: Excellent; Very good; Good; Fair) [30]	• No significant differences between the 2 intervention arms within subjects. • Mean scores of perceived health (physical, mental, and spiritual) significantly increased over time for both intervention arms. • Those who reported better health also reported greater cultural resilience, identity, and cultural pride.
Reed et al [23], 2022 (United States)	Cross-sectional study	349 American Indian or Alaska Native youth aged 15-24 years; 71.1% female	Assessed participants' use of media technologies (ie, media types, frequency, and duration) and how they use media technologies (ie, online behaviors and activities)	Select the top 3 health topics from a list of 15, including spiritual health	Self-reported mental health (How good is your mental health? Response options: 4-point Likert-type scale; 4=Excellent and 1=Poor) Select the top 3 health topics from a list of 15, including mental health	• 53.5% of participants relied heavily on the internet to access health information. • Nonsexual and gender minority participants reported better mental health than sexual and gender minority participants. • The top 3 most important health topics were Native identity, mental health, and social justice and equality. • Spiritual health was selected as the most important health topic 14% of the time.

Reference and study country	Study design	Sample characteristics	Digital aspect[a]	Religion/spirituality measures[b]	Mental health measures[b]	Main findings
Au-Yeung et al [24], 2023 (Canada)	Mixed-methods study	5 Indigenous youth aged 11-16 years; 60.0% female	Assessed participants' opinions on the JoyPop app, and the accessibility and feasibility of the app	Qualitative question: "What does a 'Good Mind' (Haudenosaunee concept) mean to you?" "The Good Mind is a physical, psychological, and spiritual journey that includes a reflective awareness of thoughts and intentions, and a way of being that is expressed through self-compassion and compassion for other beings."	Perceived mental wellness (5-point Likert scale) Qualitative question: "Would you please describe what mental wellness means to you?"	• Participants had mixed ratings for their mental health from "fair" to "very good." • Participants reported nature to be important for a "Good Mind." • Participants reported enjoying the app's features (eg, games and breathing techniques) and made suggestions to make it relevant to their culture.

[a]Refers to the digital component of the study, which may include the mode through which an intervention was given (eg, mobile text messages) or the constructs measured (eg, social media use and preferences for a mobile app).

[b]Measures refer to assessments, tools, or specific survey items that were used in the study to assess the construct of interest (eg, religion or spirituality, and mental health).

Study Design and Study and Sample Characteristics

All 5 studies examined Gen Z (adolescents and young adults; aged 11-24 years; born between 1995 and 2012). Of the 5 articles, 2 were published in 2023, 1 was published in 2022, and 2 were published in 2021. There were 2 mixed-methods studies (1 in South Africa [25] and 1 in Canada [24]), 2 cross-sectional studies (1 in China [26] and 1 in the United States [23]), and 1 randomized controlled trial in the United States [29]. Sample sizes varied across the 5 studies, ranging from 5 to 1017.

Study by Mindu et al, 2023

Mindu et al [25] conducted a mixed-methods study in South Africa to inform the implementation of a mobile phone–based mental health intervention [25]. The study did not use any specified measures for mental health but asked questions via quantitative and qualitative methods to understand participants' understandings or perceptions of mental health. Questions addressed (1) mental health awareness; (2) digital interventions for mental health; (3) access to digital devices and the internet; (4) preferences for digital mental health interventions; and (5) barriers to the use of digital mental health innovations. Quantitative results showed that almost half (49%) of the participants had heard about mental health apps, none had experience using one, and 99% indicated that mental health apps are important and can benefit youth. These results underscore the severe lack of mobile mental health apps designed for individuals in South Africa. Qualitative results revealed that religious and cultural beliefs were a barrier to using digital platforms (eg, social media), and the authors highlighted the crucial need to develop culturally appropriate and relevant digital apps that represent those who they serve. Overall, participants expressed high interest in using a digital mental health app (eg, social media) to learn about mental health and seek resources. The study authors acknowledged that while no digital methods or interventions were implemented in the study, the results provided a unique Gen Z perspective on the usability of digital methods.

Study by Gao et al, 2021

Gao et al [26] conducted a cross-sectional study in China among first-year Chinese college students. Using a health management app (Residents e-Health), a questionnaire was distributed to examine depression and anxiety, and their associations with other health-related constructs, such as stress and nutrition. The authors examined participants' religious beliefs (ie, Christian, Buddhism, other, and no religion) as a correlate of anxiety and depression. However, most of the sample (95%) did not have a religion. Belief in Christianity and belief in Buddhism were associated with greater anxiety in the sample. The study authors noted that the large number of participants ascribing to no religion limited the understanding of the relationship between religion and mental health. The overall conclusion of the study indicated that early lifestyle interventions assessing religion, as well as other demographic and behavioral factors, are important for understanding the factors contributing to mental health in Gen Z.

Study by Craig Rushing et al, 2021

Craig Rushing et al [29] conducted a randomized controlled trial in the United States to examine the efficacy of an mHealth intervention (BRAVE) for physical, mental, and spiritual health; resilience; self-esteem; and coping and help-seeking skills among American Indian or Alaska Native teenagers and young adults. Participants were randomized to participate in 1 of 2 groups: (1) An 8-week intervention arm involving 3 SMS text messages per week highlighting common coping strategies, preferred wellness strategies, help-seeking skills, and related protective factors such as cultural resilience, identity, and cultural pride; or (2) An 8-week control arm involving 3 SMS text messages per week designed to elevate and reaffirm Native voices in STEM (science, technology, engineering, and mathematics) and medicine. Participants were in both arms, and both had messaging that included a combination of information,

role model videos, images, and opportunities of engagement (eg, reply for more information and links to access resources). The findings indicated that there were no significant differences between the 2 study arms within subjects, such that participants in the intervention arm did not report better outcomes than those in the control arm. However, mean scores of perceived health (ie, physical, mental, and spiritual) significantly increased over time in both arms. In addition, participants who reported better health also reported greater cultural resilience, identity, and cultural pride. The percentage of participants who used the resources and information in the intervention arm text messages also increased over 5 months. The study authors acknowledged some limitations, including high or favorable survey measure outcomes at baseline, only a 1-week break between receiving interventions in the arms, and control messaging likely being novel and helpful. Another limitation to note is the assessment of perceived health, which combined 3 separate survey measures assessing perceived physical, mental, and spiritual health. The combination of 3 different aspects of health makes it challenging to derive valid inferences regarding mental or spiritual health on their own. Overall, the intervention demonstrated improved health outcomes and underscores the acceptability of text messaging to promote and support well-being.

Study by Reed et al, 2022

Reed et al [23] conducted a cross-sectional study in the United States, in which 349 American Indian or Alaska Native youth (aged 15-24 years) were asked about the extent to which they use media technologies, how they use technologies, and their health priorities. Several trends were revealed. The majority of participants (64.7%) reported sending 1 to 50 text messages a day. Instagram was the most popular daily technology used, and 65.3% of participants reported using social media 3-7 hours per day. Participants also self-rated their mental health. The findings indicated that nonsexual and gender minority youth (56.7%) reported better mental health than sexual and gender minority youth (36.4%). To better understand important health topics, participants were asked to select their top 3 health topics from a list. The most popular topic selected was Native identity or cultural pride (73%), followed by mental health (57%) and social justice and equality (31%). Spiritual health was selected by 14% of youth in their top 3 health topics. While spiritual health was not among the top health topics selected, it is important to note that the range of options offered spanned across several categories (eg, social justice or inequality, alcohol and drug use or abuse, and the environment). Overall, the study authors concluded that building resources that foster cultural pride and positive identity must be included in any programs or technologies for addressing mental health among American Indian or Alaska Native youth.

Study by Au-Yeung et al, 2023

Au-Yeung et al [24] conducted a Haudenosaunee (Canada's largest First Nations reserve, Six Nations of the Grand River) community-based study in which 5 Haudenosaunee youth (aged 11-16 years) tested the JoyPop mobile app (available in English and French) that is designed to promote resilience among youth. The app offers breathing exercises, mood tracking, journaling, personalizable social support, a 24-hour helpline, and games.

The results indicated that participants had mixed ratings on their self-reported mental wellness, ranging from "fair" to "very good," and that they used the app 1 to 3 times a day. Of the 5 participants, 4 were interviewed about their experiences using the app, perspectives of mental wellness, and characteristics of a "Good Mind" (an Indigenous concept on the physical, psychological, and spiritual journey that maintains balance and harmony in a person). Interview participants reported that the app was easy to use and esthetically pleasing. They also enjoyed all of the app's features, with the exception of the Circle of Trust feature (ie, personalizable social support). Interview participants identified positivity and happiness, understanding emotions, acts of kindness, personal hobbies, and positive body language as important to their mental wellness. Participants also discussed important characteristics of a Good Mind, such as positivity, kindness, and connecting with nature. Overall, the app was favorable to the participants, but they suggested incorporating specific features like words in their own language and Indigenous visuals (eg, feathers and clan animals). While the app lacked explicit content on a Good Mind, the authors recommended incorporating concepts of a Good Mind to enhance its relatability to Haudenosaunee youth, given its cultural significance to the Haudenosaunee people. Although the study had a small sample size, the authors concluded that mobile health interventions can be beneficial to Indigenous youth, as mental health apps continue to be of interest and Indigenous cultures value the promotion of health and resilience. Further, Indigenous tribes across North America have unique perspectives, and pan-Indigenous resilience apps like JoyPop will need to be tailored to specific cultural contexts.

Discussion

Overview

The purpose of this scoping review was to describe the current state of digital methods to address spiritual and mental health among Gen Z, identify the knowledge gaps, and make suggestions for how to leverage digital spiritual and mental health interventions for Gen Z. A comprehensive literature search across 8 databases identified only 5 relevant studies, emphasizing the significant lack of published research on digital methods to address the spiritual and mental health of Gen Z. Among the 5 studies, only 2 discussed digital interventions, and of these studies, 1 examined a text messaging–based intervention to improve spiritual and mental health and reported improvements in spiritual and mental health over time [27], and 1 examined the feasibility of a mental health app [24]. The sparse available literature limits conclusions on the current state of digital methods to address spiritual and mental health, and warrants future research to address these gaps.

Current State of Digital Methods for Spiritual and Mental Health

Gen Z individuals are facing a mental health crisis as they experience high rates of depression and anxiety [8,16]. For example, one of the included studies reported that the prevalences of anxiety and depression among college freshmen were 40.3% and 45.3%, respectively [26]. Gen Z individuals also report feeling lonely, having low self-confidence, and being

distressed about the future [3,5,12]. All 5 studies included in this review discussed the overall well-being of Gen Z and, to some extent, aspects of spirituality. The findings suggest that spirituality may play a role in the mental health of Gen Z and should be considered in the development and implementation of future digital applications that address mental health. The study by Mindu et al [25] particularly underscores the need for customizability in mental health applications considering that participants expressed that using digital platforms (ie, social media) conflicted with their religious and cultural beliefs. Thus, the introduction of applications that allow users to engage in practices and view content that aligns with their values and beliefs is a potential avenue for combating this barrier and could in turn strengthen one's spirituality. However, research is needed to determine the acceptability of digital mental health applications that involve spiritual content.

Nearly every facet of the lives of Gen Z involves technology, for example, using computers for school or work, using mobile apps to order food, and using social media and texting to communicate with friends. Despite the widespread use of technology among Gen Z and the increasing number of research studies employing digital methods to test and deliver mental health programs and interventions [31], only 1 of the studies included in this review examined the effects of a digital intervention on spiritual and mental health [27] and 1 assessed the feasibility of a mental health mobile app [24]. The lack of digital methods or interventions to address the spiritual and mental health of Gen Z warrants the development of accessible ways for Gen Z to practice spiritual and mental self-care. Gen Z individuals spend more time (4 or more hours daily) on social media compared with other generations [3], and poor mental health is often attributed to social media use [32]. However, social media is not necessarily harmful and is instead dependent upon what Gen Z individuals do and see online, their pre-existing strengths or vulnerabilities, and the environment in which they are raised (eg, parental monitoring) [32,33]. Digital methods for spiritual wellness that are specifically targeted for Gen Z and built to empower Gen Z to practice self-care and build healthy coping mechanisms may benefit the mental health of Gen Z. Results from this review illustrate the acceptability of a mobile intervention promoting spiritual and mental health [24,29], and the interest Gen Z individuals have toward using digital methods to address their spiritual and mental health [25]. However, given that little is known about this topic, more research is needed to truly grasp the feasibility and efficacy of digital approaches to address spiritual and mental health with regard to the well-being of Gen Z.

Gaps in the Literature

Published literature or research about the spiritual and mental health of Gen Z is limited, reporting mostly mental health statistics rather than examining determinants of mental health or interventions for improving mental health (eg, spirituality) [1,33]. Research to date on spirituality in Gen Z has only been performed by faith-based organizations or by nonacademic research institutions and has mainly focused on comparing the views of Gen Z on religion and spirituality to the views of other generations [11,12,34]. For example, the majority of Gen Z individuals (77%) identify as spiritual, preferring to ascribe to

a set of values from various beliefs [13]. While we know that the majority of Gen Z individuals identify as spiritual, empirical research that specifically examines their spiritual practices and preferences, overall spiritual well-being, and associations with mental and physical health outcomes is warranted. Among the 5 studies included in this review, 3 examined spiritual health. The randomized controlled trial [29] asked participants to rate their spiritual health using a combined measure for overall health that included physical, mental, and spiritual health, limiting the ability to assess spiritual well-being explicitly among these participants. The cross-sectional survey [23] asked participants to select the top 3 health topics important to them (eg, mental health, spiritual health, and Native identity), but the study did not examine any associations between spiritual health and mental health. Spiritual health was not defined for participants in either study. The mixed-methods study in Canada [24] interviewed participants who used an app designed to promote resilience in youth with regard to a Good Mind, an Indigenous concept on the physical, psychological, and spiritual journey that maintains balance and harmony in a person. However, this concept is specific to the Haudenosaunee people; therefore, the findings may not be applicable to the perspectives on spirituality of other young communities. In addition, only 1 article administered a valid measure to assess mental health, spirituality, or spiritual well-being (ie, Generalized Anxiety Disorder-7 [GAD-7]) [26]. The validity and reliability of instruments used to measure mental health and spirituality or spiritual well-being in the study samples were not reported in any of the included articles. Identified gaps offer research opportunities to comprehensively examine spiritual and mental health among Gen Z.

Suggestions for Leveraging Digital Spiritual and Mental Health Interventions for Gen Z

Gen Z individuals are remarkably familiar with navigating digital spaces and integrating spirituality into their lives, and are the most comfortable talking about their mental health compared with other generations [3]. Gen Z individuals who have a spiritual connection have better perceptions about their mental health and believe their spiritual health contributes to their mental health, compared with those who do not have a spiritual connection [11]. Since Gen Z individuals primarily consume information through technology, digital interventions are a promising method to teach and facilitate various practices in spiritual and mental self-care. For example, the digital intervention content of Craig Rushing et al [29] included wellness strategies, such as self-care and goal setting, which resulted in improved perceived health (eg, physical, mental, and spiritual) for participants. In the study by Mindu et al [25], digital mobile interventions through social media were concluded to be potentially useful to increase mental health literacy and knowledge of resources. Additionally, the study by Gao et al [26] suggested that early interventions that target the lifestyle behaviors of Gen Z (ie, smoking) can improve their depression and anxiety. A spiritual self-care app tailored for Gen Z, for example, may allow Gen Z to engage with full autonomy and convenience. Rather than requiring Gen Z to seek out places to practice religious or spiritual beliefs, a spiritual self-care app can be available wherever they are and

whenever they want. Digital spiritual self-care interventions should also consider incorporating topics that are deemed important to Gen Z, such as cultural relevance, inclusivity, social justice, and nature [23,24].

Mobile apps grant users the ability to customize their experience, which vastly differs from traditional means of practicing religion that ascribe to a predetermined set of beliefs, values, and practices that are often fixed [13]. Access to technology enables Gen Z individuals to autonomously decide which aspects of different spiritual beliefs and practices they resonate with. Most digital apps include features that allow users to customize their experience and the content they engage with. Thus, a mental health app that includes various components of spiritual practices that users can choose from may provide a new way for young people to tend to their spiritual and mental health. Based on this review, research examining the feasibility, acceptability, and efficacy of digital health tools specifically targeting spiritual and mental health among Gen Z is absent, indicating the need for research in this area. Researchers, companies, and nonprofit organizations can leverage existing digital spaces that Gen Z individuals frequently use (eg, Instagram and TikTok) to garner feedback on what they might desire in a digital spiritual and mental health intervention. For example, 2 of the studies [24,29] incorporated feedback from Indigenous youth on existing digital methods (eg, SMS text messaging and JoyPop) to inform the development of their digital content. Spiritual well-being apps, for example, can be used to target Gen Z and deliver evidence-based content that integrates spirituality and mental health. These studies also emphasize the importance of culturally relevant interventions that can speak to diverse cultural backgrounds and beliefs among Gen Z.

Strengths and Limitations of This Review

There are multiple strengths of this review. First, this scoping review indicates that there is a limited knowledge base surrounding digital methods for addressing the spiritual and mental health of Gen Z and summarizes the current state of the literature on this topic. This is the first scoping review to address this topic and highlights a crucial gap in supporting young people's mental health. Additionally, a librarian was consulted and involved in the search process to bolster the rigor and accuracy of the review. Covidence was used to minimize human error in screening eligible articles. Along with these strengths, there are some limitations in this review. First, a scoping review limits the objective understanding of a topic such that quantitative results cannot be compiled to determine effect sizes

across studies. Second, database searches are not uniform and require nuanced search methodologies, which can result in relevant studies being missed. Third, manuscripts during the full-text screening stage were split between the authors SYP and BD, and thus, manuscripts were assessed by a single rater. Finally, research on this topic is severely lacking, which limits the number of articles included in this review and impacts the ability to construct a cohesive narrative or draw definitive conclusions about the state of the field. This underscores the necessity of this review to highlight the gaps and urge further investigation.

Scientific Contribution

The goal of this scoping review was to assess the extent to which research on digital methods to address the mental and spiritual health of Gen Z has been conducted. The scoping review revealed a lack of available research on spirituality and mental health. Specifically, there is a dearth of studies on the use of digital methods to deliver spiritual well-being for mental health in Gen Z. Despite an increase in mental health concerns among Gen Z and the growing body of evidence on the beneficial effects of spiritual self-care on mental health, few published articles touch on this topic. The findings from this review highlight the opportunity for addressing the mental and spiritual health of Gen Z through digital methods (eg, mobile apps). The use of digital methods to address mental health is a growing area of research; however, spirituality and spiritual self-care have received little attention. There is potential for researchers to examine spiritual self-care, which is delivered through digital methods, and its impact on populations experiencing significant mental health problems. Overall, the scoping review underscores the need for future research to examine the acceptability and feasibility of digital approaches to address spiritual and mental health among Gen Z.

Conclusion

This scoping review underscores the dearth of research surrounding digital methods to address spiritual and mental health among Gen Z. Considering that digital methods to address aspects of mental health are increasingly popular and effective [35,36], research is needed to examine digital platforms that address spiritual and mental health. This is especially pertinent for Gen Z individuals as they have some of the greatest rates of mental health issues and are the most digitally savvy generation to date, and most indicate that they are spiritual. Leveraging spirituality as a way to address mental health among Gen Z via digital means offers a novel and relevant approach for addressing the mental health crisis impacting young people today.

Data Availability

The full review process, including the search terms and databases used, is available as a supplementary file.

Authors' Contributions

SYP and BD wrote and reviewed this paper. J Hermer searched and curated articles for review. JY reviewed and edited the manuscript. J Huberty supervised the review.

Conflicts of Interest

SYP is currently the Behavioral Research Scientist for the Radiant Foundation and does not receive incentives for the outcomes of the research. J Huberty is the Chief Science Officer for the Radiant Foundation's Skylight app. J Huberty was hired by the Radiant Foundation to lead scientific strategy and mentor the scientists for Skylight, but does not receive incentives for the outcomes of the research. BD and JY are employees of J Huberty and are independent from the Radiant Foundation leadership. The role of SYP and J Huberty is to ensure the quality of science regarding the Skylight app. J Hermer is a librarian at Arizona State University and is not associated with the Radiant Foundation or with J Huberty. The authors do not have stock in Skylight and receive no financial incentives from the sales of Skylight. The authors do not receive any financial benefit from the outcomes of this study.

Abstract

Background: The International Classification of Diseases, Eleventh Revision (ICD-11) improved neoplasm classification.

Objective: We aimed to study the alterations in the ICD-11 compared to the Chinese Clinical Modification of the International Classification of Diseases, Tenth Revision (ICD-10-CCM) for neoplasm classification and to provide evidence supporting the transition to the ICD-11.

Methods: We downloaded public data files from the World Health Organization and the National Health Commission of the People's Republic of China. The ICD-10-CCM neoplasm codes were manually recoded with the ICD-11 coding tool, and an ICD-10-CCM/ICD-11 mapping table was generated. The existing files and the ICD-10-CCM/ICD-11 mapping table were used to compare the coding, classification, and expression features of neoplasms between the ICD-10-CCM and ICD-11.

Results: The ICD-11 coding structure for neoplasms has dramatically changed. It provides advantages in coding granularity, coding capacity, and expression flexibility. In total, 27.4% (207/755) of ICD-10 codes and 38% (1359/3576) of ICD-10-CCM codes underwent grouping changes, which was a significantly different change (χ^2_1=30.3; P<.001). Notably, 67.8% (2424/3576) of ICD-10-CCM codes could be fully represented by ICD-11 codes. Another 7% (252/3576) could be fully described by uniform resource identifiers. The ICD-11 had a significant difference in expression ability among the 4 ICD-10-CCM groups (χ^2_3=93.7; P<.001), as well as a considerable difference between the changed and unchanged groups (χ^2_1=74.7; P<.001). Expression ability negatively correlated with grouping changes (r=−.144; P<.001). In the ICD-10-CCM/ICD-11 mapping table, 60.5% (2164/3576) of codes were postcoordinated. The top 3 postcoordinated results were specific anatomy (1907/3576, 53.3%), histopathology (201/3576, 5.6%), and alternative severity 2 (70/3576, 2%). The expression ability of postcoordination was not fully reflected.

XSL•FO
RenderX

Conclusions: The ICD-11 includes many improvements in neoplasm classification, especially the new coding system, improved expression ability, and good semantic interoperability. The transition to the ICD-11 will inevitably bring challenges for clinicians, coders, policy makers and IT technicians, and many preparations will be necessary.

Introduction

The World Health Organization (WHO) adopted the International Classification of Diseases, Tenth Revision (ICD-10) in May 1990 [1]. The ICD-10 has been widely used in over 120 countries over the past 30 years. In multiple countries, expansions of the ICD-10, such as the Chinese Clinical Modification of the International Classification of Diseases, Tenth Revision (ICD-10-CCM), based on the second edition [2], have been developed to meet specific requirements. The ICD-10-CCM has been used for national performance assessment and medical insurance payment in public hospitals. Given the advances in medical knowledge and health information, the WHO started working on the International Classification of Diseases, Eleventh Revision (ICD-11) in 2007 [3], and it was expected to be implemented by WHO member countries starting in January 2022.

The most critical changes in the ICD-11 were the establishment of a semantic knowledge base and the reconstruction of the coding system. It introduced the Foundation Component, the Common Ontology, and linearization, as well as the new concepts of precoordination and postcoordination [3-5]. The chapter on neoplasms has also changed. It adds crucial morphology to precoordination, having the highest proportion (98.9%) and the most dimensions (3.5) of postcoordination. Cancer has been one of the top 3 causes of death in China since 2005 [6]; thus, the coding system of the ICD-11 will significantly impact cause of death reporting, cancer registration, and disease diagnosis records. Stakeholders need to have a good understanding of the classification of neoplasms in the ICD-11.

This study analyzes the changes between the ICD-10-CCM and ICD-11 in terms of coding features, classification features, and expression features in neoplasm classification and hopes to provide evidence supporting the transition in China.

Methods

Ethical Considerations

According to the Measures for Ethical Review of Human Life Science and Medical Research issued by the National Health Commission of the People's Republic of China, this study utilized public data and did not involve human subjects, and thus, the requirement of ethical permission was waived. All examples were constructed and neither correspond to real clinical cases nor to any datasets.

Materials

The following 3 existing, publicly available files were used in this paper: (1) ICD-10/ICD-11 mapping tables [7], (2) ICD-11 simple tabulation [8], and (3) the second revision of the ICD-10-CCM [9].

The first 2 files were downloaded from the WHO website, and the ICD-10-CCM was released by the National Health Commission of the People's Republic of China.

Research Methods

The ICD-10-CCM neoplasm codes were manually recoded by the ICD-11 coding tool [10] based on the International Classification of Diseases, Eleventh Revision, Mortality and Morbidity Statistics (ICD-11 MMS) codes to generate an ICD-10-CCM/ICD-11 mapping table for neoplasms. The 3 existing files and the ICD-10-CCM/ICD-11 mapping table were used to analyze ICD-11 features, namely, the coding structure, coding capacity, grouping changes, expression ability, expression flexibility, and the expression of postcoordination in the neoplasm classification.

Mapping ICD-10-CCM to ICD-11 Codes

Due to the homology of the morphology section between the ICD-10 and ICD-11, mapping was performed for only the topography codes. To ensure the accuracy of the results, manual recoding was independently implemented by 2 authors who both had more than 10 years of coding experience and had received ICD-11 training. Inconsistent results were resolved by consulting a senior coder from the Collaborating Center for the WHO Family of International Classifications in China.

Statistical Standards

Leaf Codes

The ICD-10, ICD-10-CCM, and ICD-11 MMS codes that can be used at the lowest level are called leaf codes. All statistical analyses were based on the leaf codes.

Coding Capacity

This capacity involves the number of leaf codes that can be used in actual coding.

Grouping Changes

Grouping was based on the block structure of the ICD. The equivalent groups included ICD-10 group 1 (malignant neoplasms) and ICD-11 group 3 (malignant neoplasms, except

for lymphoid, hematopoietic, central nervous system, or related tissues), ICD-10 group 2 (in situ neoplasms) and ICD-11 group 4 (in situ neoplasms, except for lymphoid, hematopoietic, central nervous system, or related tissues), and ICD-10 group 3 (benign neoplasms) and ICD-11 group 5 (benign neoplasms, except for lymphoid, hematopoietic, central nervous system, or related tissues). If an ICD-10/ICD-10-CCM leaf code was not classified into the equivalent ICD-11 group, it was considered to have undergone a grouping change.

Expression Ability

For each ICD-10-CCM code, we identified the best-matching ICD-11 MMS leaf code. When all the clinical details in the diagnosis were expressed without redundant information, the code was considered fully represented. This study also defined the synonyms contained in the Foundation Component as a full representation.

Statistical Analysis

All data were analyzed with SPSS (version 25.0, IBM). The changes in coding capacity, groups, and expression ability between the ICD-10 and ICD-11 were described as rates and percentages. The chi-square test was used to determine the difference in grouping changes when mapped to the ICD-11 between the ICD-10 and ICD-10-CCM. The chi-square test was also used to analyze the difference in full expression ability among the 4 ICD-10-CCM groups, and the Bonferroni method was used for pairwise comparisons. The chi-square test was used to analyze the difference in full expression ability between the changed and unchanged groups mapped to the ICD-11. The φ correlation coefficient was used to analyze the correlation

between expression ability and grouping changes. Statistical significance was set at $P<.05$.

Results

Coding Features

Coding Structure

Chapter 2 in both the ICD-10 and ICD-11 addresses neoplasms, and the codes in both versions are alphanumeric but have different structures. The ICD-10 codes for neoplasms consist of topography codes and morphology codes. The topography codes range from C00 to D48. Except for leaf codes, the coding range, categories, and subcategories of the ICD-10-CCM are the same as those of the ICD-10. The ICD-10 morphology codes consist of 5 digits. The first 4 digits identify the histological type of the neoplasm, and the fifth digit, following a slash (/), indicates its behavior. In the ICD-10-CCM, the morphology codes consist of 6 digits, with a fifth number before the slash.

In contrast, the coding structure of the ICD-11 MMS codes has dramatically changed. It is composed of stem codes and extension codes that are connected by an ampersand (&). The precoordinated stem codes consist of sites and essential morphology types. The newly added chapter on extension codes addresses other morphology types and greater site specificity [11], as well as stage, grading, laterality, and the diagnostic method. These codes can be used for postcoordination. The stem codes range from 2A00 to 2F9Z. The extension codes for morphology are 6-digit codes composed of letters and numbers, starting with the letter *X*. Examples of the ICD-10 and ICD-11 complete neoplasm codes are shown in Table 1.

Table 1. Examples of the International Classification of Diseases, Tenth Revision (ICD-10), Chinese Clinical Modification of the International Classification of Diseases, Tenth Revision (ICD-10-CCM), and International Classification of Diseases, Eleventh Revision (ICD-11) complete neoplasm codes.

Neoplasm	ICD-10		ICD-10-CCM		ICD-11	
	Topography code	Morphology code	Topography code	Morphology code	Stem code	Extension codes
Adenocarcinoma of the common bile duct, stage III, diagnosis confirmed by histology	C24.0	8140/3	C24.003	81400/3	2C15.0	• &XS6H • &XY9Q

In the ICD-10, C24.0 represents a malignant neoplasm of the extrahepatic bile duct, and 8140/3 represents adenocarcinoma. In the ICD-10-CCM, C24.003 represents a malignant neoplasm of the common bile duct, and 81400/3 represents adenocarcinoma. In the ICD-11, 2C15.0 represents adenocarcinoma of the distal bile duct, XS6H represents stage III, and XY9Q represents a diagnosis confirmed by histology. We used the the ICD-11 coding tool website [10].

Coding Capacity

Categories, subcategories, and leaf codes can be used for statistics, but only leaf codes can be used for actual coding. In the ICD-10, chapter 2 includes 759 leaf codes [7]. In the ICD-10-CCM, the topography codes are basically expanded by refining the sites, with 3634 leaf codes for neoplasms. Taking malignant neoplasm of the nasal cavity (C30.0) as an example, the ICD-10-CCM contains 5 additional leaf codes, such as a

malignant neoplasm of nasal cartilages (C30.001) and a malignant neoplasm of the nasal concha (C30.002).

In the ICD-11, chapter 2 includes 1037 leaf codes [8]. Compared with the ICD-10, the number of ICD-11 leaf codes was expanded by 36.6%, which is conducive to better granularity of statistics and classification.

Classification Feature

The ICD-11 has readjusted the neoplasm groups. In the ICD-10, chapter 2 was divided into 4 groups: malignant neoplasms, in situ neoplasms, benign neoplasms, and neoplasms of uncertain or unknown behavior. In the ICD-11, chapter 2 was increased to 7 groups (Table 2). The newly added ICD-11 group 1 includes all neoplasms of the brain and central nervous system, regardless of behavior, and the newly added ICD-11 group 2 includes all hematopoietic and lymphoid tissues. The ICD-10 group 4 was split into 2 separate groups: ICD-11 group 6 (neoplasms of

uncertain behavior) and ICD-11 group 7 (neoplasms of unknown behavior).

Table 2. Grouping changes between the International Classification of Diseases, Tenth Revision (ICD-10) and the International Classification of Diseases, Eleventh Revision (ICD-11).

Classification system	ICD-11								
	Group 1	Group 2	Group 3	Group 4	Group 5	Group 6	Group 7	Other chapters	No mapping
ICD-10 codes, n									
Group 1	23[a]	91[a]	352	N/A[b]	N/A	N/A	N/A	8[a]	2
Group 2	N/A	N/A	N/A	57	N/A	N/A	N/A	N/A	N/A

[a]Indicates grouping changes. The ICD-10 and ICD-10-CCM no mapping codes were not included in the statistical analysis of this study. Hence, 755 ICD-10 codes and 3576 ICD-10-CCM codes were used for percentage and chi-square analyses.
[b]N/A: not applicable.

In total, 27.4% (207/755) of ICD-10 codes underwent grouping changes. Among them, 150 codes were migrated by 1 group, 56 by 2 groups, and one by 3 groups. In the ICD-10-CCM, 38% (1359/3576) leaf codes underwent grouping changes (Table 2). A chi-square test revealed significant differences in grouping changes between the ICD-10 and ICD-10-CCM (χ^2_1=30.3; P<.001).

Expression Features

Expression Ability

Because of the classification changes, 58 of the 3634 ICD-10-CCM codes for neoplasms could not be recoded. In total, 3576 codes were included in the manual recoding study.

The results of 2 separate recodings showed that 6% (213/3576) codes were mapped inconsistently. A total of 32 stem codes were inconsistent, and 181 extension codes differed. The 213 codes were all identified after consultation with the senior coder from the Collaborating Center for the WHO Family of International Classifications in China.

The final results showed that 16.6% (594/3576) codes were fully represented without postcoordination, 51.2% (1830/3576) codes were fully characterized with postcoordination, and the remaining 32.2% (1152/3576) codes were only partially described (Table 3). In addition, 7% (252/3576) codes were fully represented when using uniform resource identifiers (URIs).

Table 3. Comparison of the International Classification of Diseases, Eleventh Revision (ICD-11) expression ability among the 4 Chinese Clinical Modification of the International Classification of Diseases, Tenth Revision (ICD-10-CCM) groups.

ICD-10-CCM group	Total codes, N	Full representation				Partial representation	
		With PC[a] (a), n	Without PC (b), n	Codes (n1=a+b), n	Codes (n1/N), %	Codes (n2), n	Codes (n2/N), %
Group 1	1861	935	406	1341	72.1	520	27.9
Group 2	169	106	44	150	88.8	19	11.2
Group 3	918	501	73	574	62.5	344	37.5
Group 4	628	288	71	359	57.2	269	42.8
Total	3576	1830	594	2424	67.8	1152	32.2

[a]PC: postcoordination.

Based on the 4 ICD-10-CCM groups, ICD-11 significantly differed in expression ability (χ^2_3=93.7; P<.001). The Bonferroni method showed that the ICD-11 had the most robust expression ability in the ICD-10-CCM group 2, followed by the ICD-10-CCM group 1, and there was no significant difference between the remaining 2 groups.

Based on whether grouping changes occurred during mapping, 73.1% (1620/2217) ICD-10-CCM codes in the unchanged group

and 59.2% (804/1359) ICD-10-CCM codes in the changed group were fully expressed, and the difference was significant (χ^2_1=74.7; P<.001). Expression ability had a negative correlation with grouping changes (r=−.144; P<.001).

Expression Flexibility

The expression flexibility of the ICD-11 is reflected in many aspects. For instance, in the ICD-10, the subcategory ".8" generally describes overlapping neoplasm sites, while in the ICD-11, several methods are used. Specifically, the ICD-11 uses multiple extension codes. Sometimes, only 1 extension code is used, such as XA4YW8 (overlapping sites of the esophagus). Occasionally, the ICD-11 describes this condition through stem codes, such as 2B71.0 (adenocarcinoma of the esophagogastric junction). ICD-11 classifications can also be represented through URIs, for instance, http://id.who.int/icd/entity/419755630 (Kaposi sarcoma of multiple organs).

Expression flexibility is also reflected in the additional option of postcoordination, which can meet the different requirements of most hospitals for clinical phenotype mining. For example, a patient with hepatocellular carcinoma in the left lobe of the liver that causes chronic intermittent cancer pain and tumor anemia would be coded as 2C12.02&XA5766/MG30.10&XT5G/3A71.0. Postcoordination fully expresses the clinical phenotypes and demonstrates the relationship between diseases and clinical phenotypes.

Expression of Postcoordination

According to the ICD-10-CCM/ICD-11 mapping table, 60.5% (2164/3576) of codes had postcoordination, and the average amount of postcoordination per code was approximately 0.7. Regarding the type of postcoordination, the proportion of specific anatomy (1907/3576, 53.3%) was the highest, followed by histopathology (201/3576, 5.6%), and the remaining dimensions were basically less than 2% (Table 4).

Table 4. Expression of postcoordination in the Chinese Clinical Modification of the International Classification of Diseases, Tenth Revision/International Classification of Diseases, Eleventh Revision (ICD-10-CCM/ICD-11) mapping table.

Number and dimensions of postcoordination	Codes, n (%)
0	1412 (39.5)
No	
1	
Specific anatomy	1750 (48.9)
Histopathology	176 (4.9)
Alternative severity 2	60 (1.7)
Laterality	5 (0.1)
Course of the condition	3 (0.1)
Stem codes	3 (0.1)
2	
Specific anatomy/specific anatomy	118 (3.3)
Specific anatomy/histopathology	17 (0.5)
Specific anatomy/laterality	8 (0.2)
Histopathology/alternative severity 2	8 (0.2)
Alternative severity 2/stem codes	2 (0.1)
3	
Specific anatomy/specific anatomy/specific anatomy	11 (0.3)
Specific anatomy/specific anatomy/laterality	3 (0.1)

Discussion

Principal Findings

The different coding structure of the ICD-11 provides advantages in terms of coding granularity, coding capacity, and expression flexibility. According to the mapping tables, the grouping changes between the ICD-10 and ICD-10-CCM differed (χ^2_1=30.3; P<.001). Meanwhile, neither the ICD-10 group 2 nor the ICD-10-CCM group 2 exhibited group migration when mapped to the ICD-11. In this study, ICD-11 expression

ability (67.8%) was slightly higher than that in other studies (60%) [12,13]. Among the 4 ICD-10-CCM groups, there were significant differences in expression ability (χ^2_3=93.7; P<.001), with ICD-10-CCM group 2 having the highest expression ability. The expression ability negatively correlated with grouping changes (r=−0.144; P<.001).

The expression ability of the ICD-11 was still underestimated. There were many reasons why 1152 ICD-10-CCM codes did not have full representation, some of which can be avoided in actual cases. First, of the 296 ICD-10-CCM codes mapped to the ICD-11 group 1, only 26 (8.8%) codes were fully expressed,

which is far below the overall level. Among them, 217 codes cannot be fully expressed because most of the stem codes in ICD-11 group 1 do not include behavior. However, in coding actual cases with morphological types, some stem codes, including behavior, would be used instead of the residual category. Therefore, in actual coding, the expression ability of this group would be higher than that determined in this study.

Second, 714 codes could not be fully expressed due to site classification. Fortunately, 109 codes detailing specific sites may be resolved by refining the value set of extension codes. Examples include the frenulum of the upper lip, the ileocecal valve, and the rectouterine recess. However, there were also some codes for which the classification was different, such as peripheral nervous system neoplasms. This condition could be solved by coding the actual cases. In addition, some words, such as canceration of the gastric stump and cervical stump, need to be addressed.

Third, URIs can supplement the function of the ICD-11 MMS codes, especially for some diseases that cannot be identified by the ICD-11 codes. For instance, URIs (http://id.who.int/icd/entity/1595913346) make classic Kaposi sarcoma classifiable. The new coding system can also make other diseases identifiable [14-16], such as chronic pain and rare diseases. In summary, the ICD-11 has advantages in terms of actual coding and can address the expression needs of neoplasms.

The ICD-11 Vs the ICD-10

Compared to the ICD-10, the ICD-11 has undergone significant changes from design to use. First, the design purpose of the ICD-11 has changed. For more than a century, the ICD has been the basis for comparable statistics on causes of mortality and morbidity between places and over time. As a statistically friendly classification system, when the ICD-10 is used for clinical term records and diagnosis-related grouping, it cannot meet practical needs, resulting in various expanded versions of the WHO ICD-10 in multiple countries, which often leads to inconsistent statistical standards for data. In contrast, the ICD-11 is a clinically friendly classification system that meets diverse goals beyond mere health statistics, including clinical term records, patient safety and quality, reimbursement, decision support, and more. The ICD-11 is entirely digital, terminology is coded with the coding tool and application programming interface, and it has a semantic knowledge base; these features are beneficial for standardized data collection. In short, the ICD-11 has benefits in terms of obtaining statistics as well as multiaxial coding, coding granularity [4,17,18] and standardization, achieving the integration of terminology and classification. As shown in Table 1, although the ICD-10-CCM codes are expanded and refined at the leaf code level, the capture of clinical details is still weaker compared to the ICD-11 codes.

Second, the design concept of the ICD-11 is different. The ICD-10 is an independent classification system, and the standard terminology set for the ICD-10 has been developed independently. Differently, the ICD-11 has good semantic interoperability with other classification systems through harmonized methods. The Systematized Nomenclature of Medicine-Clinical Terms (SNOMED CT) is considered one of the most comprehensive clinical terminologies in the world [19]. The ICD-11 Foundation Component, which includes semantic network concepts and their relationships, is organized around the Common Ontology from a subset of the SNOMED CT [20,21]. The Common Ontology has been harmonized with ICD text definitions, primarily from the SNOMED CT clinical findings hierarchy (findings, disorders, and disease) and secondarily from other hierarchies (situations, events, social context, and so on) [22]. The rich Foundation Component has approximately 80,000 entries and 40,000 synonyms [5]. The ICD-11 linearizations, including the ICD-11 MMS and the International Classification of Diseases for Oncology (ICD-O), are subsets derived from the Foundation Component. The ICD-11 integrates the morphology section of the ICD-O, ICD-O linearization, and tumor node metastasis classification, and the histopathology codes of the ICD-11 are also compatible with the ICD-O [4]. Additionally, the ICD-11 integrates numerous clinical terminologies from some expanded versions of the WHO ICD-10. Compared to other classifications, the ICD-11 has advantages in terms of concept coverage and compatibility.

Third, the ICD-11 has stronger logical links between codes. If multiple codes are needed for disease expression, there is a lack of practical connections between ICD-10 codes. In the ICD-11, precoordination contains the site and morphology, and the postcoordination of morphology and the clinical phenotype is linked to stem codes through an ampersand (&) and slash (/).

In addition, the ICD-11 contains rich dimensions of postcoordination. Compared to the ICD-10, which provides information only about topography and morphology, the ICD-11 can also include other dimensions of postcoordination, such as stage, grading, laterality, and the diagnostic method. The ICD-11 coding system is more conducive to unifying national cancer registration in these dimensions. However, due to the limitations of the ICD-10 coding structure, these dimensions of postcoordination were missing when mapped to the ICD-11, with only 0.7 postcoordination per code, and its expression ability cannot be truly reflected.

Moreover, the ICD-11 has more expression flexibility. The ICD-10 coding system is fixed and single. The ICD-11 provides 2 sets of codes: ICD-11 MMS codes and URIs. In ICD-11 MMS codes, a stem code can be used alone or with optional extension codes. A URI is a string of characters that uniquely identifies a particular entity. Therefore, a coding system with good expression flexibility can meet the coding granularity and clinical phenotype mining requirements of hospitals at different levels.

Finally, the ICD-11 has different update mechanisms. The ICD-10 updates relatively slowly. In 1999, the WHO established the Update Advisory Committee as the only authoritative body revising the ICD-10. In 2005, the WHO officially published the second edition of the ICD-10 and continued to issue revisions to the relevant content of the ICD-10 through official channels every year. The ICD-11 provides a web-based coding tool instead of paper environments, which is highly beneficial for timely updates. It has a real-time updated orange version and an annually updated blue version.

XSL•FO

RenderX

Overall, the eleventh revision is more extensive than any other revision since the sixth in 1948. These design-level features make the ICD-11 competitive with other classification systems.

Challenges of Replacement

The improvements described above also pose challenges for replacing the ICD-10 with the ICD-11. Compared to the ICD-10, the ICD-11 leaf codes for neoplasms have expanded by 36.6%, and there are also approximately 16,000 extension codes. Hence, the expression ability of the ICD-11 for clinical details far exceeds that of the ICD-10 and ICD-10-CCM. However, codes with better granularity require clinicians to record diagnoses and treatments in greater detail. It is essential to carry out the necessary interventions to enhance medical record documentation according to ICD-11 before or simultaneously with country-wide implementation [23]. Clinicians will be required to have a good understanding of the ICD-11. Otherwise, the best classification system is just a decoration.

Second, coders are accustomed to using the old classification system and need time to familiarize themselves with the new coding system and tool. Studies have shown that some coders have difficulties coding on the web due to a lack of familiarity with software [24,25]. In this study, 2 skilled coders who received ICD-11 training still had 213 inconsistent codes. Web-based coding requires high professional ability. Studies have also shown that the reliability and accuracy of ICD-11 coding are lower than those of ICD-10 coding [23-25]. In the early stages of ICD-11 promotion, countries involved in the transition need to conduct ICD-11 training and transform coders' coding concepts. To maintain coding accuracy, developing high-quality ICD-11 training materials, training processes, and local ICD-11 guidelines is effective [23,26].

Moreover, many countries have applied the ICD-10 in different fields, such as mortality and morbidity statistics, diagnosis-related grouping, and cancer registries. There is also a potential challenge with IT systems being able to adopt a new classification that allows for unlimited width in fields. Stakeholders must upgrade their information systems to meet the needs of the ICD-11, which requires a significant amount of time and money to hire medical, IT, and management personnel to complete this transformation. The experience of the United States in replacing ICD versions can provide a better reference. In the United States, because of significant opposition and reservations expressed by stakeholders, it took 6 years from the adoption of the International Classification of Diseases, Tenth Revision, Clinical Modification (ICD-10-CM) to complete the transition [27], and the costs associated with the transition were estimated to be between US $475 million and US $1.5 billion dollars, including training, productivity losses, and system changes [28].

Importantly, the ICD-10 and ICD-11 will coexist for a long time before replacement, which contributes to solving some problems. The parallel implementation of the 2 classification systems can ensure government policy continuity. In January 2022, the pilot application program to promote ICD-11 was launched in China, with 59 large general public hospitals from all provinces participating. However, ICD-11 is not fully understood by other hospitals. The impacts of the new classification system implementation included coding accuracy, ICD version mapping, and more [29]. The ICD version mapping can be used for interoperability between coded data sets [30]. Hospitals do not require dual coding and use ICD-11 to report data. If a hospital needs dual coding, a mapping table can significantly reduce the time, at least by half, spent on duplicate coding. A map can also maintain the same accuracy of ICD-11 coding for all hospitals and alert coders if there are any coding errors. Usually, a high-quality map requires substantial manual curation, and some studies use algorithmic mapping approaches, such as sequential mapping [30]. Some scholars have developed hybrid methods, such as automatic mapping and manual review [31], semiautomatic mapping, and manual evaluation [32]. Although automatic coding has many benefits, supervised and manual mapping are still necessary [33]. Undeniably, there may be some issues with the use of mapping tables. A study has shown that 14.5% of International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) codes used by internists, when mapped to the ICD-10-CM, resulted in potential clinical inaccuracies [34]. In general, a high-quality map would contribute to the smooth transition of ICD-11, and multiple mapping methods can be explored. This study confirms the feasibility of using manual mapping tables for neoplasms between the ICD-10-CCM and ICD-11. To date, the results of some studies on the transition to the ICD-11 have also been optimistic [17,18].

In addition, although the WHO provides an ICD-11 coding tool, countries must continue optimizing this tool. A mapping table can improve the intelligence of the coding tool. If the terms are the same as those in the mapping table, the coding tool can automatically load the coding cluster without selecting postcoordination one by one. The accuracy and efficiency of ICD-11 coding largely depend on how well the coding tool is optimized. It is necessary to continuously optimize the coding tool before fully promoting the ICD-11.

Limitations

This study had some limitations that must be considered. First, this study focused only on the clinical condition of neoplasms. However, the chapter on neoplasms is quite complex and one of the most varied chapters on other conditions, with significant changes. Moreover, patients with cancer may experience different manifestations, including chronic, surgical, and emergency conditions. For example, a patient with long-term chronic hepatitis B causing cirrhosis and liver cancer was admitted to the hospital for emergency surgery due to a tumor rupture. Furthermore, the burden of cancer in China continues to grow with the aging population. According to statistics, the crude cancer mortality rate increased from 108.3 per 100,000 individuals in the 1990-1992 period to 170.1 per 100,000 individuals in 2015 [35]. Significantly, the research method is well thought out. Manual mapping can provide a good understanding of the new ICD-11 features and help individuals familiarize themselves with the characteristics of the new classification systems. As a method, manual mapping can be extended to other conditions. More conditions can be gradually incorporated, especially emergency and surgical conditions, in the future.

Second, this study used only manual mapping, which is time-consuming and laborious. Other methods combined with manual mapping can be continuously explored, especially automatic mapping between the ICD-10-CCM and ICD-11, including algorithmic mapping and machine learning approaches.

Conclusion

Neoplasm classification has undergone many improvements in the ICD-11, especially the new coding system, improved expression ability, and good semantic interoperability. The new coding system provides advantages in coding granularity, coding capacity, and expression flexibility. Moreover, 67.8% of ICD-10-CCM neoplasm codes can be fully represented by the ICD-11, and expression ability negatively correlates with grouping changes ($r=-0.144$, $P<.001$). The more significant the changes in a new classification system are, the less information can be expressed when mapped to other databases. The use of URIs and maintenance mechanisms can increase the expression ability for coding in actual cases. In addition, the good semantic interoperability of the ICD-11, integrating numerous clinical terminologies from the SNOMED CT, the ICD-O, the tumor node metastasis classification, and expanded versions of the WHO ICD-10, makes the ICD-11 competitive with other classification systems. The transition to the ICD-11 will inevitably bring numerous challenges for clinicians, coders, policy makers and IT technicians, and many preparations will be necessary.

Abstract

Background: Artificial intelligence (AI) has garnered considerable attention in the context of sepsis research, particularly in personalized diagnosis and treatment. Conducting a bibliometric analysis of existing publications can offer a broad overview of the field and identify current research trends and future research directions.

Objective: The objective of this study is to leverage bibliometric data to provide a comprehensive overview of the application of AI in sepsis.

Methods: We conducted a search in the Web of Science Core Collection database to identify relevant articles published in English until August 31, 2023. A predefined search strategy was used, evaluating titles, abstracts, and full texts as needed. We used the Bibliometrix and VOSviewer tools to visualize networks showcasing the co-occurrence of authors, research institutions, countries, citations, and keywords.

Results: A total of 259 relevant articles published between 2014 and 2023 (until August) were identified. Over the past decade, the annual publication count has consistently risen. Leading journals in this domain include *Critical Care Medicine* (17/259, 6.6%), *Frontiers in Medicine* (17/259, 6.6%), and *Scientific Reports* (11/259, 4.2%). The United States (103/259, 39.8%), China (83/259, 32%), United Kingdom (14/259, 5.4%), and Taiwan (12/259, 4.6%) emerged as the most prolific countries in terms of publications. Notable institutions in this field include the University of California System, Emory University, and Harvard University. The key researchers working in this area include Ritankar Das, Chris Barton, and Rishikesan Kamaleswaran. Although the initial period witnessed a relatively low number of articles focused on AI applications for sepsis, there has been a significant surge in research within this area in recent years (2014-2023).

Conclusions: This comprehensive analysis provides valuable insights into AI-related research conducted in the field of sepsis, aiding health care policy makers and researchers in understanding the potential of AI and formulating effective research plans. Such analysis serves as a valuable resource for determining the advantages, sustainability, scope, and potential impact of AI models in sepsis.

Introduction

Sepsis is a life-threatening medical emergency [1] affecting approximately 48.9 million individuals globally each year and potentially contributing to over 11 million deaths [2]. Previous studies indicated that sepsis-related hospitalization can result in fatal outcomes in 30%-50% of cases [3,4]. However, prompt stratification and the timely administration of specific treatments have the potential to lower sepsis-related mortality. Identifying sepsis at an early stage can be challenging due to the complex pattern of the disease [5,6] and the diversity of the septic population [7].

Artificial intelligence (AI) has piqued interest in its excellent potential to stratify patients with a high risk of sepsis [8]. In recent times, AI models have seen widespread application in the prediction of sepsis and have shown superior performance compared with conventional statistical methods [9,10]. Yet, no study has shed light on the variety of AI applications and their potential and limitations in sepsis through a scientific consolidation of knowledge. Bibliometric analysis aids researchers in comprehending specific research fields, a crucial aspect for guiding both future research endeavors (eg, what else should we know) and practical implementation (eg, what should we do) [11]. This research aims to address the following questions, with the intent of advancing the previous research on the application of AI in sepsis: (1) What countries, institutions, sources, and documents have demonstrated the highest productivity within the realm of AI applied to sepsis? (2) What are the hot research topics and themes of research in the application of AI in sepsis? (3) What methods are mainly applied in the existing body of literature? (4) What types of limitations appeared in the existing literature regarding the application of AI in sepsis? and (5) What are the literature gaps and future research agendas?

In this study, we could systematically investigate shifts in publication growth, offering more valuable insights to fellow researchers and policy makers engaged in priority setting and assessment.

Methods

Data Source

We leveraged extracted data from the Web of Science Core Collection as of August 31, 2023. We used Web of Science for its comprehensive coverage across multiple databases, comprising a wide range of bibliometric indicators and literature from various disciplines. Using a predefined search strategy, we intended to include all relevant literature for bibliometric analysis. We used the following key words: *artificial intelligence* OR *computational intelligence* OR *deep learning* OR *computer aided* OR *machine learning* OR *support vector machine* OR *data learning* OR *artificial neural network* OR *digital image* OR *convolutional neural network* OR *evolutionary algorithms* OR *feature learning* OR *reinforcement learning* OR *big data* OR *image segmentation* OR *hybrid intelligent system* OR *hybrid intelligent system* OR *recurrent neural network* OR *natural language processing* OR *Bayesian network* OR *Bayesian learning* OR *random forest* OR *evolutionary algorithms* OR

multiagent system AND *sepsis.* The collected records contained essential attributes, including publication date, authorship, institutional affiliation, geographic origin, and cited references. This data set served as the foundation for our subsequent analytical investigations.

Inclusion and Exclusion Criteria

The titles and abstracts underwent initial screening by 2 independent authors (MW and TNP). If there was uncertainty from one reviewer regarding whether the article met the inclusion criteria, it was included for a thorough full-text review. Following this, both authors independently assessed the full text, and any differences in opinion were resolved through consensus with the research team. We considered studies for inclusion if they met the following criteria: (1) they were written in English, and (2) they applied AI models in the context of sepsis. In this study's screening process, we included research or review articles published in peer-reviewed journals, conference proceedings, reviews, and early access articles. We excluded studies if they were published as letters, editorials, book chapters, or books.

Data Collection and Preprocessing

To ensure compatibility with Bibliometrix and VOSviewer [12], we saved the data in the "**.txt" format, a format recognized by both tools for conducting analyses. Our data set encompasses a comprehensive range of information, including titles, list of authors, name of countries, list of institutions, abstracts, keywords, name of journals, and publication dates.

Statistical Analysis

Bibliometrix and VOSviewer tools were used to uncover the knowledge structure, most influential countries, research hot spots, and productive authors, along with various bibliometric insights. The processed data were uploaded into these bibliometric tools, and analysis was conducted based on the information included within the data documents [13]. Afterward, we generated network maps among journals, authors, countries, and institutions, where individual points symbolized authors, countries, or institutions. Moreover, connected lines in the network maps depicted the relationships between these entities. Larger points and more robust lines indicated a higher number of articles and more substantial collaborative relationships, respectively [14,15].

We computed the annual growth rate of publications. The annual publication count, annual growth, and average growth rate of publications were determined through the following methods:

$$\text{[formula]}$$

Where N is the total number of articles in the current year, and N_{k-1} is the total number of articles in the previous year.

Furthermore, we conducted an analysis of publication trends based on the following criteria: the top 10 most prolific countries, institutions, journals, authors, and studies in this area. The rankings of countries, institutions, journals, and authors were determined based on the number of articles.

XSL•FO

RenderX

Results

Distribution of Articles by Publication Year

The initial search yielded 327 articles focused on the application of AI in sepsis. After applying predefined inclusion criteria, 68 articles were deleted, leaving 259 articles for the final analysis (Figure 1).

Over time, there has been a substantial rise in the number of publications in this field. Notably, the yearly publication number increased from just 2 articles in 2014 to 72 articles in 2022. It is important to note that before 2018, the yearly publication count did not cross 10 articles. The calculated annual growth rate was found to be 44.81% (Figure 2).

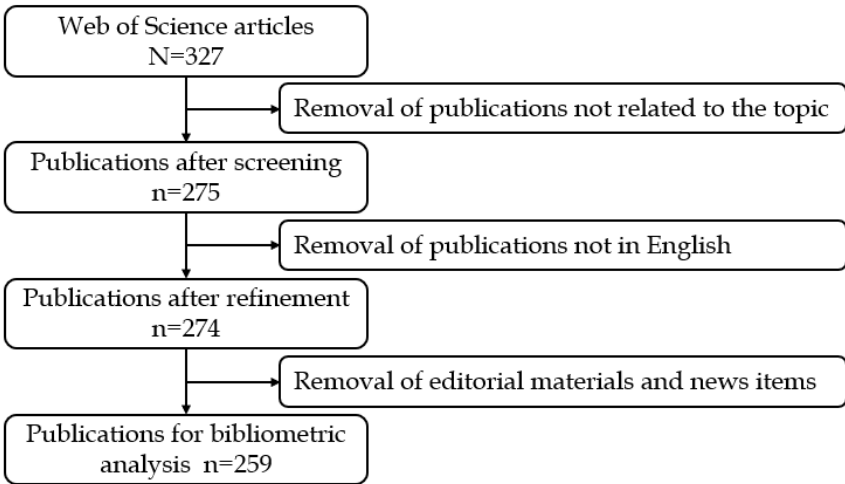
Figure 1. A diagram for the detailed selection criteria and bibliometric analysis steps of applying artificial intelligence to sepsis in the Web of Science Core Collection database.


Figure 2. Trends in the number of publications on the application of artificial intelligence to the study of sepsis from 2014 to 2023 (August).
Distribution of Source Journals

A total of 122 journals published articles on the application of AI in sepsis. Among them, the *Critical Care Medicine* journal was the most productive, having published 6.6% (17/122) of articles in this domain (Table 1). *Frontiers in Medicine*, *Scientific Reports*, and the *American Journal of Respiratory and Critical Care Medicine* were in the second, third, and fourth positions, publishing 17, 11, and 7 articles, respectively, on this topic. However, the top 10 journals published 86 articles, accounting for 33.2% (86/259) of all publications in this area.

Table 1. The top 10 journals with publications on the application of artificial intelligence in sepsis from 2014 to August 2023.

Rank	Journal	Country	Category	Publication frequency, n (%)	Impact factor in 2022	5-year impact factor
1	*Critical Care Medicine*	United States	Engineering, electrical, and electronics	17 (6.6)	8.8	8.4
2	*Frontiers in Medicine*	Switzerland	Multidisciplinary science	17 (6.5)	3.9	4.2
3	*Scientific Reports*	United Kingdom	Multidisciplinary science	11 (4.2)	4.6	4.9
4	*American Journal of Respiratory and Critical Care Medicine*	United States	Multidisciplinary science	7 (2.7)	24.7	21.9
5	*Frontiers in Immunology*	Switzerland	Clinical neurology	6 (2.3)	7.3	8.0
6	*Intensive Care Medicine*	United States	Neurosciences	6 (2.3)	38.9	27
7	*Journal of the American Medical Informatics Association*	United States	Computer science and interdisciplinary applications	6 (2.3)	6.4	6.3
8	*PLoS One*	United States	Neurosciences	6 (2.3)	3.7	3.8
9	*BMC Medical Informatics and Decision Making*	United Kingdom	Engineering and multidisciplinary	5 (1.9)	3.5	3.9
10	*Computers in Biology and Medicine*	United States	Engineering and biomedical	5 (1.9)	7.7	6.9

Distribution of Countries and Regions

This study revealed that researchers from 73 countries and regions engaged in research on these subjects and published their work in various international peer-reviewed journals. Out of the total 259 articles, the United States made the most substantial contribution with 103 publications (39.8%), followed by China with 83 publications (32%), United Kingdom with 14 publications (5.4%), and Taiwan with 12 publications (4.6%) (Table 2).

Table 2. The top 10 countries and regions with publications on the application of artificial intelligence in sepsis from 2014 to August 2023.

Rank	Country	Articles, n (%)
1	United States	103 (39.8)
2	China	83 (32)
3	United Kingdom	14 (5.4)
4	Taiwan	12 (4.6)
5	India	11 (4.2)
6	Netherlands	10 (3.9)
7	Australia	8 (3.1)
8	Canada	8 (3.1)
9	Spain	7 (2.7)
10	Germany	7 (2.7)

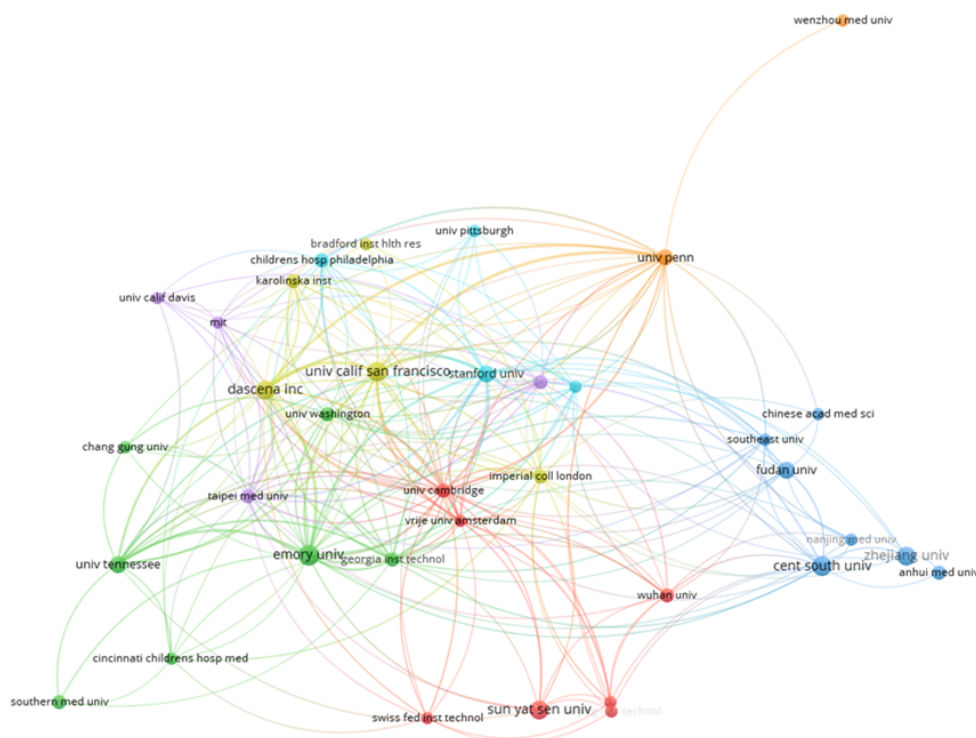
Distribution of Institutions

Table 3 shows the top 10 most productive institutes that used AI applications in sepsis. The University of California system (22/259 articles, 8.5%) ranked first among all research institutions, followed by Emory University (10/259 articles, 3.9%), Harvard University (10/259 articles, 3.9%), and Central South University (8/259 articles, 3.1%).

Figure 3 shows the institution cooperation network of 117 institutions that published at least 1 article.

Table 3. The top 10 institutes with publications on the application of artificial intelligence in sepsis from 2014 to August 2023.

Rank	Institutions	Country	Publications, n (%)
1	University of California system	United States	22 (8.5)
2	Emory University	United States	10 (3.9)
3	Harvard University	United States	10 (3.9)
4	Central South University	China	8 (3.1)
5	Dascena Inc	United States	8 (3.1)
6	University of Pennsylvania	United States	8 (3.1)
7	Zhejiang University	China	8 (3.1)
8	Stanford University	United States	7 (2.7)
9	Sun Yat-sen University	China	7 (2.7)
10	Fudan University	China	6 (2.3)

Figure 3. Institution co-operation network.


Distribution of Authors

A total of 259 articles were authored by 1444 individuals, each of whom had at least 1 article to their name. In Table 4, we present the top 10 most prolific authors who conducted and published research in these fields. Ritankar Das secured the top position with 8 articles, closely followed by Chris Barton (6 articles), Rishikesan Kamaleswaran (6 articles), and Suchi Saria (6 articles).

Our analysis shows that 1444 authors have published at least 1 article. The largest set of associated authors consisted of 20 authors in 3 clusters (Figure 4).

Table 4. The top 10 authors with publications on the application of artificial intelligence in sepsis from 2014 to August 2023.

Rank	Author	Articles, n	Citations, n	h-index	Affiliation
1	Das	8	1417	18	Dascena Inc
2	Barton	6	2277	25	University of California San Francisco
3	Kamaleswaran	6	861	14	Emory University
4	Saria	6	2635	23	Johns Hopkins University
5	Calvert	5	1152	17	University of California Berkeley
6	Hoffman	5	957	14	Dascena Inc

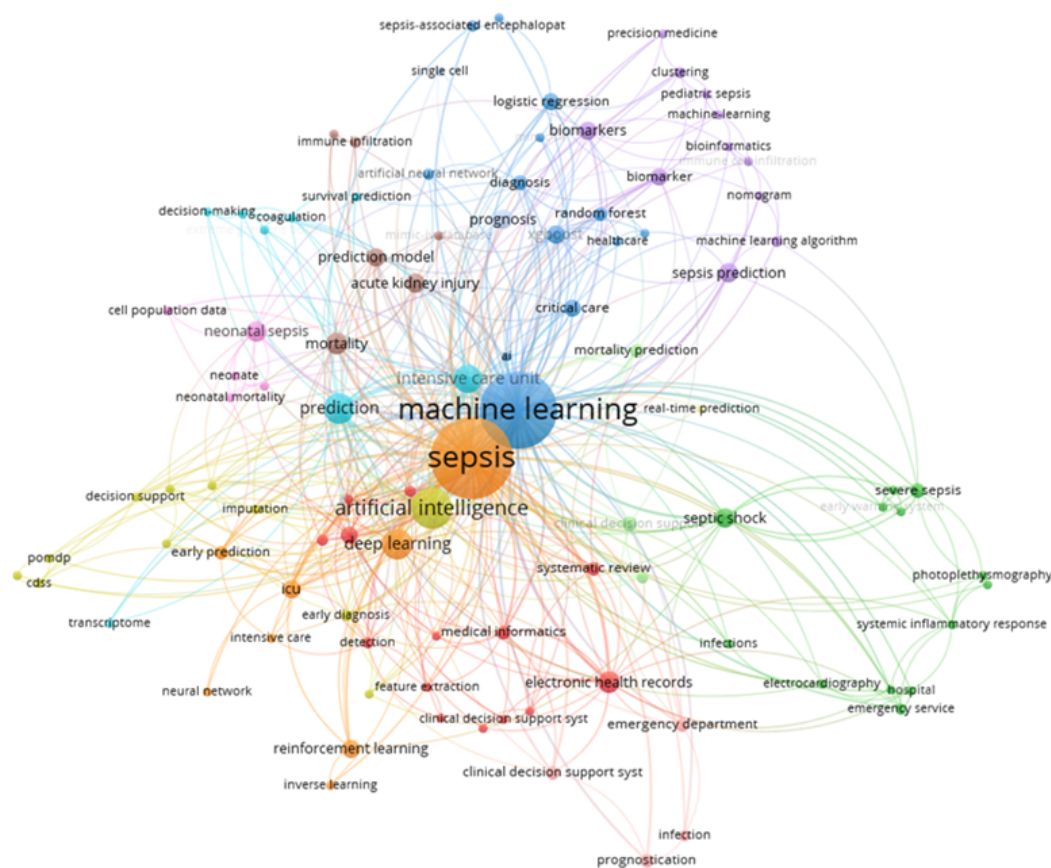
Co-Occurrence Analysis of Top 100 Keywords

Keywords encapsulate the central themes within a publication and are ideal for examining interconnected areas of research. In this study, we performed co-occurrence analysis to pinpoint the prominent research focal points in the field of AI application in sepsis research, using the top 100 keywords. The extraction and clustering of these top 100 keywords were performed using VOSviewer.

Figure 5 illustrates our use of VOSviewer to create a visual network map, consisting of 6 clusters based on the co-occurrence of the top 100 keywords. The core of this visualization network map is occupied by the following keywords: sepsis (n=138), machine learning (n=122), artificial intelligence (n=35), and deep learning (n=20).

Figure 5. The co-occurrence network of the top 100 keywords in artificial intelligence research for sepsis from 2014 to 2023 (August).


Discussion

Main Findings

This study investigated the citation analyses of AI models in sepsis research, scrutinizing the publication patterns related to their application. This study reports a noteworthy upswing in interest in this subject over the past decade, particularly increasing from 2018 to 2022.

The substantial increase in the use of AI in health care research is noteworthy. For instance, there was an 88.88% increase in the use of AI in health care research after 2012, with only 10 countries contributing to over 96% of the studies [25]. Our findings also indicate an annual growth rate of 44.81% in the use of AI in sepsis-related research. If this growth rate continues in the future, we can anticipate the publication volume in the domain of AI in sepsis-related research doubling approximately every 5 years. This increased number of publications indicates advancements, improved functionality, and the overall progress of AI in sepsis, especially when compared to other application areas.

The number of publications exhibits geographical disparities [26-28]. Recent research indicates a rise in the application of AI in health care research, particularly in developed countries [12,29,30]. These nations are investing increased funds into AI research and the development of AI tools to improve health outcomes. This study aligns with these findings, highlighting an increased number of publications originating from developed

countries. However, it underscores the importance of researchers from developing nations stepping forward to contribute toward achieving ultimate health goals. Effective collaboration among clinical experts, AI model developers, and health care providers is essential to addressing the challenges at hand [31].

Selecting the appropriate journals for publication can be a complex decision [32]. Authors take various factors into account when submitting, such as the accessibility of open-access journals and the higher impact factor associated with certain subscription journals [33]. Some authors prefer open-access journals for their widespread availability after publication and the potential for a higher number of citations [34]. Conversely, subscription journals from reputable publishers attract attention due to their high impact factors [35,36]. New researchers often struggle with the dilemma of where to submit their work. This study shows that authors frequently weigh both open-access and higher-impact–factor journals when publishing research related to the application of AI in sepsis.

This study aimed primarily to highlight the most commonly used data sets and algorithms in the current literature. The majority of studies used the Multiparameter Intelligent Monitoring in Intensive Care III (MIMIC-III) data set and supervised machine learning models [37-39]. Notably, Komorowski et al [16] introduced a reinforcement learning model to predict sepsis in patients, demonstrating average reliability levels higher than those of human clinicians. While many studies used extensive training and testing data sets, the

majority focused on single-centered data [39]. To apply these models in real-world clinical settings, external validation becomes necessary.

Strengths and Limitations

This study has several strengths. First, it is the first comprehensive bibliometric analysis that sheds light on the research trends of the application of AI in sepsis, illustrating how this field has evolved. Second, this study gauges productivity in terms of sources, authors, institutions, and countries, while also visualizing word trends. This provides novel and in-depth insights for both researchers and practitioners. This study also has some limitations to address. First, we only collected relevant publications from the Web of Science, a widely used academic resource, for bibliometric analyses [13,40-42]. Nevertheless, using other databases, such as PubMed or Scopus, might have provided slightly varied findings. Second, our inclusion criteria comprised articles published solely in English. However, inclusion of other languages, gray literature, and books might have influenced outcomes, particularly considering diverse cultural perspectives among scholars on the application of AI in sepsis. Finally,

relying solely on article titles for the search may pose limitations. However, our aim was to focus on publications specifically addressing the application of AI in sepsis. Therefore, a title screening was deemed more suitable than a broader topic search.

Conclusion

This study aimed to present a comprehensive overview of the use of AI in sepsis through a systematic analysis of existing literature. The findings of this study reveal a noticeable increase in the number of publications over the last 10 years. Until now, developed countries have been the primary contributors in this field. Researchers from developing countries should step forward, leveraging population advantages and core technologies in different regions to foster collaboration.

Leading multidisciplinary science journals, including *Frontiers in Medicine, Scientific Reports*, and the *American Journal of Respiratory and Critical Care Medicine*, emerge as key contributors to this topic based on the volume of published articles. As the application of AI in sepsis research continues to rise, this study serves as a valuable resource for researchers seeking direction and opportunities for collaboration.

Authors' Contributions

All authors contributed to the conception and design of the study; data collection, analysis, and interpretation; drafting and revising the article critically for content; and approval of the final version to be submitted.

Conflicts of Interest

None declared.

Abstract

Background: The advent of digital health technologies has transformed the landscape of health care, influencing the dynamics of the physician-patient relationship. Although these technologies offer potential benefits, they also introduce challenges and complexities that require ethical consideration.

Objective: This scoping review aims to investigate the effects of digital health technologies, such as digital messaging, telemedicine, and electronic health records, on the physician-patient relationship. To understand the complex consequences of these tools within health care, it contrasts the findings of studies that use various theoretical frameworks and concepts with studies grounded in relational ethics.

Methods: Using the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines, we conducted a scoping review. Data were retrieved through keyword searches on MEDLINE/PubMed, Embase, IEEE Xplore, and Cochrane. We screened 427 original peer-reviewed research papers published in English-language journals between 2010 and 2021. A total of 73 papers were assessed for eligibility, and 10 of these were included in the review. The data were summarized through a narrative synthesis of the findings.

Results: Digital health technologies enhance communication, improve health care delivery efficiency, and empower patients, leading to shifts in power dynamics in the physician-patient relationship. They also potentially reinforce inequities in health care access due to variations in technology literacy among patients and lead to decreases in patient satisfaction due to the impersonal nature of digital interactions. Studies applying a relational ethics framework have revealed the nuanced impacts of digital health technologies on the physician-patient relationship, highlighting shifts toward more collaborative and reciprocal care. These studies have also explored transitions from traditional hierarchical relationships to mutual engagement, capturing the complexities of power dynamics and vulnerabilities. Other theoretical frameworks, such as patient-centered care, and concepts, such as patient empowerment, were also valuable for understanding these interactions in the context of digital health.

Conclusions: The shift from hierarchical to collaborative models in the physician-patient relationship not only underscores the empowering potential of digital tools but also presents new challenges and reinforces existing ones. Along with applications for various theoretical frameworks and concepts, this review highlights the unique comprehensiveness of a relational ethics perspective, which could provide a more nuanced understanding of trust, empathy, and power dynamics in the context of digital health. The adoption of relational ethics in empirical research may offer richer insights into the real-life complexities of the physician-patient relationship, as mediated by digital technologies.

Introduction

Rationale

Digital health technologies are revolutionizing the practice of health care [1]. Driven by societal, political, and technological advancements, these technology-mediated changes are occurring at an unprecedented pace. Envisioning a future in which medicine can be personalized to individuals and diseases can be foreseen and prevented, some experts have high hopes for the potential of technology to improve human life [1,2]. However, skeptics argue that achieving personalization through technology is an elusive paradox, as it fails to account for the fundamental uncertainties and complexities of medicine and the value of human interactions [3].

In the realm of medical practice, a physician's primary goal is to diagnose and treat patients' diseases by drawing upon their biomedical expertise and years of clinical experience. Nevertheless, a physician's practice must also be guided and adapted based on their relationship with the patient. A sustained physician-patient relationship facilitates the tailoring of therapeutic interventions to best suit individual patients' needs [4]. Interpersonal skills honed over time through relational interactions with patients cannot be directly replaced by technology. Future technologies, including artificial intelligence, can only interpret what is explicitly documented as text or images in the electronic health record (EHR), which could lead to potentially missing valuable information generated within the physician-patient relationship, such as the patient's values, preferences, trust, and rapport [5,6]. Moreover, a doctor's personality and nonreflective actions, such as active listening or disregarding patient preferences, can have a significant impact not only on curing the patient's illness but also on maintaining or exacerbating it [4]. Continuity of care with the same physician has been shown to reduce hospital admissions and mortality rates [7]. The rapid integration of technology introduces complex dimensions to an already intricate relationship, necessitating an exploration of technology's impact on the physician-patient dynamic.

Digital technology offers potential for both improvements and risk, as it can efficiently reach a larger number of patients with less effort. At best, this technology-mediated efficiency may offer improved accessibility, real-time monitoring, and personalized treatments. It can also bridge geographical divides, connecting remote patients to specialists. At worst, it may be harmful on a scale far beyond what a single physician could achieve in a lifetime, potentially introducing systematic biases on a massive, automatic scale.

A potential problem with research on digital health technologies is the risk of bias, for example, when research funding comes from for-profit organizations and technology providers. As there may also be a dearth of independent research being published in this domain, we risk developing a skewed view of the evidence [8]. Additionally, while technological advancements surge ahead, ethical and regulatory frameworks have struggled to keep pace with these developments [9], making the need for new knowledge even more pressing.

Undeniably, digital technologies are here to stay and are already reshaping medical practice and the physician-patient relationship. Yet, more research is necessary to truly understand the nuanced implications of this shift. While technology promises efficiency and precision, the physician-patient relationship is rooted in intersubjective trust, empathy, and a deep understanding that transcends quantifiable data. As we further integrate technology into health care, it is therefore essential to explore its impact on this foundational relationship. Does it have the potential to augment the bond, creating new avenues for connection and understanding, or does it carry a more detrimental potential to create distance, becoming a screen that separates rather than connects human beings? By delving deeper into these questions, we can ensure that, as we advance technically, we do not lose sight of the human touch that remains at the heart of healing.

Objectives

This review explores the existing knowledge gap concerning the impact of digital health on the physician-patient dynamic. Additionally, we analyze various theoretical frameworks and concepts used in empirical studies concerning this relationship and contrast the findings of these studies with the results of research grounded in relational ethics frameworks [10]. This research focus has enabled us to identify the consequences of using digital health technologies (such as digital messaging, telemedicine, health-related websites, and EHRs) in physician-patient relationships.

Methods

Overview

Due to the rapid advancements in digital health care, there is a noticeable knowledge gap in the existing literature. A scoping review was deemed a suitable review approach, as it is well suited for providing an updated understanding of the current state of knowledge [11]. This scoping review was conducted according to the guidelines of the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) [12]. The study protocol was preregistered with the Center for Open Science [13].

Eligibility Criteria

The combined emergence of smartphones and 4G networks from around 2010 has played a crucial role in driving the development and use of digital health services [14]. This convergence has provided individuals with convenient access to health care services through mobile health (mHealth) apps, remote monitoring, and telemedicine, while also enabling health care providers to leverage real-time health data for personalized and data-driven care approaches. Only original peer-reviewed research published in English-language journals from January

XSL•FO

RenderX

1, 2010, to December 31, 2021, was included in this review. The decision to conclude the literature review on December 31, 2021, was driven by the aim to provide a comprehensive and current overview of the field up to our initial submission at the beginning of 2023. We carefully evaluated the scope and depth of available literature within this timeframe, determining that extending the search would likely not alter our core findings.

Research papers on patients and general practitioners or physicians involving health technology were included. Studies that did not specifically mention the physician-patient relationship were excluded.

Information Sources

Studies for inclusion were identified through searches in the following databases: MEDLINE/PubMed, Embase, IEEE Xplore, and Cochrane. Since our review specifically targeted empirical research on the physician-patient relationship, we primarily focused on searching medical databases. However, we also included IEEE Xplore to ensure that we did not miss any significant research in the fields of computer science and electrical engineering. To ensure trustworthy findings and direct insights, our search prioritized original papers and solely focused on high-quality research papers published in peer-reviewed medical journals. Reviews, opinion pieces, and other nonempirical texts were not included. Duplicates were removed.

Search

In collaboration with a librarian, we devised a comprehensive search string to explore the application of digital health technology within the physician-patient relationship. To ensure clarity in our scope, we used the mnemonic strategy PCC

(population, concept, and context) to determine which papers should be included. Specifically, the population consisted of physicians, patients, or both; the concept involved digital health technologies used in medical care; and the context revolved around their implementation within the physician-patient relationship. The search string encompassed relevant terms, such as "digital health," "mHealth," "eHealth," "telemedicine," or "telehealth," combined with the key phrases "physician-patient relations" or "relational ethics." Detailed explanations of these terms are provided in Table 1. The search string used was ("digital health" OR "mHealth" OR "eHealth" OR "telemedicine" OR "telehealth") AND ("physician-patient relations" OR "relational ethics").

Our particular focus was on "relational ethics" due to its potential to inform a more ethical analysis of the physician-patient relationship, thus addressing the intricacies and challenges unique to this context.

We searched the 4 databases applying the following limitations: "scholarly (peer-reviewed) journals," "date of publication from January 1, 2010 to December 31, 2021," and "English language." The search resulted in the identification of 429 journal papers. Of these papers, 427 were discovered in MEDLINE/PubMed, while 1 paper was identified as a duplicate appearing in both the Cochrane and MEDLINE/PubMed libraries. Additionally, 1 paper obtained from Embase was identified as a scoping review and was therefore excluded from our screening analysis. It is worth noting that no papers were found in IEEE Xplore during our search process. In short, all 427 papers selected for screening were found in the MEDLINE/PubMed database.

Table 1. Search terms.

Search terms	Explanation
digital health	Refers to technology related to health care services and solutions
mHealth[a]	Short for "mobile health," involves the use of mobile devices
eHealth	Refers to "electronic health," including digital health services
telemedicine	Involves remote diagnosis and treatment using technology
telehealth	Broad term covering health care services through telecommunication
Physician-patient relations	Refers to the interactions and dynamics between doctors and patients
relational ethics	Refers to an ethical framework focused on understanding and navigating the intricacies of interpersonal dynamics in the doctor-patient relationship

[a]mHealth: mobile health.

Selection of Sources of Evidence

The screening process was performed by 2 researchers. It involved reviewing the abstracts initially found for inclusion, and in cases where abstracts lacked sufficient information, the entire research paper was examined. In instances where 2 researchers could not reach a consensus on whether to include a research paper, a third researcher was consulted as an arbiter to resolve any disagreements. This process led to the inclusion of 73 research papers. Subsequently, all 73 included papers underwent a detailed and thorough examination by 2 researchers. In the event of any disagreement during this phase, a third

researcher was consulted to ensure accuracy. Studies that did not specifically mention the physician-patient relationship (n=63) were excluded, resulting in 10 studies to be reviewed.

Data Charting Process

A standardized data charting form was created for the data extraction process, and data charting was performed by 2 reviewers.

Data Items

Our objective was to collect a range of data items relevant to the research. These included the year of the study, the country

where it was conducted, the study type (qualitative or quantitative), the theoretical or ethical framework and concepts used, the type of technology studied, the research objectives, and the participants involved (patients, physicians, and other health care personnel [HCP]; Table 2). Additionally, we extracted text samples that described the impact of digital health technologies on the physician-patient relationship. Our approach involved presenting the main findings in a textual manner.

Table 2. Overview of the data from the included studies.

Authors	Year	Journal	Country	Study type	Type of technology	Aims	Participants
Audrain-Pontevia and Menvielle [15]	2018	*Health Services Management Research*	Canada	Quantitative	Online health community	Examine how online health communities impact the physician-patient relationship	Patients
Balato et al [16]	2013	*British Journal of Dermatology*	Italy	Quantitative	Mobile phone messages	Evaluate the use of telemedicine in improving treatment adherence, patient outcomes, and the physician-patient relationship	Patients and physicians
Grünloh et al [17]	2018	*Journal of Medical Internet Research*	Sweden	Qualitative	Web-based patient portal	Investigate how physicians view the idea of patient participation	Physicians
Győrffy et al [18]	2020	*PLOS ONE*	Hungary	Qualitative	Social media	Explore physicians' knowledge and attitudes toward digital health technologies and the transformation of the doctor-patient relationship	Physicians
Jiang [19]	2019	*Health Communication*	China	Quantitative	Digital messaging	Examine how the quality of face-to-face communication with providers is associated with their subsequent internet use for patient-provider communication	Patients
Kludacz-Alessandri et al [20]	2021	*PLOS ONE*	Poland	Qualitative	Teleconsultation (phone)	Study patients' satisfaction with teleconsultation in primary care and the impact of teleconsultations on GP[a]-patient communication	Patients and physicians
Macdonald et al [21]	2018	*Journal of Medical Internet Research*	Canada	Qualitative	Digital messaging and EHR[b]	Examine HCP's[c] perspectives on how eHealth affects their relationships with patients, as well as its ethical ramifications	Patients, physicians, and other HCPs
Tasneem et al [22]	2019	*American Journal of Hospice and Palliative Medicine*	United States	Qualitative	Video consultation	Investigate the need for web-based videoconferences for oncology patients	Patients and physicians
Townsend et al [23]	2015	*Journal of Medical Internet Research*	Canada	Qualitative	Health-related websites	Focus on patients' and HCP's use of health-related internet information and how it influences the patient-HCP relationship	Patients, physicians, and other HCPs
Yan et al [24]	2020	*International Journal of Environmental Research and Public Health*	China	Qualitative	Digital messaging	Understand the underlying reasons for poor doctor-patient relationships	Patients and physicians

[a]GP: general practitioner.

[b]EHR: electronic health record.

[c]HCP: health care personnel.

Synthesis of Results

To synthesize the results, we first created a summary based on the extracted data items to capture the key findings and statements from the included research papers concerning the physician-patient relationship. This summary was then compared with each research paper in its entirety to ensure accuracy.

Next, we conducted a narrative synthesis of the findings from the included studies, incorporating both the extracted text samples and the summaries of the papers. This approach allowed us to provide a comprehensive overview of the results from both quantitative and qualitative studies, enabling a comprehensive summary of the physician-patient relationship in the context of digital health technologies (Table 3). In addition, we assessed whether the papers applied any ethical frameworks or simple concepts and analyzed how their use contributed to the research (Table 4).

Table 3. Summary of evidence.

Authors	Summary: What does the paper state about the physician-patient relationship?
Audrain-Pontevia and Menvielle [15]	• The paper discusses the impact of online health communities on the patient-physician relationship. The authors explore how online health communities, which provide users with computer-mediated social support and empowerment, impact this relationship. • The authors acknowledge that, traditionally, doctors were the main source of medical information and therefore benefited from authority and power over their patients. However, with the advent of online health communities, patients now have access to social support, resources, and aid, which can make them feel more empowered and influence their relationships with their physicians. • The authors propose that online health communities offer patients the opportunity to gain the power to handle their illnesses and their health, presumably leading to increased participation during the consultation and improving their commitment to their relationship with their physician.
Balato et al [16]	• The study found that patient-physician communication improved in a group receiving SMS text message interventions, whereas it remained unchanged in the control group. This suggests that the use of digital interventions, such as SMS text messages, could potentially enhance the patient-physician relationship.
Grünloh et al [17]	• The models of the doctor-patient relationship presented in the paper describe patients as being static and unchanged, but the authors note that patients with chronic conditions often encounter new situations and need to engage in a sensemaking and learning process. • The paper suggests that the use of patient-accessible EHRs[a] can contribute to the development of the doctor-patient relationship by allowing patients to play an active role. This increased patient participation makes it more difficult for physicians to maintain a strategy that potentially excludes patients. • The authors state that eHealth does not have to be a "power struggle" in the doctor-patient relationship but can potentially help both partners improve their relationship collectively and grow individually. • The authors mention the importance of patient participation for patient safety.
Győrffy et al [18]	• The role of the doctor is in transition, with doctors expected to perform more complex tasks including health information technology and aiding in the digital orientation of patients. They see themselves transforming into mediators based on efficient communication with their patients. • Digitally engaged physicians consider themselves guides, undertaking a guardian and information managing function in the description, collection, and sharing of credible content in the online space. • For a successful leap from hierarchical patterns to the 21st-century doctor-patient relationship, the future generation of physicians should be trained differently and prepared for all the above-described changes. • Medical school curricula should emphasize health and prevention rather than only diseases and pathology via the newest digital technological solutions. • Medical students need to prepare for predictive and proactive working environments, including their new role as a guide or mediator for digitally empowered patients, in contrast with the paternalistic physicians of previous generations.
Jiang [19]	• The results of the study emphasize the important roles of patient-centered communication and the physician-patient relationship in the eHealth and mHealth[b] movement, particularly in the Chinese health care system. • The interplay of physician-patient communication in face-to-face environments and relationship factors (eg, patient trust and patient satisfaction) could exert significant effects in promoting eHealth adoption. • To encourage patients to adopt eHealth technologies, health care providers should first build a patient-centered environment (eg, responding to patients' informational and emotional needs and engaging patients in medical decision-making).
Kludacz-Alessandri et al [20]	• The study concerns patients' satisfaction with teleconsultation in primary care and the impact of teleconsultations on GP[c]-patient communication during the COVID-19 pandemic in Poland. The paper suggests that the quality of GP-patient communication is an essential factor that can improve the results of treatment and patient satisfaction. Only 55% (n=99) of the patients found teleconsultation to be as good as in-person visits with their physician.
Macdonald et al [21]	• The study discusses the concept of a "two-way conversation" that is evolving in the health care provider-patient dynamic. This shift toward more collaborative interactions with patients is, in part, facilitated by eHealth technologies. The authors examine the impact of eHealth on the current state of collaborative consultation, highlighting how it aids in having, using, and supporting conversations with patients. • Some health care professionals in the study embraced the idea of patients as "partners," as they see a partner as someone who helps in improving an outcome by educating themselves and conscientiously monitoring their condition and behavior. • One of the health care professionals stated that patients who are engaged through eHealth and informed about their condition are more useful clinically. • The paper also mentions a pedagogical approach to interacting with the eHealth users among patients.

Authors	Summary: What does the paper state about the physician-patient relationship?
Tasneem et al [22]	• The study assessed the needs of patients receiving palliative care and their perception of how telemedicine video visits might influence their care. Despite concerns about truncated physical examinations and prescription limits, the majority of patients favored having the opportunity for telemedicine video visits. They felt that the physician-patient relationship would not diminish and had few cost concerns. They believed that a video alternative to an in-person visit might increase access, save time, and increase comfort and safety by avoiding a trip to the hospital.
Townsend et al [23]	• In this study, patients reported using personal websites, blogs, chat rooms, and online links to medical test results as part of their eHealth resources. This suggests that patients are actively engaging with digital resources in managing their health, which can have implications for the physician-patient relationship. The paper discusses how the rapid explosion in online digital health resources is seen as transformational, accelerating the shift from traditionally passive patients to patients as partners. This is altering the current patient-health care professional relationship. • The proliferation of eHealth strategies is accelerating a shift in health care from a traditional and paternalistic delivery model to a more mutual patient-health care professional relationship in which informed patients are actively involved in their care and treatment decisions. • The authors mention that eHealth resources provide patients with extensive and up-to-date information, access to medical research, connections to people with similar conditions, immediacy, and convenience in patient-health care professional communications. These factors can significantly impact the physician-patient relationship.
Yan et al [24]	• The paper investigates the underlying reasons for poor doctor-patient relationships in mobile consultation from the perspective of computer-mediated communication. This suggests that the physician-patient relationship may be influenced by the mode of communication, particularly in a digital context. • The paper emphasizes the emerging use of mobile medical consultation in China, which has propelled the establishment of doctor-patient relationships in the mobile context. This again underscores the impact of digital technologies on the physician-patient relationship. • The authors also mention different models or concepts used to assess the doctor-patient relationship, suggesting that the nature of this relationship can be complex and multifaceted.

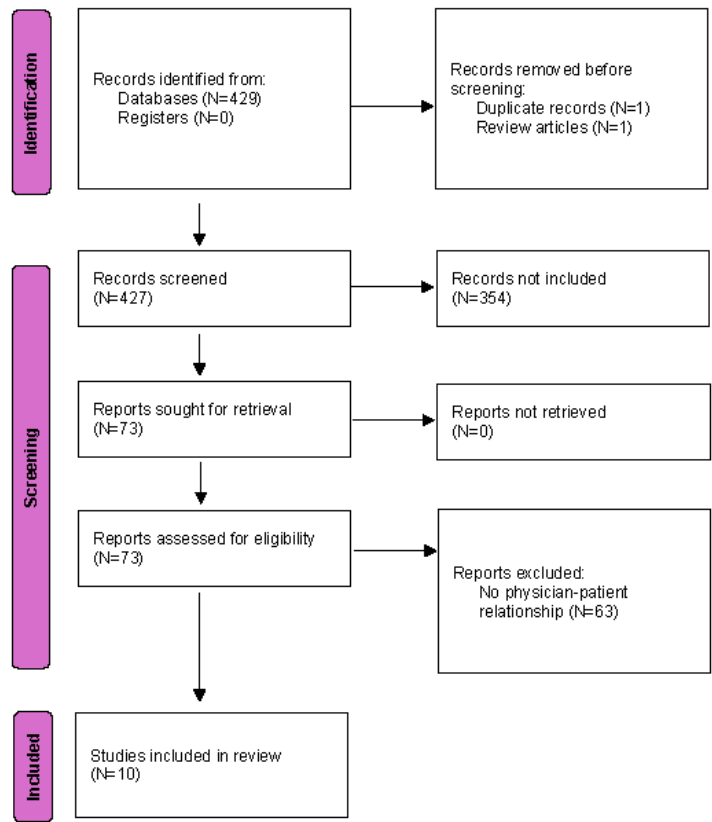
Results

Selection of Sources of Evidence

Out of the 427 studies screened, 73 studies were sought out for retrieval, and after excluding 63 studies that did not focus on the physician-patient relationship, 10 studies were included in this review. Figure 1 illustrates the search process.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) diagram: papers included in the review.


Characteristics of Sources of Evidence

The research papers included in this study [15-24] were conducted in various countries, with 3 in Canada, 2 in China, 1 in Italy, 1 in Sweden, 1 in Hungary, 1 in Poland, and 1 in the United States. These papers were published between 2013 and 2021, with half of them published in 2019 or more recently. The majority of the papers (n=7) were qualitative studies, with the remaining (n=3) papers being quantitative studies. Only 2 research papers, authored by Macdonald et al [21] and Townsend et al [23], referred to a specific ethical framework. Both used relational ethics. A total of 6 other papers adopted different theoretical frameworks and concepts, while the remaining 2 did not use any theoretical frameworks at all.

Regarding the technologies investigated, 3 papers focused on online communities, 3 papers focused on messaging, 2 papers focused on telephone or video consultation, and 2 papers focused on patient portals or EHR. The majority of the papers (n=6) included a mix of patients and physicians or other health care professionals, while 2 papers focused solely on patients and 2 others exclusively on physicians.

For further details about the characteristics of the included research papers, please refer to Table 2.

The Impact of Digital Health Technologies on the Physician-Patient Relationship

Kludacz-Alessandri et al [20] noted that, while teleconsultations offer convenience and safety, especially in situations like the COVID-19 pandemic, they may not always provide the same level of patient satisfaction as in-person visits. According to the authors, this could be due to several reasons such as the inability to read nonverbal cues, technical difficulties, or the impersonal nature of digital communication. The authors suggested that, while digital technologies offer new avenues for communication, they may not fully mirror the richness and depth of face-to-face interactions.

Yan et al [24] discussed the use of mobile medical consultation in China and noted the potential challenges in establishing effective physician-patient relationships in a digital context. According to the authors, 1 key challenge could be the varying degrees of technology literacy among patients. Not all patients may be comfortable using digital platforms for health care, and some may lack access to the necessary technology. This study indicates that this could lead to inequities in access to health care services and affect the quality of the physician-patient relationship.

When patients become more empowered through access to digital health resources and online communities, changes could occur in the power dynamics of the physician-patient

relationship. Some physicians may struggle to adapt to these changes, particularly if they are trained in a more traditional, paternalistic model of health care. This was suggested in the study by Audrain-Pontevia and Menvielle [15].

The advent of online health communities and access to a wealth of health-related information on the internet has empowered patients to take an active role in managing their health. As discussed by Audrain-Pontevia and Menvielle [15], this empowerment can lead to increased participation during consultations and improve commitment to the relationship with the physician.

Digital technologies, such as SMS text messaging, teleconsultations, and mHealth apps, can enhance communication between patients and physicians, making it more frequent, timely, and convenient. As pointed out by Balato et al [16], such digital interventions can potentially enhance the patient-physician relationship.

The use of eHealth and mHealth technologies facilitates a more patient-centered approach to care. As Jiang [19] noted, health care providers who build a patient-centered environment—responding to patients' informational and emotional needs and engaging them in medical decision-making—can promote eHealth adoption and improve health care outcomes.

Digital health technologies can improve the efficiency of health care delivery and make health services more accessible. For example, Tasneem et al [22] found that patients receiving palliative care favored the opportunity for video consultations, as they could save time while increasing access, comfort, and safety by avoiding a trip to the hospital.

eHealth resources provide patients with extensive and up-to-date information, access to medical research, and connections to people with similar conditions. Townsend et al [23] mentioned that these factors can significantly impact the physician-patient relationship, transforming patients from passive recipients of care into active partners in their health care journey.

The availability of health information online and through digital technologies enables patients to be more informed about their health conditions and treatment options. This can lead to better-shared decision-making between patients and physicians [17,18,21].

The Application of Theoretical Frameworks and Concepts

In the study by Grünloh et al [17], the use of 2 theoretical frameworks (shared decision-making and patient-centered care) and 1 concept of the physician-patient relationship (paternalism) helped highlight the roles of the medical professional and the patient, as well as the ways in which patients can contribute to the relationship.

The concept of patient empowerment (used in the study by Audrain-Pontevia and Menvielle [15]) helped with understanding how online health communities influence the patient-physician relationship, but it did not capture the complexities of the power dynamics and relational aspects inherent in these interactions.

Győrffy et al [18] focused on the attitudes of digitally engaged physicians toward transforming the physician-patient relationship. The researchers used the theoretical frameworks of patient empowerment and physician-patient collaboration to assess current and ideal physician-patient relationships. Through this, they recognized that the digital age requires physicians to transition from a role of authority to one of guidance.

Jiang [19] examined the relationship between face-to-face and online patient-provider communication through the concepts of patient-centered care, trust, and satisfaction.

Kludacz-Alessandri et al [20] investigated patients' satisfaction with teleconsultations by considering the concepts of respect and dialogue. These concepts are indeed valuable in understanding the impacts of teleconsultations on the physician-patient relationship.

The 3 studies that did not apply any theoretical frameworks had either superficial findings regarding the physician-patient relationship or it was not clear how they reached their conclusions. For example, Balato et al [16] simply quantified the physician-patient relationship through a 10-point scale questionnaire. Tasneem et al [22] asked patients only about how the technology would affect their relationship with their physician in 2 out of 15 questions. Finally, Yan et al [24] seemed to apply the concepts of mutual respect and patient satisfaction in a deep and meaningful way, but we have no way of knowing since they do not specifically state what concepts they used.

The Application of Relational Ethics

In contrast with the above-applied frameworks, the use of a relational ethics framework can help reveal the subtle and complex impacts of digital health technologies on the physician-patient relationship. For example, in the study by Macdonald et al [21], a relational ethics lens was used to examine how eHealth technology contributes to changes in relations between HCPs and patients, evolving toward more collaborative care. By focusing on every day relationships and conversations, the study was able to understand how these technologies incorporated the relational ethics of patient-centered care into practice.

Relational ethics can help address the power dynamics and vulnerabilities that come into play in the physician-patient relationship, especially with the use of digital technologies. In the study by Townsend et al [23], relational ethics was used to understand how technology impacts relational shifts in ethical patient-HCP relationships. They found that technology use could lead to a transition from a traditional hierarchical relationship to a more reciprocal relationship, which could reveal mutual vulnerabilities.

Discussion

Principal Results

The studies included in this review were diverse, with research conducted across various countries and contexts and exploring a range of technologies, such as online communities, messaging, teleconsultations, and patient portals or EHRs. In terms of user groups, they examined the experiences of patients, physicians,

and other HCPs, offering a comprehensive view of the phenomenon from different user perspectives.

Through the review, we identified several consequences of using digital health technologies in health care. The convenience and accessibility offered by these technologies have the potential to transform the health care landscape by enhancing communication, improving efficiency, and empowering patients. However, they also provide challenges and complexities such as increasing inequities in access to health care services due to variations in technology literacy among patients and decreases in patient satisfaction due to limitations in nonverbal communication and the impersonal nature of digital interactions.

The review further highlighted the shift in power dynamics in the physician-patient relationship from a traditional hierarchical model toward a more reciprocal and collaborative model. This shift is facilitated by the empowering potential of digital health technologies and online health communities but may also present challenges for physicians trained in a more paternalistic model of approach to medicine.

In addition to mapping key findings, we analyzed the theoretical frameworks used in the studies to contrast the use of relational ethics with the application of other theoretical frameworks. Of the 10 studies in this review, 2 did not apply any theoretical frameworks to their research. Others used frameworks or concepts such as patient-centered care, patient empowerment, or shared decision-making. Only 2 studies used relational ethics as their framework.

Relational ethics, by its very nature, emphasizes the value of intersubjective qualities such as empathy, trust, respect, and mutual responsibility. These qualities are critical to the practice of effective and compassionate health care, and their importance is highlighted in the context of digital health technologies interjected between the physician and the patient. While theoretical frameworks and concepts, such as patient-centered care and patient empowerment, provided valuable insights into the impacts of digital health technologies, a relational ethics perspective could provide a more comprehensive understanding. For instance, it could explore how trust is built and maintained in online versus face-to-face interactions, how the power dynamics between physicians and patients might shift in an online context, and how empathy and understanding are conveyed through digital mediums. A relational ethics framework could further enrich this understanding by examining how respect and dialogue contribute to a sense of mutual trust and understanding, how they shape the power dynamics in a teleconsultation, and how they can foster a sense of connection and empathy in a digital environment.

Comparison to Prior Work

This review underscores the potential value of using a relational ethics framework in research on the physician-patient relationship in the complex real-life context of digital health technologies. While previous works have acknowledged the importance of relational aspects in health care delivery [3,5], few have explicitly used relational ethics as a framework to examine the nuanced ethical implications of digital health technologies on the physician-patient relationship.

Limitations and Strengths of This Study

Because this review amassed studies from a variety of countries, we acknowledge that the specific cultural, societal, and health care contexts of these regions can have a significant effect on the physician-patient relationship and the use and adoption of digital health technologies. As such, our findings might not be applicable everywhere.

The review only included studies published in English, which could introduce language bias. If there were relevant studies published in other languages, they would have been left out, potentially narrowing the range of perspectives and findings we were able to consider.

While our review touched on a selection of digital health technologies—including online communities, messaging services, teleconsultations, and patient portals or EHRs—many more kinds of technology are being used in health care. As such, our findings are limited to the specific digital health technologies covered in this review.

Scoping reviews, like this one, are primarily intended to provide a broad overview of the existing literature rather than evaluate the strength of evidence or perform a meta-analysis. This means that it is difficult to draw definitive conclusions or provide firm recommendations based on our findings.

While our review encapsulates literature up to the end of 2021, reflecting the state of research at the time of our initial submission, it may not include the latest developments or studies published post-2021.

The quality of the studies included in a review can have a large effect on its findings. Since we did not conduct a critical appraisal of the quality of the studies we included, this could be seen as a limitation.

Conclusions

Overall, this review offers a comprehensive overview of the current state of evidence regarding the impacts of digital health technologies on the physician-patient relationship. It underscores the potential of these technologies to transform health care delivery, while also highlighting the challenges and complexities they introduce. The review emphasizes the need for further research using a relevant ethics framework to provide a deeper understanding of the impact of digital health technologies on the physician-patient relationship. This will be particularly crucial as digital health technologies continue to expand, evolve, and become more integrated into health care delivery.

Acknowledgments

Authors' Contributions

DN was the principal author and was involved in all aspects of the scoping review. BHG was a coauthor and screened the abstracts along with DN. ER also coauthored this paper, as well as assessed the research papers for eligibility and reviewed the included research papers along with DN.

Abstract

Background: Digital health literacy has emerged as a critical skill set to navigate the digital age.

Objective: This review sought to broadly summarize the literature on associations between digital health literacy and (1) sociodemographic characteristics, (2) health resource use, and (3) health outcomes in the general population, patient groups, or parent or caregiver groups.

Methods: A rapid review of literature published between January 2016 and May 2022 was conducted through a search of 4 web-based databases. Articles were included on the basis of the following keywords: "measured digital health literacy," "digital literacy," "ehealth literacy," "e-health literacy," "electronic health literacy," or "internet health literacy" in adult populations; participants were from countries where English was the primary language; studies had to be cross-sectional, longitudinal, prospective, or retrospective, and published in English.

Results: Thirty-six articles met the inclusion criteria. Evidence on the associations between digital health literacy and sociodemographic characteristics varied (27/36, 75% included studies), with higher education (16/21, 76.2% studies that examined the association) and younger age (12/21, 57.1% studies) tending to predict higher digital health literacy; however, other studies found no associations. No differences between genders were found across the majority of studies. Evidence across ethnic groups was too limited to draw conclusions; some studies showed that those from racial and ethnic minority groups had higher digital health literacy than White individuals, while other studies showed no associations. Higher digital health literacy was associated with digital health resource use in the majority of studies (20/36, 55.6%) that examined this relationship. In addition, higher digital health literacy was also associated with health outcomes across 3 areas (psychosocial outcomes; chronic disease and health management behaviors; and physical outcomes) across 17 included studies (17/36, 47.2%) that explored these relationships.

However, not all studies on the relationship among digital health literacy and health resource use and health outcomes were in the expected direction.

Conclusions: The review presents mixed results regarding the relationship between digital health literacy and sociodemographic characteristics, although studies broadly found that increased digital health literacy was positively associated with improved health outcomes and behaviors. Further investigations of digital health literacy on chronic disease outcomes are needed, particularly across diverse groups. Empowering individuals with the skills to critically access and appraise reliable health information on digital platforms and devices is critical, given emerging evidence that suggests that those with low digital health literacy seek health information from unreliable sources. Identifying cost-effective strategies to rapidly assess and enhance digital health literacy capacities across community settings thus warrants continued investigation.

Introduction

As health technologies evolve, digital devices, health-related apps, and web-based portals are increasingly used to deliver and access medical information and health care services [1]. While such technologies can be a gateway to health information and support [2], research also predicts a "digital divide" in which an individual's sociodemographic characteristics (eg, age, education, and income) influence their effective engagement with digital health information [3]. Digital health literacy has emerged as a vital skill set to navigate health care in the digital age [4]. Digital health literacy has been described as an extension of eHealth literacy, which captures the skills to seek, find, understand, and critically appraise health information from electronic sources to manage one's own health [5,6]. Digital health literacy has been posited to expand on the definition by emphasizing the individual as both an active participant and a distributer of digital health information, not just a passive receiver [6]. Digital health literacy has skills unique to health literacy, including computer literacy, media literacy, and critical appraisal skills to identify and evaluate reliable information and resources [1]. The importance of digital health literacy is increasingly recognized for its role in optimal individual and population health [4] and critical to limiting health inequalities [7].

Reviews have reported associations between digital health literacy and health outcomes across specific populations. Among people with long-term conditions, higher digital health literacy was predominantly associated with greater health-promoting behaviors [8]. A recent review identified that both older adults with cancer and their carers reported low digital health literacy and decreased confidence in appraising digital health information, with barriers identified including low socioeconomic status, poor digital access, and lack of familiarity and use [9]. Several reviews have examined the impact of digital health literacy on health outcomes in specific populations of interest (eg, older adults [9], those with long-term conditions [8], college students [10], and underserved [11] or vulnerable populations [12]). However, existing evidence on the relationships between digital health literacy, health outcomes, and sociodemographic characteristics across broad population groups has not been synthesized to date. Current literature on digital health literacy has focused on definitions and scales; its

associations with health outcomes; the digital divide; and influencing factors of health literacy [13]. A review of associations between (1) sociodemographic characteristics, (2) health resource use, and (3) health outcomes in the general population, patient groups, or parent or caregiver groups is currently lacking. This information is critical to inform the development and implementation of digital health strategies to improve digital health literacy in communities with the highest need. This review sought to broadly summarize the literature on associations between digital health literacy and (1) sociodemographic characteristics, (2) health resource use, and (3) health outcomes.

Methods

A rapid review was undertaken following the principles of a systematic review [14]; however, with some simplification of steps to ensure a timely and accurate synthesis of evidence to inform the development of a digital health strategy for implementation across community settings. Given the rapid nature of the review, the review and protocol were not registered with an international register.

A search for peer-reviewed publications was undertaken within the CINAHL, PsycINFO, MEDLINE, and Embase databases in May 2022. English language articles published between January 2016 and May 2022 were included. Given then rapid changes in technology and digital engagement observed in the health field, we sought to comprehensively review contemporary evidence from the preceding 5 years only. Additional searches were conducted in June 2022 using Google Scholar and by handsearching the reference lists of included papers to ensure that all relevant literature were captured in the review. Search terms synonyms were "digital health literacy," "e-health literacy," "electronic health literacy," "internet literacy," "internet health literacy," and "digital literacy." Key search terms are detailed in Multimedia Appendix 1. For the purposes of the review, studies that examined electronic health literacy or eHealth literacy were included given similarities in definitions of these concepts [13]. The inclusion and exclusion criteria are summarized in Table 1. In brief, studies that examined digital health literacy using a validated measure of digital health literacy in the general population, patient groups, or parent or caregiver groups were eligible for inclusion. Articles were excluded if

they focused exclusively on college students, since a review of this group has already been conducted [10].

Table 1. Inclusion and exclusion criteria.

Inclusion	Exclusion
Assesses digital health literacy in the general population, patients, parents, or caregivers	Study population younger than 18 years
Sample included individuals from Australia, New Zealand, the United States, Canada, the United Kingdom, or Ireland	Primary language of country is not English
Quantitative study	Qualitative study, literature or systematic review, commentary, conference abstract, opinion piece, protocol, or thesis
Published in 2016 onwards	Non–health care–related (eg, high school education)
—[a]	Not focused on patients or general population (eg, digital health literacy of health providers)
—	Focusses on digital health literacy of interventions, programs, etc
—	Assesses psychometric properties of a digital health literacy measure
—	Measures digital health literacy using a single item or proxy measure

[a]Not applicable.

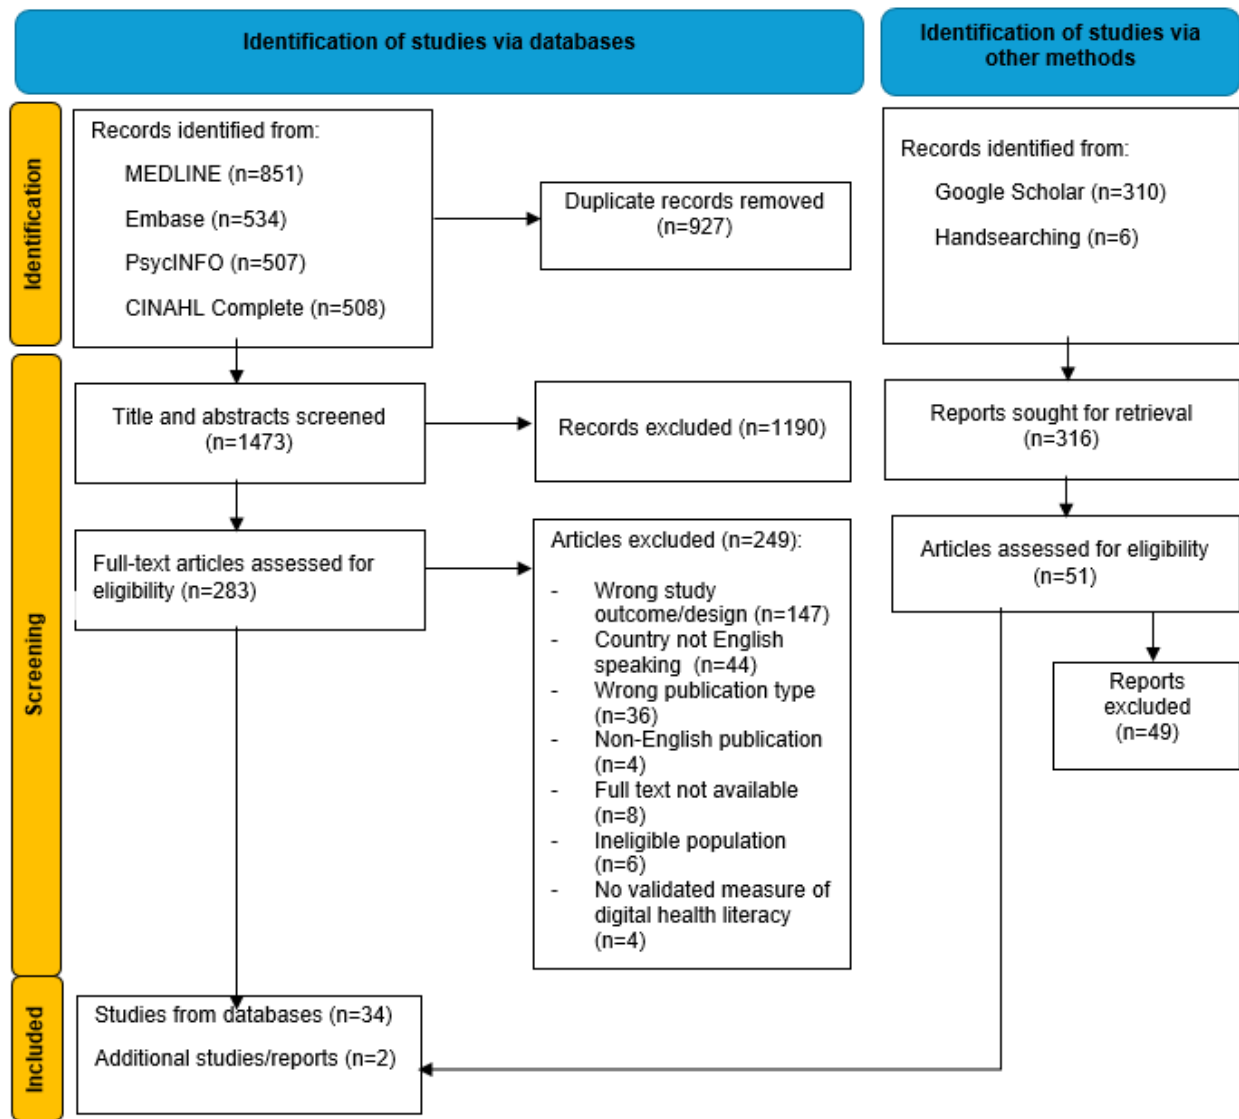
The search results were imported into a review management dashboard, Covidence, to allow for simultaneous screening between reviewers. Four reviewers (EY, NW, FS, and FT) independently screened titles and abstracts, and the full texts were screened by 5 reviewers (EY, NW, FS, FT, and SR). At both screening stages, each paper was assessed by 2 reviewers, with discrepancies resolved through discussion. The screening process was reported following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [15].

For studies included in the review, data were extracted on (1) study characteristics (eg, author, publication year, country, study design, sample size, participant characteristics, measures used to assess digital health literacy, and health literacy scores); (2) health outcomes associated with digital health literacy; and (3) sociodemographic characteristics associated with digital health literacy. Given the rapid nature of the review to inform strategy, data extraction for each article was conducted by 1 author only (EY, NW, or FS), with data extracted presented to the research team for review. Results were narratively synthesized to address the 3 aims and to group findings into identified themes.

Results

Description of Included Studies

Of the 1473 articles, 36 met the inclusion criteria (Figure 1). Studies are summarized in Multimedia Appendix 2. Twenty-five studies were from the United States, 4 studies from Australia [16-19], 4 from Canada [20-23], 1 from the United Kingdom [24], and 1 cross-cultural study that included people from Australia and India [25]. Studies included 34 cross-sectional survey designs, 1 mixed methods study [26], and 1 randomized controlled trial [27]. Sample sizes ranged from 22 [28] to 3258 [29] participants. The majority of studies (32/36, 88.9%) assessed digital health literacy using the eHealth Literacy Scale [30]. Across studies, variations on how digital health literacy scores were reported; some used a mean score (with higher scores indicating higher digital health literacy) and other studies used cutoff scores to determine those in high compared with low digital health literacy categories.

Figure 1. PRISMA Flowchart.


Five distinct population groups were identified across the studies. These included the general population, including older adults, patient groups, minority populations, and caregivers. Patient groups included people with HIV, cancer, chronic obstructive pulmonary disease (COPD), spinal injury, kidney disease, bipolar disorder, otolaryngological disease, orthopedic trauma, cardiovascular risk, diabetes, and transplant recipients. Minority groups included African Americans, Southeast Asians, adults in rural or remote regions, low-income groups, transgender and gender diverse, and young men who have sex with men. Caregivers included those of children with special health care needs, men with prostate cancer, and pediatric inpatients with subacute health conditions.

Associations Between Digital Health Literacy and Sociodemographic Characteristics

Twenty-seven (75%) studies were identified as examining associations between digital health literacy and sociodemographic characteristics, with varied findings. These are shown in Table 2 and Figure 2 and discussed in the following sections.

Table 2. Digital health literacy and associations with sociodemographic characteristics (N=27).

Sociodemographic characteristics and association with digital health literacy	Articles in which the finding occurred, n					
	Patient group	General population	Minority group	Older adults	Caregivers	Total
Age (years)						
Negative	5	3	1	1	2	12

[b]Women had higher digital health literacy.

Figure 2. Digital health literacy and associations with sociodemographic characteristics. Positive association: higher digital health literacy associated with higher outcome of characteristics (eg, higher digital health literacy associated with higher income); negative association: higher digital health literacy associated with lower characteristics (eg, higher digital health literacy associated with younger age).
Age

Twenty-one studies (21/36, 58.3%) explored associations between age and levels of digital health literacy with mixed results. Twelve studies (12/21, 57.1%) reported a negative association between age and digital health literacy, with older people more likely to have lower digital health literacy than their younger counterparts [16,19-21,24-26,31-35]. Negative associations between age and digital health literacy were found in the general population (3/21, 14.3%) [16,25,32], as well as the following specific population studies: Southeast Asian adults in Canada [21]; older adults [19,20]; people with chronic kidney disease [26], breast cancer [24], or cardiovascular risk [19]; and caregivers [34,35]. One study that used the eHealth Literacy Questionnaire [16] found that age was negatively associated with 4 of 7 digital health literacy subscales (ability to engage with digital services; using technology to process health information; motivated to engage with digital health services; and digital services that suit individual needs).

In contrast, studies (1/21, 4.8%) found a positive significant association between age and digital health literacy in people with bipolar disorder, where older age significantly predicted higher digital health literacy scores [36]. Notably, the mean age in this sample was less than that in other studies, and more than three-quarters had completed some form of higher education. Furthermore, studies (8/21, 38.1%) reported no associations between age and digital health literacy across patient [17,23,37-39], rural [22], and older [40,41] populations.

Gender

Digital health literacy and gender were reported in studies (16/36, 44.4%), with most (13/16, 81.3%) finding no gender differences [16,19,20,23,26,31-33,36,39-42]. The 3 studies that

found that women were more likely to perceive themselves as having higher digital health literacy than men were from the general population in the United States [43], adults from rural communities in British Columbia with a population of 12,000 [22], and among otolaryngology patients [37].

Education

Twenty-one (21/36, 58.3%) studies examined associations between digital health literacy and education levels, with two-thirds (16/21, 76.2%) finding higher digital health literacy positively associated with higher education levels [16,18-21,24,31-36,39,41,44,45]. Five studies (5/16, 31.3%) reported no associations between digital health literacy and education, including 4 studies of patient groups [21,28,29], 1 general population study [25], and 1 study of older adults [32]. Across these studies, large proportions of participants had greater than high school education levels (35%-84.8%).

Income

Six studies (6/36, 28.6%) examined associations between digital health literacy and income, with half reporting no associations in people living with chronic illness [19,23] or those in a general population [41]. By contrast, the 3 studies that found significant positive associations between higher digital health literacy and income reported these findings in people with chronic illness [26], among caregivers [35], and in minority populations [32].

Ethnicity

Six studies (6/36, 16.7%) examined associations between digital health literacy and ethnicity, with 2 reporting differences between ethnicity groups [25,32]. Black or African Americans had higher digital health literacy than their Caucasian counterparts in a stratified US sample [32]. Australians had higher digital health literacy than Indians in a cross-cultural

study [25]. Conversely, 4 studies found no differences in digital health literacy levels across ethnicity groups among those with chronic illness [26], spinal cord injury [38], cancer survivors [24], or caregivers of people with prostate cancer [35].

Employment

Of the 3 studies (3/36, 8.3%) that examined associations between digital health literacy and employment, 1 patient group study (spinal cord injury [23]) and 1 general population study [43] found higher digital health literacy among those who were employed versus those who were unemployed. By contrast, another study found no differences in employment groups and digital health literacy in an older US sample [40].

Chronic Disease or Comorbidities

One study (1/36, 2.7%) reported small but significant findings for higher digital health literacy in people with no chronic conditions, compared with those with a chronic condition, in a sample of South Asians in Canada [21].

General Health Literacy

Only 1 study (1/36, 2.7%) examined associations between digital health literacy and general health literacy, finding no associations in an older adult sample [40].

Marital Status, Language Spoken, Socioeconomic Status, Household Size, Rural or Urban Location, or Country of Birth

No associations between digital health literacy and the following sociodemographic characteristics were found: marital status [17,25,38,41,46,47], language spoken [16,20], socioeconomic status or deprivation [24,40], household size [40], or rural or urban location [24].

Associations Between Digital Health Literacy and Health Resource Navigation

Twenty studies (20/36, 55.6%) examined associations between digital health literacy and health resource navigation distributed across all participant categories. Categories of health information engagement included eHealth information seeking; eHealth behaviors; access to and use of e-resources; use of health information sources; and eHealth satisfaction, and are shown in Table 3, Figure 3, and in the following sections.

Table 3. Digital health literacy and digital health resource navigation (N=17).

Health outcomes	Association with digital health literacy	Articles in which association occurred, n					
		Patient group	General population	Minority group	Older adults	Caregivers	Total
eHealth information seeking	Positive	1	2	2	2	—[a]	7
eHealth information seeking	None	—	—	2	—	—	2
eHeath resource engagement	Positive	2	1	2	1	1	7
Access to and use of technology	Positive	1	1	2	1	2	7
Use of a variety of health information sources	Positive	—	—	1	1	—	2
Confidence or comfort with using digital resources	Positive	—	—	—	1	—	1
Confidence or comfort with using digital resources	None	—	1	—	—	—	1
eHealth satisfaction and trust	Positive	—	1	1	—	1	3

[a]Not applicable.

Figure 3. Digital health literacy and associations with health resource navigation.
Digital Health Information Seeking

Nine studies (9/36, 25%) examined digital health literacy and digital health information seeking, and of these, 7 showed that higher digital health literacy was significantly positively associated with e-information seeking. These included studies of general populations [47,48], middle-aged to older adults [41,49], minority populations [18,21], and of people with HIV [50]. In addition, higher digital health literacy was associated with greater exposure to medical and health websites in a US general population [48] and among Southeast Asians in Canada [21]. Digital health literacy was also associated with eHealth information consumerism in older adults [41].

By contrast, 2 studies (2/36, 5.6%) found no associations between digital health literacy and eHealth information–seeking behaviors. In a sample of older Hispanic people in the United States, digital health literacy was not associated with use of, nor willingness to use the internet for health information [51]. A study of transgender and gender diverse people found no interactions between digital health literacy and web-based health-seeking behaviors [29].

eHealth Resource Engagement

Ten studies (10/36, 27.8%) examined associations between digital health literacy and eHealth resource engagement with 7 studies reporting positive associations [18,21,31,33,34,36,47]. Higher digital health literacy was associated with signing up for email updates, watching health-related videos, seeking resources from people with similar lived experience, and using health indicator tracking in a general population [47] and among caregivers [34]. Digital health literacy was also associated with willingness to participate in mobile health research interventions, wearing a smart watch or tracking device, and downloading a health app among minority race or ethnicity groups [18,21].

Higher digital health literacy was associated with increased eHealth resource use in older adults [33] and people living with chronic illness [36] and greater use of patient portals in people with chronic disease [47], older adults [33], and transplant recipients [31]. However, no differences were found among varying digital health literacy levels and willingness to participate in research that used web-based forums, support groups, or counseling in an African American sample [18].

Access to and Use of Technology

Seven studies (7/36, 19.4%) examined digital health literacy and associations with access to and use of technology with mostly positive associations reported. Access to the internet for personal use was associated with higher digital health literacy among caregivers [35]. Greater internet use was also associated with higher digital health literacy in a low-income population in the United States [52], in Southeast Asians in Canada [21], and in caregivers of children with special needs [34]. Access to and use of digital devices and the internet were associated with higher digital health literacy in an Australian population [16]. Access to any mobile device was also associated with higher eHealth literacy among breast cancer survivors [24]. Furthermore, among older adults, those who owned 2 or more electronic devices had higher digital health literacy than those with 1 or no devices, although no differences in internet use were found across digital health literacy levels [40].

Use of a Variety of Health Information Sources

Two studies (2/36, 5.6%) examined digital health literacy and the use of a variety of health information sources. High digital health literacy was associated with the use of more health information sources compared with those with low digital health literacy among older adults [40] and among Black or African Americans [18]. Health information sources included the

internet, health books and magazines, TV programs, literature in medical offices, and discussions with health care providers [40]. This study also probed the relationship between digital health literacy and the sources of information used. People with high digital health literacy were more likely to rely on doctors' knowledge for medical decision making and drew upon more sources of health information than those with low digital health literacy [40]. Similarly, among Black or African Americans, higher digital health literacy was also significantly associated with citing the internet, nurses, books, radio, or news apps as sources of health information [18].

Confidence or Comfort With Using Digital Resources

Two studies (2/36, 5.6%) examined confidence in using digital resources and digital health literacy. Older adults with higher digital health literacy were more likely to experience no stress when using a computer than those with lower digital health literacy [40]. By contrast, among population groups digital health literacy was not associated with comfort in using the internet [25].

eHealth Satisfaction and Trust

Three studies (3/36, 8.3%) examined digital health literacy and associations with eHealth satisfaction and trust with positive outcomes reported. Higher digital health literacy was associated with greater telemedicine satisfaction among rural and remote communities [22]. Increased digital health literacy was also associated with greater positive perceptions of eHealth in caregivers [34].

In addition, higher digital health literacy was associated with greater perceived trust in eHealth information in a sample of Black or African Americans and Caucasians after controlling for socioeconomic status and social media use [32]. Notably, among individuals with low digital health literacy, older adults had higher perceived trust in Facebook and less trust in support groups than their younger counterparts [32]. Furthermore, in those with low digital health literacy, Black or African Americans were more likely to report greater perceived trust in web-based blogs or diaries and twitter than their younger or Caucasian counterparts; by contrast, for those with high digital health literacy, Black or African Americans were more likely than Caucasians to trust support groups [32].

Associations Between Digital Health Literacy and Health Outcomes

Seventeen studies (17/36, 47.2%) examined associations between digital health literacy and health outcomes. The outcomes are grouped into 3 main categories: psychosocial health outcomes, chronic disease and health management behavioral outcomes, and perceived health status. These are shown in Table 4 and Figure 4 and described in the following sections.

Table 4. Digital health literacy and health outcomes.

Category and subcategory of outcomes, and association with digital health literacy	Articles in which the association occurred, n					
	Patient group	General population	Minority group	Older adults	Caregivers	Total

[a]Not applicable.

Figure 4. Digital health literacy and behaviors for managing health and chronic disease.
Psychosocial Health Outcomes

Digital health literacy and its relationship with psychosocial health outcomes included diverse subcategories related to psychological outcomes, interpersonal factors, and satisfaction with health care encounters.

Psychological Outcomes

Four studies (4/36, 11.1%) examined associations between digital health literacy and psychological outcomes. Higher digital health literacy was significantly associated with greater empowerment through information seeking [49] and less affective distress [44] in older adult populations. Higher digital health literacy was also related to increased information seeking, which was associated in lower cancer fatalism (ie, inevitable death following a cancer diagnosis) in a general population from the United States [48]. By contrast, no associations were found between digital health literacy and worry among caregivers of children with special needs [34].

Interpersonal Outcomes

Two studies (2/36, 5.6%) examined relationships between digital health literacy and interpersonal outcomes. One study found that digital health literacy was significantly associated with the size of social networks for seeking information and support for health decision-making in a sample of caregivers of people with prostate cancer [35]. However, digital health literacy was not associated with social functioning, family relationships, or communication skills among caregivers of children with special needs [34].

Satisfaction With Health Care Encounters

Two studies (2/36, 5.6%) examined associations between digital health literacy and health care encounters among older adults. Higher digital health literacy was significantly associated with greater satisfaction [41] and less perceived strain in medical encounters [44] in older populations.

Behaviors for Managing Health or Chronic Disease

Digital health literacy and individuals' management of health or chronic disease were related to (1) disease self-efficacy, disease management, and health risk behaviors; (2) health service engagement; and (3) health status across patient groups.

Disease Management and Self-Efficacy

Four studies (4/36, 11.1%) examined digital health literacy and disease management and self-efficacy. Three studies examined associations between digital health literacy and individual management of chronic disease and health conditions, with mixed results. In caregivers of men with prostate cancer, higher digital health literacy was associated with greater likelihood of getting a second opinion, awareness of treatment options, and size of social network for information and support in treatment decision-making [23]. In a study of young men who have sex with men, low digital health literacy was associated with decreased likelihood of evaluating personal risk for HIV/STIs, educating others about HIV/STIs, and getting tested for HIV/STI after completing an HIV/STI education intervention [27]. By contrast, in a sample of transgender and gender diverse people [29], no relationship between self-reported digital health literacy and adherence to human papillomavirus vaccination was found.

In 1 study of people living with COPD, those with higher digital health literacy reported greater self-efficacy with managing their chronic disease [39]. In another study that examined associations between digital health literacy and associations with health risk behaviors, higher digital health literacy was associated with greater HIV transmission risk behaviors (eg, unprotected sexual activities or illicit drug use) among women infected with HIV [50].

Health Service Engagement

Three studies (3/36, 17.6%) examined associations between digital health literacy and health service engagement with positive findings reported in 2 studies. Higher digital health literacy was associated with greater number of general practitioner visits through increased searches for health information among older adults [49]. Higher digital health literacy levels were also associated with greater likelihood of attending a physical examination by a physician in the prior 12 months in a Black or African Americans sample [32]. By contrast, 1 study found no associations between digital health literacy and health service engagement in a study of transplant recipients. Participants with low digital health literacy were less likely to have talked with a doctor about injury information than those with higher digital health literacy [31].

Differences in Digital Health Literacy Across Patient Groups and Health Status

Three studies (3/36, 17.6%) compared digital health literacy across different patient or health status groups and identified varying levels of digital health literacy. Among low-income pregnant women with gestational diabetes or type II diabetes, those with gestational diabetes trended toward higher digital health literacy than those with type II diabetes [28]. In another study, kidney transplant recipients were found to have higher digital health literacy than liver transplant patients [31]. Another paper [46] found higher digital health literacy levels among people with very severe COPD than among those with less severe COPD. In addition, those with lower lung–specific health-related quality of life also had higher digital health literacy levels [46]. These findings were attributed to those with more severe disease accessing the e-resources more frequently to find strategies and information on how to self-manage their disease [46].

Perceived Health Status

Five studies (5/36, 13.9%) examined associations between digital health literacy and perceived health status, with studies broadly reporting positive associations. Higher digital health literacy was significantly associated with higher self-reported health status among veterans with spinal cord injury [38] and among African Americans [18]. Digital health literacy was also associated with better self-care, perceived improved quality of life, and increased health status in a community sample aged between 40 and 93 years [41]. Similarly, higher digital health literacy was associated with higher scores on mobility, self-care and usual activities, and lung-specific health-related quality of life in people with COPD; however, digital health literacy was not associated with generic health-related quality of life in this sample [46]. By contrast, no associations were found between

digital health literacy and health status in a sample of older US adults [40].

Physical or Neurocognitive Health Outcomes

One study each (2/36, 5.6%) explored digital health literacy on physical [38] or neurocognitive health outcomes [45]. Among veterans with spinal cord injury or disorder, no associations were found between digital health literacy and level or duration of injury [38]. In people with HIV, lower neurocognitive function was moderately associated with lower digital health literacy scores [45].

Discussion

Principal Findings

This review advances our understanding of consumer digital health literacy through identifying and synthesizing recent literature that explored digital health literacy and its relationship with sociodemographic characteristics and health outcomes. The findings present mixed results regarding the relationship between digital health literacy and sociodemographic characteristics. However, studies broadly suggested that increased digital health literacy was positively associated with improved health outcomes. Based on the findings, we derive implications for practice in closing the digital health divide.

Education was the most common characteristic associated with digital health literacy. People with higher education levels were more likely to have increased literacy skills to better read and interpret web-based health information. Moreover, education has been shown to be a predictor of use of eHealth resources [16]. Education is considered a major determinant of *health literacy*, since educational levels often influence literacy skills, employment status and income, and, as such, enable access to better living circumstances and access to health care [53]. However, some individuals with higher education levels may still have inadequate health literacy [54]. Examining specific skills and knowledge, rather than sociodemographic characteristics alone, may offer a more comprehensive understanding of this relationship in future [53].

Some studies showed that older individuals were more likely to have lower digital health literacy than their younger counterparts, although other studies found no associations. Research has shown that digital health literacy decreases with age, and this is explained by age-related cognitive changes, decreased vision and hearing, reduced motor functioning, and decreased health status [55]. Notably, in our current review, studies with patient populations found no associations between age and digital health literacy levels, and 1 recent study [36] with older people had higher digital health literacy scores than their younger counterparts. Furthermore, in this study [36] the sample was younger and highly educated, and the findings could be related to increased use of digital products. People with chronic health conditions are likely required to engage with digital health resources to manage their health condition, which may account for their higher digital health literacy levels. Thus, while some findings suggest that older people require additional supports to improve digital health literacy capacities, given the varied outcomes, more in-depth analysis of these relationships

between digital health literacy and age is recommended for future research including a full systematic review and meta-analysis. Findings showed predominantly no differences in digital health literacy across gender. While several studies reported that women had higher digital health literacy levels than men, the majority found no associations, suggesting that gender is not a likely predictor of digital health literacy. These findings may be attributed to increased use of electronic devices across populations and the closing gap in education levels between men and women [16].

Of the few included studies that examined ethnicity and digital health literacy, findings were also mixed. While some studies reported higher digital health literacy in White populations than in minority groups [25,35], other studies found no differences across ethnic groups [26,38], or conversely that people from minority groups had higher digital health literacy levels [24,32]. Findings from the current review suggest that ethnicity is not a reliable predictor of digital heath literacy; however, further evidence is needed. In addition, studies on digital health literacy among culturally and linguistically diverse communities were limited to a qualitive study, which was excluded from the current review [56]. Quantitative studies in culturally and linguistically diverse populations that met the study criteria were lacking. Thus, further studies are needed to explore these associations and to identify facilitators and barriers to digital health literacy for people in culturally and linguistically diverse communities.

The majority of studies reported positive associations between digital health literacy and health resource navigation, including higher levels of e-information seeking, e-resource engagement, access and use of technology, engagement with health information sources, eHealth satisfaction and trust, and comfort and use of digital resources. The findings suggest a bidirectional relationship between digital health literacy and eHealth resource use: those with greater access to digital devices and greater use of the internet had higher digital health literacy. It is likely that those with more confidence engaging with digital products will be more inclined to seek out health information in digital formats. The findings suggest that ensuring access to technology, as well as fostering skills to engage with eHealth resources is essential to promoting digital health literacy. Furthermore, for people with limited access to the internet or devices, we recommend providing information in nondigital formats.

Our review found that studies examined associations between digital health literacy and health outcomes including psychosocial outcomes, behaviors for managing health or chronic disease, and perceived health status. Studies showed that higher digital health literacy was associated with greater satisfaction with medical encounters, less perceived strain in medical encounters, increased empowerment, greater social networks for health information, and reduced affective distress and cancer fatalism. In these studies, higher digital health literacy enabled individuals to seek and understand information, which enabled them to feel more empowered to manage their health. However, findings were less consistent for associations between digital health literacy and chronic disease and health management outcomes.

Studies of chronic disease populations showed that digital health literacy was associated with greater disease knowledge and increased disease management efficacy, consistent with a prior systematic review [57]. However, while some studies suggested that digital health literacy was associated with increased health decision-making behaviors and health service use, other studies found no associations with health promotion behaviors or health service use.

Our findings support conclusions drawn from existing reviews [8], which identified that more studies are needed in the digital health field to examine whether digital advances are facilitating better outcomes for those with greater skills in using e-resources for health purposes. Furthermore, our findings from the review also highlight gaps in recent evidence on the impacts of digital health literacy on prevalent chronic health conditions (eg, cancer, heart disease, diabetes, stroke, and COPD). Given the increased use of telehealth during the COVID-19 pandemic, and importance of chronic disease self-management, research to understand how digital health literacy influences a person's capacity to engage with digital health resources to manage their health is needed. Furthermore, research on understanding the impacts of digital health literacy on health outcomes in chronic disease populations is recommended. In addition, only 2 included studies examined digital health literacy in caregiver populations. Caregivers, particularly those of adult care recipients, may have unique health information needs given their role in providing support. Given the evidence gap, we recommend further research on caregivers to identify their digital health literacy needs and how these can be addressed across health settings.

Study Limitations

Across all studies, digital health literacy was assessed using self-reported measures (eg, eHealth Literacy Scale) rather than assessments of specific digital knowledge and skills. Thus, these perceived digital health literacy skills may not translate to everyday digital health behaviors. Studies also varied in their reports of digital health literacy scores (eg, means vs cutoff criteria), thus limiting comparability across studies. Furthermore, included studies captured digital health literacy levels across a range of participant groups, which limit in-depth understanding of digital health literacy within specific populations. Thus, findings should be interpreted with caution for specific groups. Only bivariate associations were reported in the current review. Thus, nuanced understanding of relationships between digital health literacy and health outcomes and sociodemographic characteristics may be excluded. In addition, the aim of the rapid review was to inform the development and implementation of emerging digital health strategies across community settings in real time. In contrast to a full systematic review, the rapid review approach trades some methodological rigor for efficiency in addressing a critical topic and may therefore be vulnerable to bias. While MeSH terms were not used in the database search to limit outputs to articles that focused on measuring digital health literacy, ~1500 publications were still identified. Finally, the findings were limited to studies conducted from English-speaking countries. Thus, articles that capture key findings of the review may have been excluded. Notwithstanding, we note that the current findings highlight

substantial gaps in research pertaining to digital health literacy within English-speaking countries and identify areas for future investigation.

Conclusions

Findings from this review suggest that sociodemographic characteristics may predict digital health literacy levels in some but not all contexts, but evidence suggests that these are not deterministic. Although in its infancy and with limited evidence, studies show some associations between increased digital health literacy and various improved health behaviors and outcomes. Further investigations of digital health literacy on positive chronic disease outcomes are needed, particularly across underrepresented but key populations, including diverse cultural and chronic disease groups. Empowering individuals with the skills to critically access and appraise reliable health information on digital platforms and devices is vital, given emerging evidence that suggests that those with low digital health literacy seek health information from unreliable sources. Identifying cost-effective strategies to rapidly assess and enhance digital health literacy capacities across community settings thus warrants continued further investigation. Our findings also confirm a warning that those with greatest digital skills may obtain greatest benefit from access to digital health resources and vice versa, with the implication that digital divides (gaps between knowledge of digital skills and access to health information) may become entrenched without specific efforts to overcome such divides. Our review contributes to the global digital health movement by identifying areas that require further investigation. It emphasizes the pivotal role of digital health literature in improving health care outcomes and promoting a more inclusive health care system. Digitalization and digital technologies transform and enhance the delivery of health care services; therefore, digital health literature becomes essential to engage health consumers and empower them to actively participate in their own health care and address health inequalities.

Abstract

Background: The rehabilitation of children with disabilities has received considerable attention from the United Nations. However, the state of rehabilitation services for children with disabilities worldwide remains far from optimistic, even in economically affluent middle- and high-income countries.

Objective: This scoping review aimed to identify the rehabilitation needs of children with disabilities and their barriers to rehabilitation services in middle- and high-income countries.

Methods: A systematic search was conducted using MEDLINE and Web of Science for papers published from January 2013 to December 2023. Studies were included if they were peer-reviewed, full-text articles related to children with disabilities, reporting on their access to rehabilitation services, and conducted in countries classified by the World Bank 2023 as middle- and high-income economies. Exclusion criteria included duplicates, unavailable full texts, and studies without distinct outcomes. A total of 27 studies were selected following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, focusing on children, their families, or service providers.

Results: The suitability, availability, and affordability of rehabilitation services were identified as the major needs and barriers for children with disabilities in middle- and high-income countries. This included communication barriers, a need for more personnel and facilities, and the stagnation and inadequacy of economic subsidies.

Conclusions: Middle- and high-income countries have relatively well-established rehabilitation infrastructure and support systems. They are nevertheless insufficient for meeting the needs of children with disabilities. More attention should be paid to these issues to improve the well-being of children with disabilities. The data provided by this review can help raise awareness of rehabilitation needs and barriers at the policy level.

Introduction

Worldwide, over 240 million children are impacted by disabilities [1], which predominantly manifest as functional impairments. These impairments substantially inhibit their ability to engage in foundational activities such as learning, daily functions, and social integration. Defined by age, individuals younger than 18 years who experience physiological, psychological, or cognitive deficits, whether congenital or acquired, are classified as children with disabilities [2]. Children are in a crucial period of growth and development. Timely intervention and treatment not only promote the physical and cognitive development of children with disabilities but also minimize the impact of disabilities on their lives to the greatest extent possible [3]. Rehabilitation for children with disabilities encompasses a comprehensive approach that integrates medical, educational, and social rehabilitation methods. Its primary aim is to assist children in overcoming physiological, psychological, or societal barriers. The ultimate goal is to maximize their quality of life, functionality, and autonomy [4]. Compared with their healthy peers, children with disabilities have higher rates of morbidity, require increased medical attention, and have longer hospital stays [5]. The rehabilitation needs of children with disabilities are more pressing. However, children with disabilities often face greater challenges in meeting their rehabilitation needs. Children with disabilities sometimes face the impact of different social attitudes and cultural traditions, experiencing discrimination and exclusion, which results in their service needs being overlooked [5]. Furthermore, barriers related to transportation and the natural environment also limit the fulfillment of the needs [6].

Rehabilitation welfare policies for children with disabilities have been established in most regions [7-9]. However, these policies seem to have not yielded satisfactory outcomes [10]. Children with disabilities still face considerable drawbacks in various indicators used to assess child welfare. In sub-Saharan African countries [11], common deficiencies, such as attitudinal problems, poverty, inadequately trained, health care professionals, and physical inaccessibility are seen. The existence of regional disparities contributes to the insufficient distribution of health care resources and funding [12,13]. This further affects the accessibility of rehabilitation services for children with disabilities residing in different regions. The disparity in national economic levels directly impacts the allocation of medical resources and funding, resulting in significant variations in the level of support available for children with disabilities residing in different regions [14,15]. The World Bank classifies the global economy into 4 distinct categories based on 3 income thresholds: US $1135, US $4465, and US $13,846 per capita gross national income (GNI) for the year 2022. These categories are low-income, lower-middle-income, upper-middle-income, and high-income [16]. Previous research has predominantly focused on countries classified as low-income economies [12,17,18]. Even in middle- and high-income countries with relatively better economic conditions, the status of rehabilitation support for children with disabilities is equally concerning [19]. Compared with low-income countries, these nations and regions possess a greater abundance of resources and experience in providing rehabilitation services. However, there are still issues with the accessibility of rehabilitation services for children with disabilities in these regions [17]. The growth of the population and the increasing prevalence of chronic illnesses have raised additional demands for rehabilitation services. Disparities in economic levels have exacerbated regional inequalities in the allocation of rehabilitation resources [18]. Additionally, differences between early-established welfare policies and current rehabilitation needs also impact the fulfillment of these demands [20]. There has been relatively limited exploration in existing literature regarding the specific influencing factors that pertain to middle- to high-income countries and regions. The purpose of this study was to systematically review the existing literature on the state of rehabilitation services for children with disabilities, especially in middle- and high-income countries. This review aims to explore the factors influencing the accessibility and effectiveness of these services and to identify gaps in current policies that could be addressed to better meet the diverse needs of children with disabilities across different economic contexts.

Methods

Review Design

We conducted a scoping review to map the evidence regarding the accessibility of rehabilitation services for children with disabilities across the world. The review was based on a systematic search of relevant sources that have been used previously in the field of disability [21,22]. Scoping reviews have broad, comprehensive objectives compared with systematic reviews, which are often guided by more narrow, focused research questions [23]. We chose this approach given the limited range of rigorous study designs described in traditional systematic review papers. In addition, because this scoping review was intended to provide a descriptive overview of the applicable literature [24], we did not critically assess the papers. We acknowledge that the studies included in the review may have methodological strengths and limitations. Therefore, we approach the selection and analysis with caution. We are particularly mindful that some studies may not be methodologically suited to provide precise explanations. However, we make an effort to highlight the contributions of each study and their role in the broader context. While scoping reviews may not be the most robust tool for evidence synthesis, they provide us with a valuable starting point to understand the unmet health care needs of children with disabilities and point the way for future research. The outline for this review followed the 5-stage framework described by Arksey and O'Malley [23], which includes (1) identifying the research question, (2) identifying relevant studies, (3) selecting studies, (4) charting the data, and (5) accumulating, summarizing, and reporting the results.

Identifying the Research Question

The purpose of this scoping review was to understand the current status of rehabilitation services for children with disabilities, explore the influencing factors, and make constructive observations. This is important for improving the well-being of

children with disabilities and responding to the World Health Organization's (WHO's) 2030 Rehabilitation Initiative.

Identifying Relevant Studies

We searched the electronic databases MEDLINE and Web of Science using combinations of the keywords, which are Rehabilitation, Disabled Children, and Health Services for Persons with Disabilities. Specific search strategies can be found in Multimedia Appendix 1. We screened the titles and abstracts of publications from the past 10 years (2013-2023) to find relevant articles and capture the most recent evidence. The literature within this time frame encompasses alterations in policy, technology, and rehabilitation services, thereby augmenting the filterability and analyzability of research data and literature [25-27]. Through this strategy, we aimed to provide highly relevant and practical information.

Eligibility Criteria and Study Selection

Studies were eligible if they met the following criteria: (1) a study related to a child with a disability; (2) the participants were children with disabilities, their family members (parents, relatives), or staff providing services; (3) the study reported the disabled child's access to rehabilitation services; and (4) the study was conducted in countries classified by the World Bank 2023 as middle- and high-income economies. Studies were excluded if the full text of the electronic source was not available. Duplicate reports of the same study were combined if they reported different results or excluded if they had the same results. The first round of screening removed duplicate studies and eliminated articles based on titles and abstracts. Our selection process was conducted in 2 stages to ensure accuracy and relevance. In the first stage, XYJ and LY independently reviewed titles, abstracts, and full texts of identified publications. Each conducted their assessments separately to maintain objectivity, documenting their findings to ensure alignment with our inclusion criteria.

In the second stage, these authors met to jointly reassess the retained papers, focusing specifically on their relevance to our review's topic. This collaborative review helped refine the selection further. Any disagreements encountered during this reassessment were resolved through detailed discussions until a consensus was reached regarding each paper's compliance with the inclusion criteria.

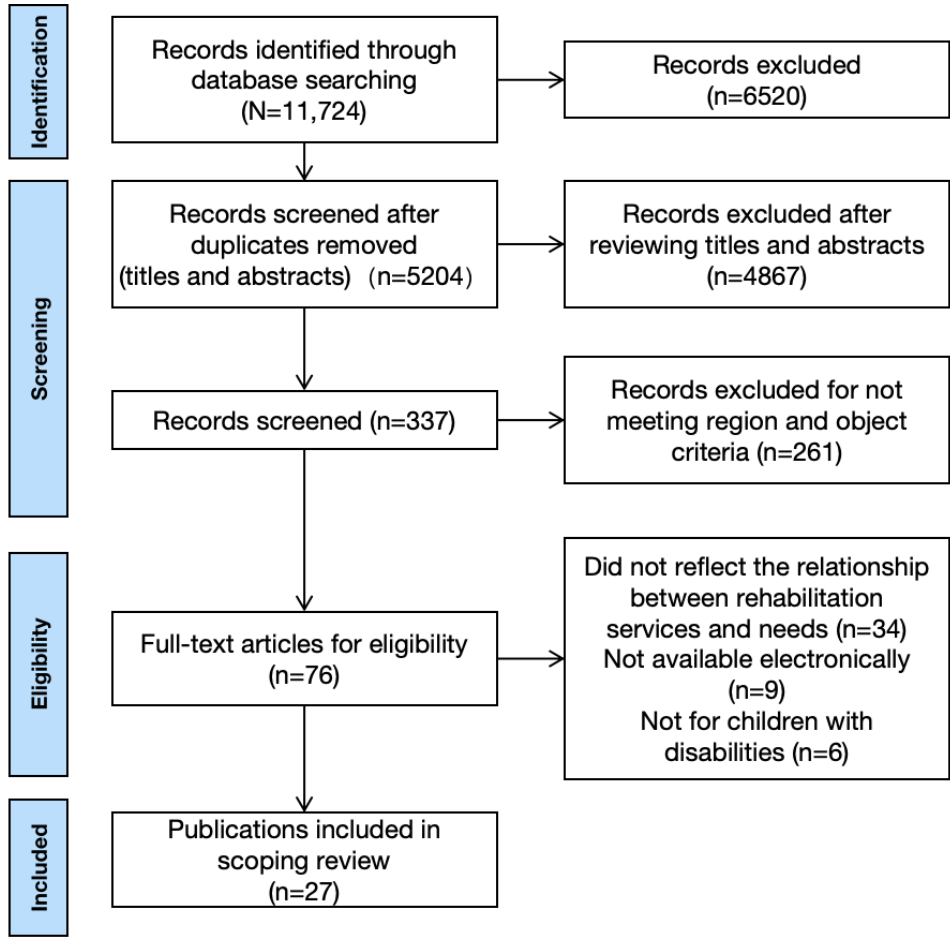
Data Charting

Participant demographics (eg, information on children with disabilities and type of disability), access to rehabilitation services, and study-related data (eg, the author or researcher, year of publication, study objectives, and whether the study was in a middle- or high-income country) were extracted and put into Excel (Microsoft Corp). Two independent reviewers conducted the extraction of pertinent data from the papers included in the scope-defining review. Next, we read the full texts of the remaining papers and extracted the following: the author or researcher, date of publication, study objectives, inclusion criteria, age of child or children, sample size, age of parents, type of disability, city or country or setting of the study, research method, study results, and the facilitators of and barriers to rehabilitation services. Any disagreements among reviewers that cannot be resolved through discussion or consensus will be resolved by a third reviewer. Penchansky and Thomas [28] have compiled a set of specific dimensions that delineate the relationship between patients and the health care system. Their analysis demonstrates discernible distinctions among these dimensions. These specific dimensions encompass the aspects of availability, accessibility, accommodation, affordability, and acceptability. The extracted information has been categorized using these 5 dimensions.

Results

Search Results

The initial search produced 11,724 documents after removing 6520 duplicates; 4867 documents were further removed after screening titles and abstracts. We then screened 76 full-text papers and excluded an additional 49 papers. The reasons for exclusion during full-text screening were the following: (1) did not reflect the relationship between rehabilitation services and need (n=34); (2) full text was not available electronically (n=9); and (3) did not target children with disabilities (n=6). Figure 1 illustrates the search process. All the included studies are listed in Multimedia Appendix 2 [15,29-54].

Figure 1. PRISMA (Preferred Reporting Items for Systematic reviews and Meta-Analyses) flow diagram of the study selection process.


Characteristics of the Included Articles

The majority of the studies (21/27, 77.8%) of children's rehabilitation services were conducted in high-income economies, with 22.2% (6/27) at upper-middle income levels. Regarding regions, the highest number of studies were conducted in East Asia and Pacific (9/27, 33.4%) and Europe and Central Asia (8/27, 29.6%), followed by North America (7/27, 25.9%), Middle East and North Africa (2/27, 7.4%), and sub-Saharan Africa (1/27, 3.7%).

The selected studies investigated the rehabilitation needs of children with disabilities and the barriers they face. Of these studies, 33.4% (9/27) solely involved children with disabilities, while the remaining papers gathered information from parents of children with disabilities (12/27, 44.4%) or professional caregivers (4/27, 14.8%). In some studies, children with disabilities could not articulate their needs due to their unique physical conditions. Consequently, researchers gained insights into the children's rehabilitation requirements and challenges by conducting interviews with their parents. For instance, parents were asked about their perceptions of their child's experience with rehabilitation services or to elaborate on the effect of their child's disability on the family's quality of life.

Overall, the included studies had diverse goals, such as investigating the unmet health care needs of children with disabilities, insurance plans, quality of life for children and families, participation in activities, and intervention programs. Nevertheless, the primary focus of the reviewed papers was on the health care requirements of children with disabilities and the barriers they face, with relatively limited attention given to treatment techniques or clinical outcomes. Table 1 lists the descriptive statistics of the included documents. All selected documents will be included as supplementary materials in the form of appendices.

Table 1. General characteristics of the studies eligible for inclusion in the review.

Characteristics	Publications

Rehabilitation Needs and Barriers to Accessing Services

The scale by Penchansky and Thomas [28] addresses access to health care and consists of 5 categories, which include accessibility, acceptability, affordability, appropriateness, and availability. This classification's validity has been confirmed through interview data analysis. Accessibility describes the physical connection between the family and the location of rehabilitation services. Acceptability refers to clients' and providers' satisfaction with health care services. Affordability relates to the connections between financial constraints, financial capacity, and health insurance availability. Appropriateness refers to the match between supply and patient demand. Availability describes the connection between supply and demand for resources. This study used Penchansky's scale to identify information about barriers to rehabilitation services (Table 2).

Table 2. Factors affecting the fulfillment of rehabilitation needs of children with disabilities.

Factors	Reference
Accessibility

Accessibility

The accessibility of rehabilitation services refers to the reduction of various barriers that may exist in accessing these services, intending to achieve equality for all. Ensuring that children with disabilities can easily access rehabilitation services has a significant impact on meeting the rehabilitation needs of these children [55]. On the one hand, geographic distance is strongly linked with time costs for children with disabilities to access rehabilitation [29]. On the other hand, the distance barrier also interferes with the ability of rehabilitation specialists to connect and share experiences. Geographical isolation hinders information exchange in resource-poor regions, often leaving rehabilitation experts in these areas isolated and unsupported "information islands" [27]. Apart from the challenges associated with the coverage and frequency of "public transportation," Jeong [40] found that "personal transportation" includes factors such as the availability of vehicles also influencing the accessibility of rehabilitation services.

Acceptability

The acceptance of rehabilitation services by children with disabilities is affected by personal factors such as stigmatization and doubts about service effectiveness [28,29,55,56]. According to 3 papers [39,41,42], disability is often stigmatized, leading to a reluctance among parents to seek rehabilitation treatment for their children with disabilities. This stigma associated with disability can deter families from pursuing the necessary care and therapies [57]. Discrimination may also lead to rehabilitation professionals refusing to provide their services. This directly impacts the trust relationship between children with disabilities and service providers, ultimately influencing the decision to seek rehabilitation services [30]. In a reviewed study [58], a Chinese mother faced discrimination due to her child's autism, leading to trust issues in rehabilitation services and service discontinuation. The current situation of this discrimination may explain how children with disabilities are deprived of their rehabilitation rights through voluntary abandonment in a so-called equitable institutional environment. Furthermore,

rehabilitation care is a long-term process. Short-term outcomes are often limited. Some families of children with disabilities may develop a negative attitude toward rehabilitation services because they perceive that the short-term impact falls short of their initial expectations [56].

Affordability

The relationship between disability and poverty is reciprocal [56,57]. Families of children with disabilities were more likely to experience financial burdens owing to their child's health condition [30]. Such families face multiple financial challenges, including rehabilitation expenses [30,58,59], assistive equipment, institutional care [29], home renovations [15], and travel expenses [60]. While governments in middle- to high-income countries generally offer financial assistance and insurance, some families having children with disabilities still experience significant economic burdens [61-63], and current insurance benefits fall short of completely covering the rehabilitation needs of children with disabilities [31]. The gap between financial assistance and the actual needs continues to widen [32,33]. It is worth noting that the current financial assistance system primarily focuses on children with confirmed disabilities. This might exclude children with disabilities who require rehabilitation but do not have a formal diagnosis [34].

Appropriateness

Effective rehabilitation treatment relies heavily on the appropriateness of rehabilitation services, which includes matching treatment services, goals, and assistive devices with patients' needs [64]. As reported by mothers in a study conducted in Kelantan, Malaysia, profit-oriented organizations may overlook the individual needs of children with disabilities, which can diminish the effectiveness of rehabilitation services. Parents have noted that insufficient responsiveness from professionals has reduced the practical utility of the services [56]. The professionalism of rehabilitation professionals is crucial for the appropriateness of services. Insufficient professionalism can result in delays in addressing the conditions of children with disabilities. Rehabilitation training is widely available in middle- to high-income countries. However, there is a lack of professional ability among rehabilitation personnel. This deficiency leads to children with disabilities not receiving timely and accurate treatment, even when they diligently follow their rehabilitation plans [56]. Due to limitations in the size and staff of rehabilitation institutions, the frequency and number of treatments can also impact the effectiveness and satisfaction of rehabilitation services. In a family survey of Saudi Arabian children with hearing impairment [26], more than half of the participants believed that the number of treatment sessions provided was inadequate to meet their rehabilitation demands.

Communication gaps between the staff of rehabilitation institutions and the parents of children with disabilities can lead to misunderstandings and negative perceptions [35,36]. A lack of collaborative communication among staff within rehabilitation institutions can increase feelings of isolation among rehabilitation professionals. It also has the potential to reduce job motivation [28]. Even though rehabilitation facilities in middle- and high-income countries are relatively well-established, the lack of communication and interaction has

still been identified as a serious issue. Studies indicate that poor internal and external communication within institutions, along with a lack of collaboration, increases the co-ordination burden on parents of children with disabilities [58]. This also hinders the transfer of treatment between different rehabilitation systems and the sustainable development of children with disabilities [32]. The compatibility of assistive facilities is also a key factor. For instance, in the provision of rehabilitation equipment for children with physical disabilities, nonportable wheelchairs are often voluntarily abandoned because they do not meet the actual needs of children with disabilities [37].

Availability

The availability of rehabilitation services for children with disabilities emphasizes the presence and provision of rehabilitation resources, as well as the reasonable scheduling of rehabilitation service delivery, which are key factors in meeting the rehabilitation needs of children with disabilities. Factors related to this include cumbersome procedures, the need for information and emotional support, the need for specialized medical facilities, and scheduling convenience. If the family cannot afford the cost of the wait times, they will give up on rehabilitation [38]. Australian parents of children with physical disabilities report that flexible scheduling and location of rehabilitation services provide them with convenience [35].

Studies highlight the need for information on rehabilitative options [29]. Available research showed that middle- and high-income countries have relatively well-established rehabilitation facility structures, yet the exchange and communication of rehabilitation information have not received adequate attention. The quantity and quality of information provided by rehabilitation service institutions are often unsatisfactory. This compels parents of children with disabilities to seek solutions on their own [58]. It is worth noting that children with disabilities and their caregivers experience both physical and mental stress. While it has been proven that psychological support is beneficial for their mental well-being [26,40,41], it remains one of the common unmet needs within rehabilitation programs [42,57]. Regional disparities in rehabilitation services create challenges for children with disabilities who seek higher-quality rehabilitation services [38]. To access higher-level services, they are compelled to bear higher treatment costs [29,39,65]. The current situation of oversaturated health care resources and low-quality health system services also prolongs the access cycle and reduces the level of services for children with disabilities [38,55].

The most commonly discussed issue in the literature was availability, followed by affordability. Notably, Europe or Central Asia, North America, and East Asia or Pacific were the main regions reporting both of these issues.

High-income countries reported the greatest need for specialized facilities and emotional support, followed by financial issues not covered by insurance and treatment costs. Communication barriers and doubts about the effectiveness of rehabilitation treatment were also highlighted as acceptability concerns. Professionalism and access to spiritual support were also mentioned. In contrast, participants from middle-income countries expressed greater concern with the accessibility,

appropriateness, and acceptability of rehabilitation services. This disparity might be related to the fact that half of the studies in middle-income countries focused on rehabilitation service workers.

Discussion

Principal Findings

This scoping review aimed to provide an overview of the rehabilitation needs and related obstacles faced by children with disabilities residing in middle- and high-income countries. The final review comprised 27 peer-reviewed papers published between 2013 and 2023, categorized into 5 groups based on rehabilitation-related factors, allowing for a summary and comparison of related studies. The findings of this review suggest that even in economically prosperous middle- and high-income countries, common factors still affect children with disabilities' achievement of rehabilitation services. The appropriateness, accessibility, and affordability of rehabilitation services were identified as the main factors related to the needs and barriers of families of children with disabilities. Having identified these factors, it is possible to propose recommendations aimed at the formulation of intervention strategies.

The accessibility of rehabilitation services is a fundamental issue related to the presence or absence of service resources. In line with research conducted in low-income countries, it is consistent that children with disabilities generally face difficulties in accessing adequate health care services [66]. This issue is not only confined to low-income countries but also in middle- and high-income countries with more developed health care systems [67]. However, there are differences between the 2 when it comes to the specific challenges they face: unlike the generally low availability of rehabilitation resources in low-income countries, the main influence factor in middle- and high-income countries is the uneven distribution. The availability of rehabilitation resources is generally high but concentrated in economically developed areas [68]. In underdeveloped regions, children with disabilities face challenges in accessing rehabilitation resources, resulting in a relative scarcity of rehabilitation resource provision [28]. Capitalizing on the spillover effect of developed regions, rehabilitation resources should be strategically allocated to less developed regions. This can improve the overall quality of services for families of children with disabilities, enhancing the capabilities of existing health care and rehabilitation professionals while attracting new talent to underserved areas. By increasing both the quantity and quality of professionals, the accessibility and effectiveness of services could be improved. Through the implementation of these measures, we can mitigate the uneven distribution of resources between regions and reduce disparities in rehabilitation levels [68].

Access to affordable and adequate health care for children with disabilities remains a pervasive challenge in middle- and high-income regions. It was discussed in 12 papers in 8 different countries. In contrast to low-income countries, the economic pressure in this context does not arise from a lack of assistance but rather from the effectiveness of the assistance system itself

[26,35,64]. As economic levels and rehabilitation costs continue to rise, the actual medical expenses surpass the financial support available to families. This discrepancy has rendered the previously established financial subsidy policies inadequate in meeting the current rehabilitation support needs. This diminishes the effectiveness of assistance. Although such countries generally have relatively completed insurance systems and benefit arrangements [25], an unmet need for support also exists. For instance, current insurance benefits fall short of completely covering rehabilitation costs for children with disabilities [39]. Evaluating the effectiveness of financial assistance programs and adjusting subsidy standards for children with disabilities based on actual circumstances is necessary. By understanding the specific needs of different types of children with disabilities and making targeted adjustments to subsidy policies, resource allocation can be improved, leading to enhanced utilization efficiency. Extending insurance coverage to encompass a diverse range of rehabilitation-related expenditures will better meet the individualized needs of children with disabilities. Besides traditional physical and speech therapy, occupational therapy, psychological counseling, and special education resources should also be incorporated. Achieving this goal necessitates close co-operation among health care service providers, policymakers, and other stakeholders to adopt policies to address complex rehabilitation needs. Simultaneously, the long-term and intricate nature of the rehabilitation process for children with disabilities must be considered, and adjustments in assistance to offer more flexible and enduring support should be made.

Effective communication is a pivotal issue in improving the appropriateness of rehabilitation for children with disabilities. In low-income countries, this issue has received relatively little attention in research [12]. However, in this review, 6 out of 15 middle- to high-income countries (40%) have reported this concern. This encompasses the need for communication between children with disabilities and rehabilitation staff, knowledge exchange among rehabilitation professionals, and referrals between rehabilitation institutions. Educating and training rehabilitation service providers in effective communication strategies is crucial, encouraging them to actively listen to families' opinions and address their concerns. Future research should delve into the collaboration between rehabilitation experts and institutions, emphasizing resource sharing, information flow, and referral and treatment models for children with disabilities. This approach aims to enhance the sustainability of rehabilitation services for children with disabilities.

This review has several limitations that should be noted. First, even though we used an extensive search strategy to find all relevant studies, the search scope was constrained because our study was not a systematic review. Second, most studies were conducted in North America, Europe, and Asia or the Pacific, making comparisons by continent and economic development level difficult. Furthermore, some of the studies were carried out at the district level, making it difficult to extrapolate to the nation's overall rehabilitation status. Finally, rather than focusing on more general disability identification, interventions, and clinical research, we mainly considered the rehabilitation

needs of children with disabilities and the related barriers. Therefore, this might not reflect access to rehabilitation services in the broadest sense, as mentioned in WHO's 2030 Rehabilitation Initiative. Future research could further refine rehabilitation initiatives related to children with disabilities to obtain more complete information.

Conclusion

This scoping review highlighted the rehabilitation needs of children with disabilities and the barriers to rehabilitation services in middle- and high-income countries. The affordability, availability, and appropriateness of rehabilitation services were major factors affecting access. Despite the established service supply in these countries, access falls short of meeting the needs of children with disabilities. To address these challenges, it is necessary to expand financial coverage, improve infrastructure and professional training, and strengthen supporting institutions.

Data Availability

All data generated and analyzed during this study are included in this published paper and its Multimedia Appendices.

Authors' Contributions

XYJ and LY performed data curation, writing, reviewing, and editing of the original draft. WJ and LH contributed to the investigation and editing. WHJ performed supervision and project administration. All the authors have read and agreed to the published version of the manuscript.

Abstract

Background: A common challenge for individuals caring for people with Alzheimer disease and related dementias is managing the behavioral and psychological symptoms of dementia (BPSD). Effective management of BPSD will increase the quality of life of people living with dementia, lessen caregivers' burden, and lower health care cost.

Objective: In this review, we seek to (1) examine how indoor environmental quality parameters pertaining to light, noise, temperature, and humidity are associated with BPSD and how controlling these parameters can help manage these symptoms and (2) identify the current state of knowledge in this area, current gaps in the research, and potential future directions.

Methods: Searches were conducted in the CINAHL, Embase, MEDLINE, and PsycINFO databases for papers published from January 2007 to February 2024. We searched for studies examining the relationship between indoor environmental quality parameters pertaining to light, noise, temperature, and humidity and BPSD.

Results: A total of 3123 papers were identified in the original search in October 2020. After an additional 2 searches and screening, 38 (0.69%) of the 5476 papers were included. Among the included papers, light was the most studied environmental factor (34/38, 89%), while there were fewer studies (from 5/38, 13% to 11/38, 29%) examining the relationships between other environmental factors and BPSD. Of the 38 studies, 8 (21%) examined multiple indoor environmental quality parameters. Subjective data were the only source of environmental assessments in 6 (16%) of the 38 studies. The findings regarding the relationship between agitation and light therapy are conflicted, while the studies that examined the relationship between BPSD and temperature or humidity are all observational. The results suggest that when the environmental factors are deemed overstimulating or understimulating for an individual with dementia, the behavioral symptoms tend to be exacerbated.

Conclusions: The findings of this scoping review may inform the design of long-term care units and older adult housing to support aging in place. More research is still needed to better understand the relationship between indoor environmental quality parameters and BPSD, and there is a need for more objective measurements of both the indoor environmental quality parameters and behavioral symptoms. One future direction is to incorporate objective sensing and advanced computational methods in real-time assessments to initiate just-in-time environmental interventions. Better management of BPSD will benefit patients, caregivers, and the health care system.

Introduction

Background

Alzheimer disease and related dementias (ADRD) are a major public health challenge. The number of Americans aged ≥65 years with Alzheimer disease was estimated to be 6.7 million in 2023 [1]. In 2023, total payments for health care, long-term care, and hospice services for people aged ≥65 years with dementia were estimated to be US $345 billion in the United States. The number of people with Alzheimer disease in the United States is projected to grow to 13.8 million by 2060 [1].

A major component of the high psychological and financial costs of ADRD is related to addressing the needs of people living with dementia who have behavioral and psychological symptoms of dementia (BPSD), also called neuropsychiatric symptoms. BPSD encompass the challenging behaviors exhibited by people living with dementia that comprise a variety of symptoms that commonly include, but are not limited to, apathy, anxiety, depression, agitation, delusions, hallucinations, motor disturbances, and sleep changes. These symptoms are associated with faster disease progression [2], increased caregiving burden [3], and earlier placement into long-term care settings [4]. Pharmacological intervention is often not effective and is associated with undesirable side effects [5], with nonpharmacological therapy being a first-line approach to management [6].

The causes of BPSD are multiple, ranging from intrinsic neuropathologic factors to human factors such as caregiver interactions and the social-environmental milieu [7]. There is considerable evidence suggesting that environmental factors can affect the progression of different diseases as well as human behaviors [8,9]. The environment as a risk factor for ADRD has been reviewed, suggesting links between increased risks of ADRD and factors such as poor air quality, environmental toxins, and occupation-related exposures [10,11]. However, what has been less clearly examined is the potential direct relationship between person- or residence-level experienced environmental factors and contemporaneous behavioral changes associated with ADRD. This is important because most older people and people living with dementia spend the majority of their time indoors [12].

There has long been debate regarding the definition of the environment [13]. For the purpose of this review, we are focusing on the ambient environment as defined by Harris et al [14]. Factors pertaining to the ambient environment, such as light, noise, temperature, and humidity, contribute to the visual, acoustic, and thermal comforts of the occupants and may be associated with their BPSD [15]; for example, inadequate light has been suggested to be a risk factor for sundowning syndrome (people with late-stage dementia exhibiting more agitated behaviors in the late afternoon and evening) because of the role of light in vision and its role in circadian rhythm modulation [16,17]. Therefore, designing an indoor environment that would address the needs of people living with dementia is paramount and may reduce their BPSD. A first step to creating an optimal indoor environment for people living with dementia with BPSD is to understand which environmental factors are related to BPSD and how they impact the symptoms.

Previous papers have reviewed the effect of the long-term care environment on physical activity levels [18], the achievement of therapeutic goals such as safety and socialization [19], and neuropsychiatric symptoms [20,21]. However, these reviews have primarily focused on the parameters of the built environment (eg, size and layout of spaces), interior design, and occupancy and staffing ratios, rather than aspects of the environmental quality that impact comfort, such as temperature and humidity, noise levels, and lighting. Comfort is especially important to consider for people living with dementia because BPSD represent an expression of discomfort, stress, and unmet needs when insight and communication become more difficult [22]. Nevertheless, anosognosia and aphasia also prevent the subjective measurement of comfort. Thus, it is necessary to understand the impact of various objective aspects of environmental quality that may improve comfort and, in turn, BPSD.

Objectives

Accordingly, we conducted this scoping review to (1) examine how indoor environmental quality parameters pertaining to light, noise, temperature, and humidity are associated with BPSD and how controlling these parameters can help manage these symptoms and (2) identify the current state of knowledge on the relationship between indoor environmental quality parameters and BPSD, current gaps in the research, and potential future directions.

Methods

Overview

We followed the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) reporting guidelines for this scoping review. We conducted a scoping review because we aimed to (1) provide an overview of the broad literature examining the relationship between indoor environmental quality parameters and BPSD and (2) identify gaps and future directions.

The databases used were CINAHL, Embase, MEDLINE, and PsycINFO. A literature search strategy was crafted for each database that would retrieve records containing a combination of appropriate index terms and text words pertaining to the following concepts: dementia (dementia, Alzheimer disease, etc), environmental conditions (heat, temperature, light, humidity, etc), and BPSD (anxiety, depression, apathy, agitation,

pacing, etc). The complete search strategies can be found in Multimedia Appendices 1-3. The original search was performed on October 7, 2020, and updated on April 21, 2022, and February 22, 2024. The inclusion and exclusion criteria are presented in Textbox 1.

Six reviewers (WMA-Y, CW, MN, LM, RH, and KW) completed the screening process, which consisted of two stages: (1) title and abstract screening and (2) full-text screening. First, the title and abstract of each paper were reviewed by 2 reviewers independently to examine whether the studies met the inclusion criteria. The reviewers then met iteratively to reconcile any differences in their decisions regarding whether a particular paper should be included. If the 2 reviewers could not come to an agreement, a third reviewer would help reach a decision. After title and abstract screening was completed, the included papers at this stage were retrieved for full-text screening, and the process was repeated after reading the papers in their entirety.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Written in English

- Peer reviewed

- Studies of older adults with Alzheimer disease and related dementias (ADRD), not including mild cognitive impairment

- Relationships between indoor environmental quality parameters, including light, noise, temperature, and humidity and the behaviors of people living with dementia

- Exposure to environmental conditions leading to behavioral change

- Observational or controlled

- All residential settings

- Studies using measurements of people's behaviors and psychological symptoms as 1 of the outcomes

- Studies that include measurements or descriptions of the indoor environmental quality parameters (light, noise, temperature, and humidity)

Exclusion criteria

- Review articles, commentaries, opinions, theses, and letters to editor

- Studies on genetics as risk factors for ADRD

- Studies that examine the effect of decoration, furniture arrangement, and home-like feeling on participants' behaviors

- Studies on the environment as a risk factor for developing ADRD

- Studies on horticultural therapy, music therapy, multisensory stimulation therapy, virtual or augmented reality, or outdoor activities

- Studies published before 2006 (the 15-year cutoff was chosen to include articles that best represent the current state of knowledge)

Six reviewers (WMA-Y, MN, ZB, LM, RH, and SG) extracted data from the included papers after the screening process was completed. A survey built in Qualtrics (Qualtrics International Inc) was created to assist this process. The survey listed questions covering study design, year of publication, the region and residential settings in which the research was conducted, sample size, demographics of the sample, which environmental conditions were assessed and how they were examined, and which BPSD were evaluated and how they were measured. Next, the papers were categorized by the examined environmental factor or factors: (1) light level, (2) noise level, (3) temperature or humidity, and (4) multiple indoor environmental quality parameters. If there were unified themes of BPSD examined in the articles (eg, agitation and mood-related symptoms), the study results of each theme would be synthesized by summarizing the counts of different study designs and providing a narrative summary [23]. All study data were also summarized into tables. In doing so, the current state of knowledge, gaps in research, and future directions were identified.

Ethical Considerations

Institutional review board approval was not required for this scoping review because the research did not involve human participants.

Results

Overview

A total of 3123 articles were identified in the search initiated on October 7, 2020. After excluding papers published before 2006 as well as duplicates, the titles and abstracts of 1887 articles were screened, after which 1707 (90.46%) articles were excluded, and 180 (9.54%) were retrieved for full-text screening. Ultimately, of these 180 articles, 26 (14.4%) were included. The search was updated on April 21, 2022, and on February 22, 2024, and 12 articles were added to the final pool; hence, 38 papers were included in this scoping review (Figure 1). Of the 38 papers, 8 (21%) were randomized controlled trials (RCTs), 14 (37%) were quasi-experiments, 5 (13%) were pretest-posttest studies, 6 (16%) were cross-sectional studies, 4 (11%) were case series, and 1 (3%) was a cohort study (refer to Table 1 for more information).

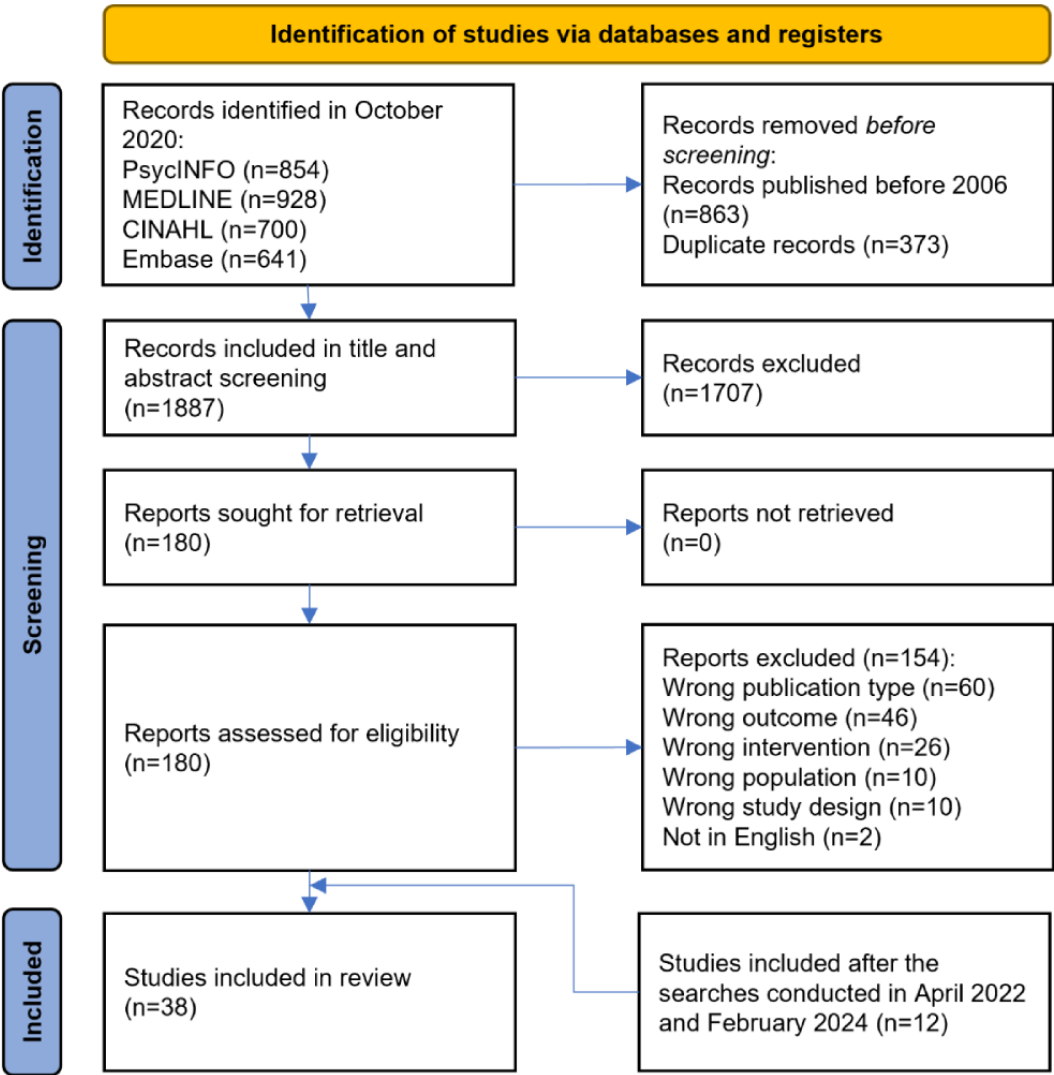
Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of the search and screening results.


Table 1. Summary of residential settings, region, study design, intervention, sample size, participant cognitive status, and participant age for all included studies.

Study, year	Residential settings	Region	Study design	Intervention (if any)	Sample size	Participant cognitive status	Participant age (y)
Algase et al [24], 2010	Assisted living units, nursing homes	North America	Cross-sectional study	__a	M[b]: 28, F[c]: 94	MMSE[d] score: mean 7.4 (SD 7.2)	Mean 83.7 (SD 6.48; range 68-102)
Bankole et al [25], 2020	Personal homes	North America	Case report or series	—	M: 6, F: 6 (the 12 participants lived with primary caregivers)	All participants had dementia	Mean 79.67 (SD 7.5; range 68-92)
Barrick et al [26], 2010	Memory care units, psychiatric hospital	North America	Quasi-experiment	Four lighting conditions were presented during multiple 3-week intervention periods: bright light in the morning (7-11 Am), bright light in the evening (4-8 PM), bright light all day (7 AM-8 PM), and standard lighting (ie, the baseline condition); bright light was administered at 2000 to 3000 lux, while standard lighting was administered at 500 to 600 lux	M: 35, F: 31	Cognitive status was measured using the MDS-COGS[e] and MMSE; the distribution of cognitive impairment severity among participants was as follows: mild=3, moderate=18, severe=31, and very severe=14	North Carolina, United States: <65=6 (13%), 65-79=24 (52%), and ≥80=16 (35%); Oregon, United States: <65=0 (0%), 65-79=4 (20%), and ≥80=16 (80%)
Bautrant et al [27], 2019	Nursing homes	Europe	Pretest-posttest study	Skylike ceiling tiles in part of the shared premises, gradual decrease of the illuminance at night, soothing streaming music, reinforcement of the illuminance during the day, walls painted in light beige, oversized clocks in corridors, and night team clothes color (dark blue) different from that of the day team (sky blue)	M: 2, F: 17	Severe dementia; MMSE scores were <15 for all patients	≥65; mean 86.3 (SD 5.4)
Bicket et al [28], 2010	Assisted living units	North America	Cross-sectional study	—	M: 80, F: 246	Demented: 194, nondemented: 131	Demented: mean 86.1 (SD 8.1), nondemented: mean 84.3 (SD 9.6)
Bromundt et al [29], 2019	Nursing homes	Europe	Quasi-experiment (balanced crossover, within-participant study)	This was a 17-week trial with a balanced crossover, within-participant study design; the intervention involved exposure to individually timed dawn-dusk simulator over participants' beds for 7-8 weeks	M: 3, F: 17	S-MMSE[f] score: mean 13.15 (SD 10.30); S-MMSE score at baseline: mean 14.35 (SD 10.51), S-MMSE score at the end of the study: mean 11.95 (SD 11.56)	Mean 85.6 (SD 5.8)

Study, year	Residential settings	Region	Study design	Intervention (if any)	Sample size	Participant cognitive status	Participant age (y)
Burns et al [30], 2009	Nursing homes	Europe	Randomized controlled trial	Full-spectrum bright light therapy (10,000 lux) for 2 hours from 10 AM to noon for 2 weeks; the control group was administered standard fluorescent tube light (100 lux) for 2 hours from 10 AM to noon for 2 weeks	M: 16, F: 32	MMSE score at baseline: 5.1 for the standard lighting therapy group and 6.9 for the bright light therapy group	Standard light therapy group: mean 82.5 (SD 1.5), bright light therapy group: mean 84.5 (SD 1.7)
Cohen-Mansfield et al [31], 2010	Nursing homes	North America	Quasi-experiment (indoor environmental quality parameters were not manipulated)	Presentation of 9 categories of stimuli: live human social, real pet, simulated social, self-identity, inanimate social, music, manipulative, reading, and task- or work-related	M: 42, F: 151	MMSE score: mean 7.2 (SD 6.3; range 0-23)	Mean 86 (range 60-101)
Cohen-Mansfield et al [32], 2011	Nursing homes	North America	Quasi-experiment (indoor environmental quality parameters were not manipulated)	Presentation of 9 categories of stimuli: live human social, real pet, simulated social, self-identity, inanimate social, music, manipulative, reading and task- or work-related	M: 42, F: 151	MMSE score: mean 7.2 (SD 6.3; range 0-23)	Mean 86 (range 60-101)
Cohen-Mansfield et al [33], 2012	Nursing homes	North America	Quasi-experiment (indoor environmental quality parameters were not manipulated)	Presentation of 9 categories of stimuli: live human social, real pet, simulated social, self-identity, inanimate social, music, manipulative, reading and task- or work-related	M: 42, F: 151	MMSE score: mean 7.2 (SD 6.3; range 0-23)	Mean 86 (range 60-101)
Cohen-Mansfield [34], 2020	Nursing homes	North America	Cross-sectional study	—	M: 26, F: 43	CPS[g] score: mean 4.19	Mean 86.58 (SD 7.93)
Dowling et al [35], 2007	Nursing homes	North America	Randomized controlled trial	During either morning (9:30-10:30 AM) or afternoon (3:30-4:30 PM), bright light (>2500 lux in gaze direction) was administered Monday through Friday for 10 weeks; Brite Lite IV (Apollo Light Systems, Inc) light boxes were used when necessary to supplement the ambient light	M: 13, F: 57	MMSE score: mean 7 (SD 7; range 0-23)	Mean 84 (SD 10; range 58-98)
Figueiro et al [36], 2014	Nursing homes	North America	Pretest-posttest study	Low-level *bluish-white* lighting designed to deliver high circadian stimulation during the daytime was installed in 14 nursing home resident rooms for 4 weeks	M: 5, F: 9	BIMS[h] score: mean 7.7 (SD 2.3)	Mean 86.9 (SD 4.4)

Study, year	Residential settings	Region	Study design	Intervention (if any)	Sample size	Participant cognitive status	Participant age (y)
Figueiro et al [37], 2019	Assisted living units, long-term care units	North America	Randomized controlled trial	Crossover design clinical trial administered an all-day active or control lighting intervention for two 4-week periods (separated by a 4-week washout); the active lighting intervention provided high circadian stimulus, and the control intervention provided low circadian stimulus that was below the threshold for activation of the circadian system	M: 16, F: 30	MMSE score between 4 and 24 or BIMS score between 3 and 12	Mean 85.1 (SD 7.1)
Figueiro et al [38], 2020	Assisted living units, long-term care units	North America	Pretest-posttest study	Participants were exposed to a single daytime (from approximately 6 AM-8 AM to 6 PM) tailored lighting intervention that provided high levels of circadian-effective light; the light-delivery method (ie, custom-built floor lamps, light boxes, and light tables) was dependent on where individual participants spent most of their day	M: 20, F: 27	MMSE scores: F=mean 15.2 (SD 3.4) and M=mean 13.6 (SD 2.9); BIMS scores: F=mean 4.0 (SD 1.7) and M=mean 5.6 (SD 2.9)	Mean 85.3 (SD 7.1)
Figueiro et al [39], 2023	Assisted living units, memory care units	North America	Quasi-experiment	With a crossover, placebo-controlled design, 3 different lighting modes (light tables, light trays, and ambient room lighting) were used to deliver high levels of circadian stimulus to the participants' eyes for two 8-week intervention periods in a counter balanced order with a 4-week washout between the study's 2 conditions (dim light control vs active intervention)	M: 3, F: 11	Moderate to severe ADRD[i] indicated by a GDS[j] score of 4.0 to 6.0; the mean BCRS[k] score was 4.83 (SD 1.01), and the mean GDS score was 4.89 (SD 1.1)	Mean 84.1 (SD 8.9)
Garre-Olmo et al [40], 2012	Nursing homes	Europe	Cross-sectional study	—	M: 37, F 123	MMSE score: mean 4.1 (SD 6.3); Barthel Index score: mean 10.5 (SD 19.3)	Mean 82.6 (SD 11.6)

Study, year	Residential settings	Region	Study design	Intervention (if any)	Sample size	Participant cognitive status	Participant age (y)
Hickman et al [41], 2007	Memory care units, specialized older adult center	North America	Quasi-experiment	Ambient bright light therapy was delivered through a high-intensity, low-glare lighting system installed in the public areas that involved 4 lighting conditions: morning bright light, evening bright light, all-day bright light, and standard lighting. The bright light conditions were delivered at 2000 to 2500 lux, while the standard lighting condition was delivered at 500 to 600 lux	M: 35, F: 31	Mild to moderate dementia: M=12 (34.3%), F=9 (29%); severe dementia: M=15 (42.9%), F=16 (51.6%); very severe dementia: M=8 (22.9%), F=6 (19.4%)	<65: M=5 (14.3%), F=1 (3.2%); 65-79: M=18 (51.4%), F=10 (32.3%); ≥80: M=12 (34.3%), F=20 (64.5%)
Hjetland et al [42], 2021	Nursing homes	Europe	Randomized controlled trial	A 24-week cluster-randomized, placebo-controlled trial with an intervention involving ambient light administered at 1000 vertical lux and 6000 K from 10 AM to 3 PM, with gradually increasing and decreasing light levels before and after this interval, delivered by Glamox AS	M: 22, F: 47	MMSE score: mean 6.4 (SD 6.7)	Mean 83.5 (SD 7.1)
Jao et al [43], 2015	Assisted living units, nursing homes	North America	Case report or series	—	M; 9, F: 29	MMSE score: mean 12.9 (SD 6.5; range 2-23)	Mean 82.7 (SD 6.3; range 68-94)
Joosse [44], 2011	Nursing homes	North America	Cross-sectional study	—	M: 11, F: 42	MMSE score: mean 6.83 (SD 6.67; range 0 to 19); specifically, 37 (70%) scored <13 (severe dementia), and 16 (30%) scored 13 to 20 (moderate dementia)	Mean 86.53 (SD 9.32; range 61 to 103)
Kim et al [45], 2021	Dementia clinic	Asia	Quasi-experiment	The treatment group (14 participants) sat approximately 60 cm away from a small (136×73×16 mm) light-emitting diode light box for 1 hour each in the morning for 2 weeks, and the control group (11 participants) wore dark, blue-attenuating sunglasses during the 1-hour exposures; the morning light exposure started 9 to 10 hours after each individual's dim light melatonin onset	M: 7, F: 18	MMSE-KC[l]: treatment group (M: 2, F: 12)=mean 16.36 (SD 5.09), control group (M: 2, F: 12)=mean 16.90 (SD 4.91)	Treatment group: mean 77.36 (SD 5.79), control group: mean 78.55 (SD 7.71)

Study, year	Residential settings	Region	Study design	Intervention (if any)	Sample size	Participant cognitive status	Participant age (y)
Kolberg et al [46], 2021	Nursing home dementia units	Europe	Randomized controlled trial	A 24-week cluster-randomized, placebo-controlled trial with an intervention involving ambient light administered at 1000 lux and 6000 K from 10 AM to 3 PM, with gradually increasing and decreasing light levels before and after this interval	M: 22, F: 47	MMSE score: median 4.0 (IQR 1.0-9.2)	Median 85.0 (IQR 79.0-88.0)
Konis et al [47], 2018	Dementia care communities	North America	Quasi-experiment	The daylight exposure of participants was increased by taking them to the perimeter zone of a daylit room from 8 AM to 10 AM for socialization over a period of 12 weeks; the perimeter zone was the region of the room within 3 m from the windows; it was administered every day throughout the study	M: 21, F: 56	Alzheimer disease: daylight group=17 (37%) patients, control group=8 (25.8%) patients; frontotemporal dementia: daylight group=1 (2.2%) patient, control group=1 (3.2%) patient; Lewy body dementia: daylight group=0 (0%) patients, control group=1 (3.2%) patient; vascular dementia: daylight group=2 (4.3%) patients, control group=1 (3.2%) patient; dementia not otherwise specified: daylight group=19 (41.3%) patients, control group=17 (54.8%) patients; mild cognitive impairment: daylight group: 6 (13%) patients, control group=2 (6.5%) patients; not specified: daylight group=1 (2.2%) patient, control group=1 (3.2%) patient	Mean 85.3 (SD 7.0)
Lee et al [48], 2016	Long-term care units (Richmond Manor and Maple Manor)	North America	Cohort study	—	M: 6, F: 6	Early or middle stage of ADRD	Richmond Manor: mean 82.9 (SD 8.9), Maple Manor: mean 77.6 (SD 9.8)
Lin et al [49], 2018	Dementia care centers	Asia	Quasi-experiment	Experimental group participants received 20 minutes of white noise consisting of ocean, rain, wind, and running water sounds between 4 PM and 5 PM daily over a period of 4 weeks, with volume maintained at 55-70 dB; the comparison group received routine care	M: 23, F: 40	NR[m]	Experimental group: mean 81.57 (SD 10.52), comparison group: mean 79.29 (SD 8.41)

Study, year	Residential settings	Region	Study design	Intervention (if any)	Sample size	Participant cognitive status	Participant age (y)
Liu et al [50], 2021	Nursing homes, communities	Asia	Quasi-experiment	Participants in the experimental group were exposed to ambient light at 2500 lux for at least 60 minutes per day from 9 AM to 10 AM, Monday through Friday, over 8 weeks	M: 7, F: 28	Mild dementia: 10, moderate dementia: 16, severe dementia: 9	60-95
Liu et al [51], 2022	Nursing homes	Asia	Quasi-experiment	Participants in the experimental group were exposed to ambient light at 2500 lux for at least 60 minutes per day from 9 AM to 10 AM, Monday through Friday, over 8 weeks	M: 7, F: 28	Mild dementia: 10, moderate dementia: 16, severe dementia: 9	60-95 experimental group: mean 83.9 (SD 7.1), comparison group: mean 80.2 (SD 7.2)
McCurry et al [52], 2011	Personal homes	North America	Randomized controlled trial	Intervention 1: participants attempted to reach the goal of walking for 30 minutes continuously per day; intervention 2: participants sat in front of a light box (SunRay; The SunBox Company) for 1 hour per day, timed to be within 2-hour window before the participants' habitual bedtime; intervention 3: combination treatment comprising walking, light exposure, and guided sleep education (NITE-AD[n])	M: 59, F: 73	MMSE scores: walking group=mean 19.2 (SD 7.7); light group=mean 17.9 (SD 7.0), NITE-AD group=mean 19.1 (SD 5.8), control group=mean 18.7 (SD 6.9)	Walking group: mean 82.2 (SD 8.5), light group: mean 80.6 years (SD 7.3), NITE-AD group: mean 80.0 (SD 8.2), control group: mean 81.2 (SD 8.0)
Olsen et al [53], 2016	Personal homes, nursing homes	Europe	Cross-sectional study	—	M: 67, F: 126	Nursing home residents (Clinical Dementia Rating Scale): mild dementia=9%, moderate dementia=43.6%, severe dementia=47.4%; home-dwelling people with dementia (Clinical Dementia Rating Scale): mild dementia=43.5%, moderate dementia=47%, severe dementia=5.2%	Nursing home residents: mean 84.6 years (SD 6.50), home-dwelling people with dementia: mean 82.6 (SD 6.84)
Onega et al [54], 2016	Long-term care units	North America	Randomized controlled trial	Individuals were seated approximately 27 inches away from a bright light that delivered 10,000 lux of light (treatment arm) or a low-level light that delivered 250 lux of light (control) for 30 minutes twice a day 5 times a week for 8 weeks	M: 17, F: 43	MMSE scores ranged from 0 to 22; participants were classified into 3 categories based on the MMSE scores: 7 (11.7%) had mild dementia, 11 (18.3%) had moderate dementia, 42 (70%) had severe dementia	Mean 82.6 (SD 9.6)

Study, year	Residential settings	Region	Study design	Intervention (if any)	Sample size	Participant cognitive status	Participant age (y)
Riemersma-van der Lek et al [55], 2008	Group care facilities	Europe	Randomized controlled trial	Random assignment by facility to long-term daily treatment with whole-day bright (approximately 1000 lux) or dim (approximately 300 lux) light and by participant to evening melatonin (2.5 mg) or placebo for a mean of 15 (SD 12) months (maximum period of 3.5 years)	M: 19, F: 170	Treatment group, placebo: MMSE score=mean 14.3 (SD 7.0); treatment group, light: MMSE score=mean 14.5 (SD 6.2); treatment group, melatonin: MMSE score=mean 15.3 (SD 5.3); treatment group, light+melatonin: MMSE score=mean 14.7 (SD 6.8)	Mean 85.8 (SD 5.5)
Saidane et al [56], 2023	Nursing homes	Europe	Pretest-posttest study	Naturalistic light systems that replicated the spectrum distribution of natural light from dusk to dawn	5	NR	NR
Sloane et al [57], 2007	Long-term care units	North America	Quasi-experiment	The study used a cluster-unit crossover experimental design to evaluate 4 ambient lighting conditions: morning (7-11)=high-intensity light, evening (4-8)=high-intensity light, all day (7 AM-8 PM)=high-intensity light, and industry minimum standard lighting	M: 35, F: 31	Mild to moderate cognitive impairment: 21 (31.8%), severe cognitive impairment: 31 (47%), very severe cognitive impairment: 14 (21.2%)	Mean 79
Son and Kwag [58], 2020	Center for dementia	Asia	Quasi-experiment	In the experimental group, a walking program with white noise was applied 3 times a week for 4 weeks; white noise was provided by a white noise generator, with volume maintained at 40 to 50 dB; in the control group, only the walking program was applied	M: 16, F: 16	NR	Range 71-80; experimental group: mean 75.06 (2.82), control group: mean 75.31 (SD 3.07)
Tartarini et al [59], 2017	Nursing homes	Oceania	Case report or series	—	M: 14, F: 7	Psychogeriatric Assessment Scale scores of ≥10	Range 61-92
Wahnschaffe et al [60], 2017	Nursing homes	Europe	Pretest-posttest study	From midwinter on, a ceiling-mounted dynamic lighting system was installed in the common room of a nursing home and programmed to produce high illuminance with higher blue light proportions during the day and lower illuminance without blue light in the evening	M: 5, F: 7	MMSE score: mean 12.1 (SD 9.2)	Mean 79.1 (SD 11)

Study, year	Residential settings	Region	Study design	Intervention (if any)	Sample size	Participant cognitive status	Participant age (y)
Wahnschaffe et al [61], 2017	Nursing homes	Europe	Case report or series	—	M: 1, F: 19	*ICD-10*[o] criteria: Alzheimer disease=9, vascular dementia=2, frontotemporal dementia=1, Korsakoff syndrome=1, and dementia subtypes (which were not further specified)=7	Mean 83.8 years (SD 8.8)

[a]Not applicable.

[b]M: male.

[c]F: female.

[d]MMSE: Mini–Mental State Examination.

[e]MDS-COGS: Minimum Data Set Cognition Scale.

[f]S-MMSE: Standardized Mini–Mental State Examination.

[g]CPS: Cognitive Performance Scale.

[h]BIMS: Brief Interview for Mental Status.

[i]ADRD: Alzheimer disease and related dementias.

[j]GDS: Global Deterioration Scale.

[k]BCRS: Brief Cognitive Rating Scale.

[l]MMSE-KC: Korean version of the MMSE developed as part of the Korean version of the Consortium to Establish a Registry for Alzheimer's Disease assessment packet.

[m]NR: not reported.

[n]NITE-AD: Nighttime Insomnia Treatment and Education in Alzheimer's Disease.

[o]ICD-10: International Classification of Diseases, Tenth Revision.

The following sections synthesize the findings of the included studies, categorized by the indoor environmental quality factor or factors examined (Table 2).

Table 2. Summary of environmental conditions and behavioral and psychological symptoms of dementia (BPSD) outcomes examined, the subjective and objective methods of assessment, and the main results for all included studies.

Study, year	Environmental condition or conditions measured or manipulated	Subjective indoor environmental quality parameter assessment (if any)	Objective indoor environmental quality parameter assessment (if any)	Behavioral or psychological outcomes	Subjective BPSD assessment (if any)	Objective BPSD assessment (if any)	Main results
Algase et al [24], 2010	Light level, noise level, temperature, humidity, environmental ambience, crowding	Ambience scale, presence or absence of people within 8 feet of the participant	Gossen Color-Pro 3F light meter (Gossen Color-Pro 3F light meter, Bogen Photo Corp), Quest Technologies Sound Level Meter Model 2400, and RadioShack Thermometer with Indoor Humidity Gauge 63-1013	Wandering	Observations from videotapes	__[a]	Brighter light, more variation in sound levels, and a higher engaging quality of the environment were associated with wandering, and a higher soothing quality of the environment was associated with periods when wandering did not occur
Bankole et al [25], 2020	Light level, noise level, temperature, humidity, atmospheric pressure	—	Off-the-shelf sensors	Agitation, depression, sleep, quality of life, overall level of BPSD	NPI-Q[b], CMAI-C[c], PSQI[d]	Shimmer3 sensor for people with dementia and Pebble sensor for caregivers in phase 1; Pebble for both people with dementia and caregivers in phase 2	Temperature, atmospheric pressure, and time showed strong correlations with agitation, which was self-reported by the primary caregivers
Barrick et al [26], 2010	Light level	—	—	Agitation	CMAI[e], observational agitation using the presence or absence of 8 agitated behaviors	—	No therapeutic conditions improved agitation in comparison to standard lighting
Bautrant et al [27], 2019	Light level, skylike ceiling tiles, soothing streaming music, walls painted in light beige, oversized clocks in corridors	—	—	Agitation, wandering, screaming, episodes of BPSD	Number and duration of disruptive BPSD episodes were systematically collected	—	BPSD prevalence reduced after plain environmental rearrangements aimed at improving spatial and temporal orientation were put in place
Bicket et al [28], 2010	Light level	TESS-NH/RC[f]	—	Quality of life, overall level of BPSD, fall risk	NPI[g]	—	The Assisted Living Environmental Quality Score was positively associated with the Alzheimer's Disease–Related Quality of Life score (P=.01), while it was strongly negatively associated with NPI total score (P<.001) and negatively correlated with fall risk (P=.04)

Study, year	Environmental condition or conditions measured or manipulated	Subjective indoor environmental quality parameter assessment (if any)	Objective indoor environmental quality parameter assessment (if any)	Behavioral or psychological outcomes	Subjective BPSD assessment (if any)	Objective BPSD assessment (if any)	Main results
Bromundt et al [29], 2019	Light level	—	—	Agitation, mood, circadian rhythm (rest-activity pattern), activities of daily living, quality of life, alertness, verbal interaction, well-being, cheerfulness, memory, disturbing behavior	CMAI, VAS[h]	Wrist actimetry (Motion-Watch 8; CamNtech)	Dawn-dusk simulator exposure led to significantly better mood in the morning hours (P=.002), while it did not significantly influence circadian parameters and sleep parameters (P>.05)
Burns et al [30], 2009	Light level	—	—	Agitation, depression, sleep	CMAI, CS-DD[i], MOUSEPAD[j], CRBRS[k], sleep charts	Actiwatch (supplied by CamNtech)	Results suggested that the bright light intervention had a limited effect in reducing agitation, but it improved sleep in older adults with dementia
Cohen-Mansfield et al [31] 2010	Light level, noise level, number of persons in proximity	Environment portion of ABMI[l]	—	Engagement	Observational measurement of engagement	—	Attention and engagement were the best when light level was moderate; engagement was the best when there was a moderate level of noise; attention to the engagement stimulus was significantly higher when there were 4 to 9 people in proximity in comparison to more or fewer people (P<.01)
Cohen-Mansfield et al [32], 2011	Light level, noise level, number of persons in proximity	Environment portion of ABMI	—	Agitation	ABMI, CMAI	—	Lighting and background noise did not affect agitation significantly, which may be due to little variation in these variables and their reliance on subjective perception scales
Cohen-Mansfield et al [33], 2012	Light level, noise level, number of persons in proximity	Environment portion of ABMI	—	Pleasure	Lawton Modified Behavior Stream	—	Pleasure was most likely to occur in environments with moderate noise levels
Cohen-Mansfield [34], 2020	Light level, noise level, temperature, location, time of day, total group size	Reported by therapeutic recreation staff	—	Mood, engagement, sleepiness	GOME[l]	—	Background noise and time of day significantly affected outcome variables after controlling for participants' cognitive functioning and group topic; background noise was related with decreased engagement and increased sleepiness; there was little variation concerning temperature and light
Dowling et al [35], 2007	Light level	—	Cal LIGHT 400 calibrated precision light meter for monitoring light levels in gaze direction for each participant	Agitation, depression, overall level of BPSD, appetite or eating disorders, aberrant motor behavior, dysphoria	NPI-NH[n]	—	Bright light therapy was found not to clinically affect neuropsychiatric behaviors

Study, year	Environmental condition or conditions measured or manipulated	Subjective indoor environmental quality parameter assessment (if any)	Objective indoor environmental quality parameter assessment (if any)	Behavioral or psychological outcomes	Subjective BPSD assessment (if any)	Objective BPSD assessment (if any)	Main results
Figueiro et al [36], 2014	Light level	—	Daysimeter worn on the wrist to estimate light exposure of each participant	Agitation, depression, circadian rhythm (rest-activity pattern), activities of daily living, sleep	CMAI, CS-DD, PSQI	Daysimeter	300 to 400 lux of a bluish-white light significantly improved sleep efficiency, total sleep time, and global PSQI scores ($P<.05$) and decreased depression (CSDD) and agitation (CMAI) scores ($P<.05$)
Figueiro et al [37], 2019	Light level	—	Daysimeter as a pendant to estimate light exposure of each participant	Agitation, depression, circadian rhythm (rest-activity pattern), sleep, quality of life	CMAI, CS-DD, PSQI	Actiwatch 2 (Philips Respironics)	The experimental group had significantly improved PSQI scores compared to the control group ($P<.001$); regarding secondary outcomes, the experimental group had significantly greater improvements in depression and agitation compared to the control group ($P<.05$)
Figueiro et al [38], 2020	Light level	—	Daysimeter as a pendant to estimate light exposure of each participant	Agitation, depression, mood, sleep	CMAI, CS-DD, PSQI	Actiwatch 2 (Philips Respironics)	Long-term daily light exposure showed a positive correlation with reduced PSQI scores with increasing efficacy as the study went on; there were significant improvements in depression starting at around week 3; agitation also improved around week 9
Figueiro et al [39], 2023	Light level	—	—	Depression, circadian rhythm (rest-activity pattern), sleep	CSDD, PSQI, SDI[o]	Actiwatch 2 (Philips Respironics)	Under the active condition, both objective and subjective sleep improved significantly ($P=.02$)
Garre-Olmo et al [40], 2012	Light level, noise level, temperature	—	DT-8820 environment meter (Shenzhen Everbest Machinery Co Ltd) in each participant's bedroom and in the dining room and living room of each nursing home	Affect, mood, pain, quality of life	QUALID[p], NPI-NH, PAIN-AD[q]	—	High temperature in the bedroom was associated with lower quality of life, high noise levels in the living room were associated with low social interactions, and low lighting levels in the bedroom were associated with more severe negative affective mood
Hickman et al [41], 2007	Light level	—	—	Depression	CSDD	—	The treatment had different effects on men and women; study results did not support the use of ambient bright light therapy as a treatment for depressive symptoms in persons with dementia; however, a subpopulation of persons with dementia may benefit from this intervention
Hjetland et al [42], 2021	Light level	—	—	Mood, circadian rhythm (rest-activity pattern), activities of daily living, cognition, sleep, overall level of BPSD	NPI-NH	Actiwatch 2 (Philips Respironics)	There was discrepancy in the subjective and objective sleep measures; actigraphically measured sleep outcomes showed no statistically significant differences between patients in the intervention and control groups; however, better sleep was reported using the SDI in the intervention group

Study, year	Environmental condition or conditions measured or manipulated	Subjective indoor environmental quality parameter assessment (if any)	Objective indoor environmental quality parameter assessment (if any)	Behavioral or psychological outcomes	Subjective BPSD assessment (if any)	Objective BPSD assessment (if any)	Main results
Jao et al [43], 2015	Light level, noise level, environmental ambience, crowding, staff familiarity, environmental stimulation	PEAR[r]-Environment subscale	Gossen Color-Pro 3F light meter (Bogen Photo Corp) and the Quest Technologies Sound Level Meter	Apathy	PEAR-Apathy subscale	—	Among the 6 characteristics of environmental stimulation, stimulation clarity and stimulation strength were the only 2 significant factors affecting apathy scores; ambience, crowding, staff familiarity, light, and sounds did not show significant effects on apathy
Joosse [44], 2011	Noise level, number of persons in proximity, spatial environment	—	SoundPro DL 2 (Quest Technologies) sound level meter	Agitation	Wisconsin Agitation Inventory	—	After controlling for potential confounding variables of mental status, hearing impairment, and visual impairment, sound was found to contribute to agitation
Kim et al [45], 2021	Light level	—	—	Depression, sleep, overall level of BPSD	KNPI-Q[s], CSDD-K[t], PSQI, VAS-GV[u], VAS-GA[v]	Actiwatch 2 (Philips Respironics)	The study findings suggest that morning blue-enriched light therapy has a benefit in improving sleep and cognitive function in patients with Alzheimer disease
Kolberg et al [46], 2021	Light level	—	—	Agitation, affect, anxiety, delusion, depression, hallucination, mood, circadian rhythm (rest-activity pattern), sleep, overall level of BPSD	CSDD, NPI-NH	—	Compared to the control group, the intervention group had a larger reduction on the composite scores of both the CSDD and the NPI-NH, as well as on the NPI-NH Affect subsyndrome and the CSDD mood-related signs subscale at follow-up after 16 weeks
Konis et al [47], 2018	Light level	—	Digital charge-coupled device spectrometer	Depression, overall level of BPSD	CSDD, NPI-NH	—	Participants in the daylight intervention experienced an average decrease over the trial in the NPI-NH and CSDD scores, while the control participants showed average but nonsignificant increases in both NPI-NH and CSDD scores; difference in outcome changes of the intervention group achieved statistical significance for the CSDD but not for the NPI-NH
Lee et al [48], 2016	Number of persons in proximity, spatial environment, social environment, crowding, light level	TESS-NH[w]	—	Mood, social engagement	MOSES[x]	—	Residents who stayed in the traditional, large-scale unit showed significantly worse decline in irritable behaviors compared to those who stayed in the small-scale, home-like unit across time; the small-scale, home-like unit had significantly better ratings in stimulation (lighting, visual and tactile stimulation, and noise) as well as personalization according to the TESS-NH

Light

Overview

Of the 38 included papers, 34 (89%) examined light as a factor associated with BPSD. Of these 34 studies, 20 (59%) were conducted in North America [24-26,28,31-39,41,43, 47,48,52,54,57], 3 (9%) in Asia [45,50,51], and 11 (32%) in Europe [27,29,30,40,42,46,53,55,56,60,61]. Of the 34 studies, 31 (91%) were conducted in long-term care settings, 2 (6%) were conducted in the participants' personal residence [25,52], and 1 (3%) was conducted in both the personal residence and the long-term care setting [53]. The median sample size was 63 (IQR 20-122; range 5-326) participants, and the participants' average age ranged from 73 to 87 years. Light was measured using a variety of light meters or subjective perception scales such as the Therapeutic Environment Screening Survey for Nursing Homes [62] and the environment portion of the Agitation Behavior Mapping Instrument (ABMI) [63].

Agitation

Of the 34 studies, 16 (47%) examined the effect of light on agitation either as a syndrome or related to individual agitated behaviors such as wandering or screaming [24-27,29,30,32,35-38,46,54-56,60]. Of these 16 studies, 14 (88%) examined the effect of changing light exposure in RCTs (n=6, 43%) [30,35,37,46,54,55] or quasi-experimental study designs (n=8, 57%) [26,27,29,32,36,38,56,60], while 2 (12%) examined the effect of light on agitated behaviors in a purely observational or natural history study [24,25]. Among the light therapies studied were bright light therapy [30,35,46,54,55] and outdoor environment simulations, such as dawn-dusk simulation [29,56]. A wide range of light intensities was deployed in these light therapies, ranging from 1000 lux [36] to 10,000 lux [54]. The duration and time of day of application of these light therapies were heterogeneous as well; for example, in the study by Onega et al [54], bright light therapies were applied twice a day (once in the morning and once in the afternoon), while in the study by Kolberg et al [46], light therapy was applied from 10 AM to 3 PM with varying light levels before and after this interval. Due to the heterogeneity of the light therapies and study designs, direct comparison across the studies was infeasible. Among these 16 studies, in addition to the multiple approaches to applying light therapy, there was also heterogeneity in the way agitation was assessed. The Cohen-Mansfield Agitation Inventory [64], which measures the frequencies of 29 different agitated behaviors, was the scale used most commonly to assess the level of agitation in people living with dementia across weeks. Other scales used included the Pittsburgh Agitation Scale [65] and the ABMI [63], both of which are based on direct observations of the patient.

The 6 RCTs, which ranged in study duration from 8 weeks to 15 months, used bright light [30,35,37,46,54,55]. However, the results from the RCTs were conflicting. The symptoms of agitation or restlessness were reduced in 3 (50%) of the 6 RCTs [37,54,55] but not in the remaining 3 (50%) [30,35,46]. The lack of improvement in agitation after bright light exposure in these studies [30,35,46] could be due to measurement errors in the subjective assessment of either light level or level of agitation or because of changes in medications not being tracked, as suggested by the authors.

The additional 10 light studies included 8 (80%) quasi-experimental studies [26,27,29,32,36,38,56,60] and 2 (20%) observational studies [24,25]. Of the 8 quasi-experimental studies, 5 (62%) reported that light therapy could reduce agitated behaviors [27,36,38,56,60], while 3 (38%) showed no effect [26,29,32]. Of these 3 studies, 1 (33%) did not yield significant results in part due to a lack of variation in light level [32]. Of the 2 observational studies, 1 (50%) showed that brighter light was associated with wandering [24].

The study by Figueiro et al [38] showed that the effects of light therapy on patients' agitation varied depending on the participants' cognitive status. The study, which examined the effect of long-term, all-day exposure to circadian-effective light on the sleep, mood, and behavior in persons with dementia, revealed that the lighting intervention was more effective for people with severe dementia than for those with mild or moderate dementia in reducing agitation [38].

Disturbed Sleep and Circadian Rhythm

Of the 17 studies examining the relationship between light and sleep or circadian rhythm [25,29,30,34,36-39,42,45,46,51-53,57,60,61], 5 (29%) were RCTs [30,37,42,46,52], 5 (29%) were quasi-experimental studies [29,39,45,51,57], 3 (18%) were pretest-posttest studies [36,38,60], 2 (12%) were cross-sectional studies [34,53], and 2 (12%) were case series studies [25,61]. All studies that administered light therapy led to better sleep outcomes such as higher sleep efficiency [36], longer nighttime sleep duration [57], fewer awakenings [51], higher circadian rhythm stability [51], or lower Pittsburgh Sleep Quality Index scores indicating better sleep quality [37].

There can be discrepancies between self-reported sleep quality and objectively measured sleep quality. In the study by Hjetland et al [42], ambient bright light treatment was administered to nursing home patients with dementia in a placebo-controlled RCT. While better sleep was reported using the Sleep Disorders Inventory in the bright light therapy group than in the standard lighting group at weeks 16 and 20, actigraphically measured sleep outcomes showed no statistically significant differences between the 2 groups.

Mood-Related Symptoms

Of the 13 studies involving lighting that addressed the relationship between symptoms of depression in people living with dementia and light in the environment [25,30,35-39,41,45-47,54,55], 6 (46%) were RCTs [30,35,37,46,54,55], 4 (31%) were quasi-experimental studies [39,41,45,47], 2 (15%) were pretest-posttest studies [36,38], and 1 (8%) was a case series [25]. A decrease in depressive symptoms was reported in 9 (75%) of the 12 lighting intervention studies [30,36-39,46,47,54,55]; for example, in the RCT described in the study by Onega et al [54], those who were exposed to bright light over a 2-week period showed a significant improvement in depressive symptoms (*P* values ranging from .001 to .017 for DSAOA, DMAS-17, and Cohen-Mansfield Agitation Inventory [CSDD]) while those in the placebo control group showed no improvements in their depressive symptoms. In the quasi-experimental study by Konis et al [47], the participants in a daylight intervention experienced a decrease over the trial in the Cornell Scale for Depression in Dementia (CSDD) score, while the control participants showed a statistically nonsignificant increase in the CSDD score (a higher CSDD score indicates more severe depression). In a pretest-posttest experimental study by Figueiro et al [36], 300 to 400 lux of a blueish-white light was found to significantly decrease depressive symptoms as measured by the CSDD. Some of the studies (2/12, 17%) reported that the efficacy of a lighting intervention is dependent on participants' characteristics. In the study by Hickman et al [41], analysis indicated a sex-by-treatment interaction. Significant sex differences were found in CSDD scores in response to evening light, all-day light, and standard lighting. Male participants experienced significantly more depressive symptoms under morning light than under standard lighting (*P*=.007). By contrast, female participants experienced fewer depressive symptoms under

morning light than under standard lighting, although this result was not statistically significant (*P*=.09).

Similarly, the study by Bromundt et al [29], in which a visual analog scale was used to assess mood, indicated that the improvement in mood from dawn-dusk simulation was dependent on age. In the study, the younger subgroup experienced a stronger positive effect from dawn-dusk simulation on mood [29].

The study by Jao et al [43] examined the effect of light on apathy. The study, which was a case series of people living with dementia in nursing home or assisted living settings, assessed apathy by rating 14 separate 20-minute videos on different days per participant using the Person-Environment Apathy Rating–Apathy subscale [66]. Ambient light (and sound) measurements were collected during the 20-minute video sessions. Light level was found to have had no significant effect on apathy.

The RCT conducted by Kolberg et al [46] in nursing home dementia units with 69 participants examined the effect of light on anxiety and found that the group that received bright light treatment as the intervention had a larger reduction on the composite score of the Neuropsychiatric Inventory–Nursing Home version Affect subsyndrome, which indicated better improvement in depression and anxiety at follow-up after 16 weeks compared to the control group.

Noise

Overview

Of the 11 studies that examined the relationship between noise and dementia-related behaviors, 5 (45%) were experimental studies [31-33,49,58], 5 (45%) were cross-sectional observational studies [24,25,34,40,44], and 1 (9%) was a case study report [43]. Of these 11 studies, 8 (73%) were conducted in North America [24,25,31-34,43,44], 2 (18%) in Asia [49,58], and 1 (9%) in Europe [40]. Of the 11 studies, 10 (91%) were conducted in long-term care settings, and 1 (9%) was conducted in participants' private home environments [25]. The median sample size was 69 (IQR 38-193; range 10-193) participants, and the participants' average age ranged from 75 to 86 years. Noise was measured using objective sound level meters in 10 (91%) of the 11 studies, while 1 (9%) study [32] used the environment portion of the ABMI [67].

Agitation and Wandering

Of the 5 observational studies, 2 (40%) examined the relationship between noise and agitation among participants with dementia [25,44], and 1 (20%) of the 5 experimental studies aimed to decrease agitation using a white noise intervention [49]. Noise level did not distinguish between episodes of agitation in 1 (50%) [25] of the 2 observational studies, although the study was limited by sample size (10 participants) [25]. In addition, the study by Bankole et al [25] was the only study to examine environmental conditions in the private home setting, which may be distinct from long-term care settings in terms of the effects of noise on agitation. The observational study by Joosse [44], which had 53 participants and used a sound level meter to measure noise levels, found that a higher accumulation

of exposure to noise over a day was significantly predictive of agitated behavior in residents with dementia in a long-term care facility [44]. The study by Cohen-Mansfield et al [32] did not find an association between noise and agitation in residents in nursing homes. However, the study was limited by a lack of objective measurement of sound. Finally, in the study by Lin et al [49], an intervention providing daily ambient white noise (55-70 dB) for 20 minutes in the afternoon over a 4-week period significantly decreased the frequency of agitated behavior for participants in the experimental group but not for those in the control group, suggesting that the type of noise, rather than an absence of noise, may be calming.

The observational study by Algase et al [24] examined the effect of noise levels on wandering behavior. In the study of 122 nursing home residents, greater variation in ambient noise level was associated with periods of wandering. There was a significant increase in the risk of wandering (odds ratio 1.09) per SD of variation in ambient noise level [24].

Mood-Related Symptoms

The effect of noise on symptoms related to aspects of mood (apathy, affect, or anxiety) was considered in 7 studies that examined associations with depression [25], apathy [31,43], affect or mood [33,34,40], and anxiety [58]: 3 (43%) quasi-experimental studies [31,33,58], 2 (29%) cross-sectional studies [34,40], and 2 (29%) case series studies [25,43]. When noise levels were moderate, rather than low or high, studies found that participants were more highly engaged (ie, less apathetic) [31,34,40] and exhibited greater pleasure or a more positive attitude [33,34]. High levels of background noise in particular were related to less engagement in 2 (67%) of the 3 studies that examined affect or mood [34,40] but were not related to negative affect, leading the authors to conclude that high background noise may cause participants to become less attuned to their environment and bored or sleepy but not uncomfortable or upset [40]. Another study provided evidence of the need for stimulating sound: Jao et al [43] did not find an association between apathy and overall noise level but did find an association between apathy and a lack of clear, discernible sound stimuli (ie, only chaotic background noise). Finally, signs of anxiety in participants with dementia were decreased with an intervention that applied white noise during a walking program in the experimental group only [58].

Temperature or Humidity

Of the 5 studies that examined the relationship between temperature or humidity and BPSD [24,25,34,40,59], 3 (60%) were cross-sectional studies [24,34,40], and 2 (40%) were case series [25,59]; furthermore, 3 (60%) were conducted in North America [24,25,34], 1 (20%) in Europe [40], and 1 (20%) in Oceania [59]. Of the 5 studies, 4 (80%) were conducted in nursing homes or assisted living units [24,34,40,59], while 1 (20%) was conducted in participants' private home environments [25]. The median sample size in these studies was 69 (IQR 21-122; range 10-160) participants. The participants' mean age ranged from 79.7 to 86.6 years.

The case series study by Tartarini et al [59] found that the level of agitation of participants with dementia in a nursing home

facility increased significantly when the indoor average temperatures diverged from 22.6 °C. At the same time, the duration of exposure to high temperature (>22.6 °C) and low temperature (<22.6 °C) was linearly correlated with Cohen-Mansfield Agitation Inventory scores. In the cross-sectional studies by Algase et al [24] and Cohen-Mansfield [34], the authors suggested that there was not enough variation in the indoor temperature level or humidity level to identify a relationship with participants' behaviors.

Multiple Indoor Environmental Quality Parameters

A total of 8 studies [24,25,31-34,40,43] examined multiple indoor environmental quality parameters (refer to Table 2 for the combination of parameters examined in each study). Of these 8 studies, 7 (88%) were conducted in North America [24,25,31-34,43], and 1 (12%) was conducted in Europe [40]; furthermore, 3 (38%) were quasi-experimental studies [31-33], 3 (38%) were cross-sectional studies [24,34,40], and 2 (25%) were case series [25,43]. While the indoor environmental quality parameters—light level and noise level—were measured in the quasi-experimental studies, they were not manipulated. The intervention used in the quasi-experimental studies involved 9 categories of stimuli not related to the indoor environmental quality parameters.

Of the 8 studies, 5 (62%) reported some associations between indoor environmental quality parameters and BPSD. One of the themes that these studies suggested was that both overstimulation and understimulation from indoor environmental quality parameters can worsen BPSD. Algase et al [24] reported that brighter light and more variations in sound levels were associated with wandering. The studies by Cohen-Mansfield et al [31,33] that examined the effect of the physical environment on pleasure, engagement, and mood had similar findings. It was found that in nursing homes, pleasure was most likely to be experienced by participants with dementia in environments with moderate noise levels [33]. In addition, attention and engagement duration in participants with dementia were higher when light was normal in comparison to a dark room, and their attention and attitude were significantly less positive when the lighting in the room was bright than when the lighting was normal [31]. In the same study, all indicators of engagement significantly favored a moderate level of noise over no noise or low noise levels, and engagement duration was significantly longer for a moderate level of noise compared to high and very high levels of noise.

The cross-sectional study by Garre-Olmo et al [40] measured the physical environment in multiple spaces within the nursing home and found that indoor environmental quality parameters (light, temperature, and noise) in individual living spaces in the nursing home were uniquely associated with participants' quality of life, behaviors, and mood as measured with the Quality of Life in Late-Stage Dementia Scale; for example, the authors found that low lighting levels in the bedroom were associated with signs of negative affect, high temperature in the bedroom was associated with lower quality of life experienced by the participants, and high noise levels in the living room were associated with low levels of social interaction.

To examine the relationship between multiple environmental factors and agitation in persons with cognitive decline in their home environments, Bankole et al [25] installed environmental sensors in people's homes that provided continuous data over a 30-day period; in addition, the participants with cognitive decline wore actigraphy devices that provided objective measures of their activity level continuously. Furthermore, 10 caregivers used smartwatches or tablets to report episodes of agitation experienced by the people with cognitive decline in real time, which enabled more direct analysis of the relationship between the behaviors and contemporaneous environmental conditions. Personalized neural networks were built for 6 dyads, which predicted episodes of agitation with light level as a predictor. These networks achieved F_1-score values, which are measures of predictive performance in binary classifications, ranging from 86.12% to 97.07%. F_1-score values can range from 0% to 100%, with a higher F_1-score indicating a better predictive performance. Regarding temperature, the study [25] found that temperature showed strong positive correlation with Teager energy scores from actigraphy device data, which are measures of the aggregate energy of movement [68] and were associated with the agitation exhibited by the people living with dementia.

Of the 8 studies, 3 (38%) failed to identify a link between multiple domains of environmental conditions and BPSD. Jao et al [43] studied the association between apathy in residents with dementia in long-term care facilities and the characteristics of care environments, which included light level, noise level, environmental ambience, crowding, staff familiarity, and environmental stimulation. The authors found that light and sound levels did not show statistically significant effects on apathy [43]. Cohen-Mansfield et al [32] found that lighting and background noise were not associated with levels of agitation in nursing home residents with dementia but that may be due to small variations in these factors. Similarly, Cohen-Mansfield [34] reported no association between noise and mood in people with dementia attending recreational groups.

As seen in Table 2, of the 38 included studies, 6 (16%) relied solely on self-report data for measuring the environment, 13 (34%) used only sensors, and 2 (5%) use both sensors and self-report data, while the environment was not measured but manipulated in 17 (45%) studies. For measurements of BPSD in people living with dementia, of the 38 studies, 36 (95%) used informant-report scales, such as the Neuropsychiatric Inventory Questionnaire; less than half of these studies (n=16, 44%) also used behavioral sensors such as actigraphy to provide objective data.

Discussion

Overview

The definition of environment encompasses several major elements: physical environment (eg, light level, noise level, temperature, and humidity), social environment (eg, number of people in proximity), and built environment (eg, furnishings). The focus of this scoping review is on the effects of the indoor environmental quality parameters pertaining to light, noise,

temperature, and humidity on BPSD. Given the fact that most older individuals, including people living with dementia, spend most of their time indoors, better understanding of how these physical indoor environmental quality parameters may affect behavioral health is critical. Overall, this review outlines preliminary evidence on the notable linkages between indoor environmental quality parameters and BPSD. Further research remains to be conducted in the field.

Principal Findings

The evidence base suggests that light during the day is helpful in modulating circadian rhythm, as well as alleviating sleep disturbance and mood-related disorders. Overall, overstimulation and understimulation of environmental factors can lead to challenging behaviors in people living with dementia; for example, when the environment exhibits high levels or low levels of noise, people living with dementia may exhibit more challenging or disturbing behaviors [44,49]. Similarly, challenging behaviors may be associated with the ambient temperatures experienced by the people living with dementia because there was more agitation observed when the environment was either relatively too hot or too cold for the person living with dementia [59]. Such findings are consistent with the existing models that explain the causes of BPSD, including the unmet needs model [69] and the progressively lowered stress threshold model [70]. Ultimately, finding the proper balance of environmental factors for providing the most personal comfort and quality of life for people living with dementia and caregivers may help to minimize the occurrences of BPSD.

Future Directions of Research

Light is the most researched indoor environmental quality parameter. Most studies on light therapy have shown that it improves sleep and mood in people living with dementia. However, the findings regarding its effect on agitation are conflicting and warrant further research.

The evidence base generally suggests that when noise levels exceed tolerable ranges, behavioral symptoms become more frequent and severe. Studies indicate that both the time duration of exposure to noise and the type of noise exposure could contribute to behavioral symptoms. Future research should explore these factors further.

Studies examining the effects of temperature or humidity on BPSD are largely observational. There exists a need to better understand how thermal comfort affects BPSD in people living with dementia, especially because there are studies suggesting that older adults may need a higher ambient temperature to attain thermal comfort compared to younger adults [71,72].

Environmental factors were often evaluated using self-reported data, which can be prone to biases. The lack of objective measurement of the environment makes measuring and linking the specific effects of the indoor environmental quality parameters on the behaviors of people living with dementia difficult. Of the 38 included studies, 30 (79%) focused on a single environmental factor, measured over relatively short periods of time, limiting the ability to examine more holistically how the environment affects BPSD. To some degree, this single-domain focus may reflect the complexity as well as the cost of deploying multiple sensor types in multiple indoor spaces. As technology advances, indoor environmental quality parameter sensors are expected to become more affordable and scalable.

Although most environmental exposure occurs indoors, studies need to consider in parallel the outdoor environment in terms of its effects on behavior, which is especially important for studies conducted in personal residences because people also spend time outdoors. Going forward, studies should adopt a more holistic approach by deploying sensors to objectively and longitudinally measure the total environment.

While environmental conditions can be objectively sensed and measured, very often, BPSD of the people living with dementia are either reported by the person affected by dementia or observed and interpreted as occurring by an external observer (usually a caregiver) present when the behavior occurs. In this scoping review, 36 (95%) of the 38 included studies relied on these self-reports or observer reports of BPSD. This type of reporting may contain subjective bias. In addition, a variety of scales have been used for assessing the occurrences of BPSD, which differ in their content, structure, and timing of recall. This likely adds to imprecision in comparing the results across multiple studies. More research is needed to examine how different scales for evaluating BPSD relate to each other and, in turn, to multiple environmental conditions. At the same time, whenever possible, the assessment of BPSD should be corroborated with unobtrusive technology such as actigraphy, which can provide objective data.

As evidenced by multiple studies in this review, the effect of the environment on people living with dementia may be dependent on age, sex, and cognitive state. In addition, manifestations of BPSD may be unique for each person living with dementia as well. Recent work by Iaboni et al [73] showed that the features from wearable multimodal sensors varied in their importance to their predictive models for agitation by both individual and behavior type. Finding the optimal environment for each person living with dementia will help support aging in place, which will improve their quality of life and lower the cost of health care. This may be best achieved by being able to examine the environment and behavior at the individual level with a goal of achieving person-centered assessments of well-being in their environment. The use of continuous multimodal sensing data and frequent self-report facilitates the ability to evaluate and analyze data at the individual or "n-of-1" level [73-75], supporting the principle that each individual is unique. Care providers need to know the unique environments, needs, and preferences of each person with dementia to provide the best care and minimize troubling BPSD. Future research should seek to build effective computational models that will incorporate multiple continuous data streams, both environmental and behavioral, that will predict the occurrences of BPSD so that proactive intervention can be implemented [25].

Implications for Clinical Practice and Policy

At a macro level, the findings of this review, although they are rudimentary, can help inform the design of long-term care

facilities and residential homes for people living with dementia. Individual assessments of responses to environmental factors can be conducted upon admission; for example, large windows may be used in long-term care facilities to let in sunlight, and this should be supplemented by a dawn-dusk simulation system to address the excessive, or lack of, sunlight in different seasons to modulate residents' sleep and circadian rhythm. In addition, the temperature in long-term care facilities and older adults' homes should be kept at an optimal range that would maximize the comfort of residents. Moreover, quiet flooring and sound-absorbing panels may be used in the long-term care facilities to reduce the noise level; as evidenced by the studies in this review, overly stimulating or noisy environments can increase BPSD. These measures may increase the cost of building and sustaining these long-term care facilities because, for example, maintaining a narrow temperature range can place additional strain on heating, ventilation, and air-conditioning systems in these facilities and may not be energy efficient. However, if the long-term care facilities are more attuned to the needs of people living with dementia, it may result in a decrease in BPSD, improving the quality of life of the people living with dementia and the caregivers as well. This would reduce staff burnout and turnover, ultimately lowering health care costs. Implementing such measures on a broad societal level requires further cost-benefit analysis.

Limitations

This scoping review has limitations. One of the limitations is that we included studies with heterogeneous designs (eg, observational or experimental), which made the synthesis of results difficult. However, 1 of the aims of this scoping review was to provide an overview of the current state of knowledge regarding the relationship between indoor environmental quality parameters and BPSD. As such, heterogeneous studies were included. Another limitation is that only articles published in English were included. Moreover, only a subset of indoor environmental factors (light level, noise level, temperature, and humidity) were included in this review, while there are other factors relating to BPSD as well, such as psychosocial and biological influences [76]. Notably, this review did not include indoor air quality, another environmental factor that increasingly can be assessed objectively in situ. Air quality has been associated with depression and anxiety in older adults based on spatiotemporal models [77]. A recent study suggested that total volatile organic compound level, among other indoor factors, was significantly correlated with specific areas where behavioral changes occurred in people with moderate to severe dementia in a nursing home [78]. This review only provides evidence for the relationship between a subset of the indoor environmental quality parameters and BPSD, but the relationship likely is best interpreted in a much larger context.

Conclusions

This review suggests that indoor environmental quality parameters pertaining to light level, noise level, temperature, and humidity may be associated with BPSD. An environment that maximizes the comfort of people living with dementia may decrease their BPSD. Most of the studies (34/38, 89%) in this scoping review pertained to the environmental factor light level, while relatively few studies (5/38, 13%-11/38, 29%) examined the relationship between the remaining indoor environmental quality parameters and BPSD. Among the included studies, there were conflicting findings in the relationship between bright light and agitation, which will need further research. A variety of subjective scales were used to assess the environment and BPSD, which makes synthesizing and comparing results across studies difficult. Going forward, as computational methods and objective sensing technology advance and become more affordable, the behaviors of people living with dementia and their environments should be measured holistically and objectively so that future nonpharmacological intervention can be evidence based.

Conflicts of Interest

The Oregon Health & Science University (OHSU), ZB, and JK have a financial interest in Life Analytics, Inc, a company that may have a commercial interest in the results of this research and technology. This potential conflict of interest has been reviewed and managed by OHSU. All other authors declare no other conflicts of interest.

Abstract

Background: Mental disorders have ranked among the top 10 prevalent causes of burden on a global scale. Generative artificial intelligence (GAI) has emerged as a promising and innovative technological advancement that has significant potential in the field of mental health care. Nevertheless, there is a scarcity of research dedicated to examining and understanding the application landscape of GAI within this domain.

Objective: This review aims to inform the current state of GAI knowledge and identify its key uses in the mental health domain by consolidating relevant literature.

Methods: Records were searched within 8 reputable sources including Web of Science, PubMed, IEEE Xplore, medRxiv, bioRxiv, Google Scholar, CNKI and Wanfang databases between 2013 and 2023. Our focus was on original, empirical research with either English or Chinese publications that use GAI technologies to benefit mental health. For an exhaustive search, we also checked the studies cited by relevant literature. Two reviewers were responsible for the data selection process, and all the extracted data were synthesized and summarized for brief and in-depth analyses depending on the GAI approaches used (traditional retrieval and rule-based techniques vs advanced GAI techniques).

Results: In this review of 144 articles, 44 (30.6%) met the inclusion criteria for detailed analysis. Six key uses of advanced GAI emerged: mental disorder detection, counseling support, therapeutic application, clinical training, clinical decision-making support, and goal-driven optimization. Advanced GAI systems have been mainly focused on therapeutic applications (n=19, 43%) and counseling support (n=13, 30%), with clinical training being the least common. Most studies (n=28, 64%) focused broadly on mental health, while specific conditions such as anxiety (n=1, 2%), bipolar disorder (n=2, 5%), eating disorders (n=1, 2%), posttraumatic stress disorder (n=2, 5%), and schizophrenia (n=1, 2%) received limited attention. Despite prevalent use, the efficacy of ChatGPT in the detection of mental disorders remains insufficient. In addition, 100 articles on traditional GAI approaches were found, indicating diverse areas where advanced GAI could enhance mental health care.

Conclusions: This study provides a comprehensive overview of the use of GAI in mental health care, which serves as a valuable guide for future research, practical applications, and policy development in this domain. While GAI demonstrates promise in augmenting mental health care services, its inherent limitations emphasize its role as a supplementary tool rather than a replacement for trained mental health providers. A conscientious and ethical integration of GAI techniques is necessary, ensuring a balanced approach that maximizes benefits while mitigating potential challenges in mental health care practices.

Introduction

Background

Mental disease is among the top 10 leading causes of global burden [1]. One out of every 2 people worldwide will develop at least 1 mental disease in their lifetime [2]. Depression and anxiety disorders are among the most prevalent mental health conditions, significantly impacting individuals' quality of life. It is estimated that approximately 280 million people worldwide are living with depression, with another 301 million experiencing anxiety [3]. These mental diseases can lead to debilitating symptoms, impairing social functioning, and affecting overall well-being [4,5]. People with depression or anxiety are also at a high risk of suicide. More than 700,000 people take their lives every year, with >77% of global suicides occurring in low- and middle-income countries [6].

Despite concerted efforts to address mental health problems, several challenges persist. Limited access to mental health services, especially in resource-limited countries, resulted in a huge treatment gap in mental health care [7]. The lack of sufficient trained mental health professionals further exacerbates this problem, leading to long waiting times for consultations and inadequate support [8]. In addition, stigma and discrimination surrounding mental health continue to hinder individuals from seeking the help they need. Many individuals feel ashamed or worried about the potential consequences of disclosing their mental health conditions, thus impeding early intervention and treatment [7].

Artificial intelligence (AI) appears as a viable alternative for facilitating accessibility, affordability, and anonymity in psychiatric diagnosis and treatment due to its capability to mimic human cognitive functions to learn and make decisions [9]. This is particularly true in machine learning (ML), which constitutes a crucial foundation for AI and focuses on the development of algorithms to learn patterns from training data. ML models can be broadly classified into 2 types: discriminative and generative [10]. In AI systems, discriminative AI models refer to a subset of AI techniques and models that focus on learning the mapping from input data to output labels or categories [10,11]. This approach aims to classify or predict outcomes based on input features without necessarily understanding the underlying relationships or causality in the data. Examples of discriminative AI include image recognition systems and diagnostic systems [11,12].

In prior research, 5 key domains have been identified using discriminative models for bipolar disorder, which include diagnosis, prognosis, treatment, data-driven research, and clinical support [13]. While discriminative AI has been a crucial component of the AI landscape over the past decade and has reached a relatively advanced stage of development, the field of generative AI (GAI), by contrast, remains in its nascent stage.

GAI is a type of ML technology that possesses the ability to automatically generate fresh output data by using the provided input data [10]. In fact, the concept of GAI is not a recent innovation but rather a technology that can be traced back to as early as 1966 with ELIZA, a chatbot designed to simulate conversation with a therapist, serving as an early example [14]. However, it is only in recent years that the culmination of extensive research and developments in AI and ML has resulted in the emergence of advanced GAI systems. Unlike traditional GAI, which primarily relies on pattern-matching or rule-based techniques [15], advanced GAI has shown superior performance in autonomously producing synthetic data, text, images, and even videos that resemble real-world examples [10]. Although such an emerging field presents a novel and exciting technological advancement, limited research has attended to inform the application landscape of GAI in mental health care. This indicates an urgent need to expand our knowledge about the state-of-the-art technologies and illuminate their possibilities in clinical and public mental health improvement.

Objective

The objective of this scoping review is to synthesize available literature describing the use of GAI for mental health to inform the current state of knowledge in this area. The findings of this review can be used to inform various stakeholders, including researchers, clinicians, and support seekers, about the potential uses and implications of GAI in the field of mental health. To achieve this purpose, the review is divided into 2 sections aiming to provide a more thorough overview of the GAI's implementation in mental health care. The first section offers a brief review of research using traditional GAI approaches. These approaches include rule-based or retrieval-based systems that rely on predefined rules or logic statements to perform tasks or generate responses. This contrasts with the discriminative AI approach that involves training models on labeled data to classify inputs into different categories or predict outcomes. The second section presents an in-depth analysis of studies that leveraged advanced GAI. The in-depth review is responsible for the identification of key use cases for advanced GAI alongside its benefits and challenges, while the brief review informs additional areas in which advanced GAI could be leveraged to facilitate the development of evidence-based interventions that can improve mental health outcomes.

Methods

Overview

A scoping review, according to Tricco et al [16], is a methodical strategy for "charting" or "mapping" a larger subject than a systematic review usually tackles. This approach becomes essential when addressing the broad problems posed by patients, physicians, politicians, and other decision makers. Therefore, to achieve the objective of this study, we conducted a scoping

XSL•FO

RenderX

review following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) [16].

Search Strategy

The search for relevant studies was conducted between January 1, 2013, and July 28, 2023. The chosen time range is critical for including the latest findings and approaches, ensuring that the research stays relevant and applicable in the evolving field of GAI development [17]. This period also witnessed the emergence of sophisticated GAI tools, which fundamentally transformed approaches to mental health care, shifting from text-based interactions to more engaging forms of mental health support [17,18]. To cover both general and health care–specific sources, we searched records within 3 reputable international databases (ie, Web of Science, PubMed, and IEEE Xplore). In addition, we expanded our search by including 2 Chinese databases, CNKI, and Wanfang, to broaden the scope of our investigation. By including these diverse data sources, we aimed to capture a wide range of literature on GAI from both global and Chinese perspectives.

Given the novelty of the advanced technology, 2 preprint servers (eg, medRxiv and bioRxiv) were consulted from January to July 2023 to inform the scope of literature delineating the use of GAI models for addressing mental health issues. This is a common practice often used by many researchers to locate other emerging applications not yet captured by peer-reviewed literature [19-22]. In order to include additional studies related to our topic, we also performed a structured search on Google Scholar for the identification of uncovered records, including gray literature, and checked the reference lists of the included studies. The search query mainly consists of 2 components: GAI and relevant terms (eg, *GAI* OR *generative model* OR *ChatGPT*) and mental health and related terms (eg, *mental health* OR *depression* OR *anxiety* OR *bipolar disorder*). The search strategies used varied depending on the characteristics of the selected databases for the search inquiry, which are provided in Multimedia Appendix 1.

This review considers only original research for inclusion. Studies were included if they were empirical, leveraged AI-based technologies to generate new outputs for mental health enhancement, and were published in English or Chinese language. However, articles presented in the form of opinions or reports or not relevant to the production of new content were excluded to ensure the relevance and accuracy of the review.

This scoping review categorizes the GAI into advanced GAI and traditional GAI approaches. Advanced GAI features state-of-the-art AI technology for creating new content, images, audio, video, or codes with tools such as ChatGPT, MidJourney, New Bing, and Dall-E2. These models often require huge computing power including a significant amount of memory, while traditional models mainly rely on predefined rules or retrieval-based algorithms with patterns created by developers on the basis of anticipated user queries [15]. Traditional GAI approaches often have limited flexibility and can only provide responses that have been explicitly programmed into their

system [23]. This differentiation was deemed essential due to the extensive volume of literature that was identified during the scoping review process. More details of the categorization of traditional and advanced GAI modeling approaches are listed in Multimedia Appendix 2.

Data Screening and Extraction

All collected records were first imported into EndNote Software (version 20; Clarivate), a literature management software for data screening and storage. Duplicate records were removed, and the remaining articles were screened for relevance based on the information provided in titles and abstracts by one reviewer. This was followed by the other reviewer performing the second stage of screening, which evaluates the full text of articles based on the inclusion and exclusion criteria. Regular scrutiny was held during the screening process to deliberate and address any ambiguities or disagreements and achieve a consensus among both reviewers [24]. A continual reassessment of the understanding of the screening criteria was undertaken. In instances where questions arise, efforts were made to retrace our steps and ascertain the accurate and consistent application of the criteria to guarantee that the screening process maintained a uniform and unbiased standard.

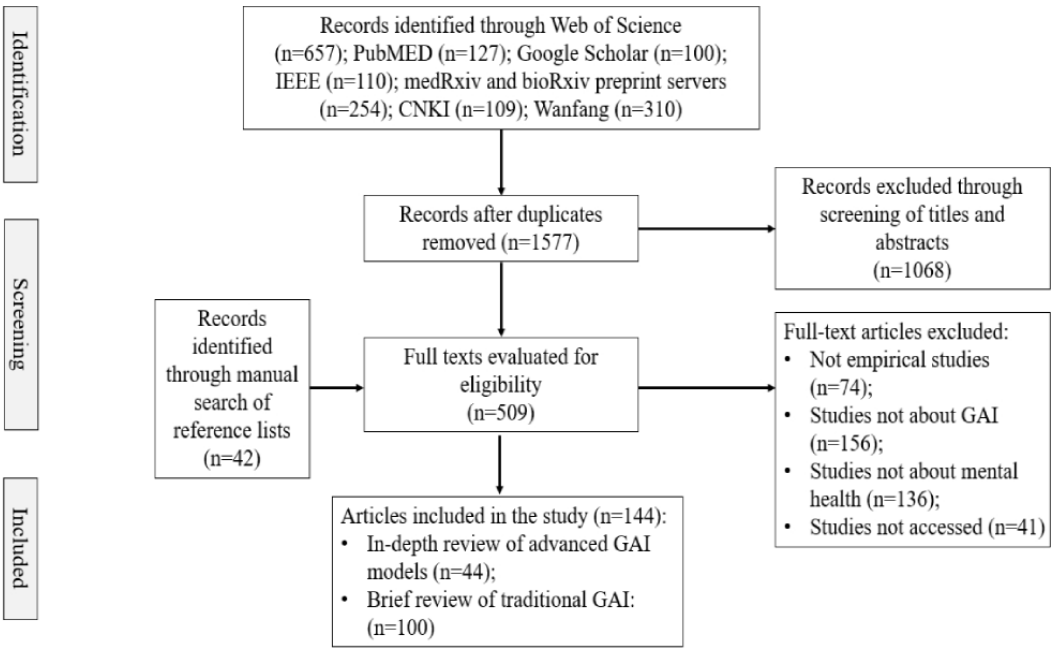
After that, pertinent data were extracted, and a thorough analysis of the application of advanced GAI models for mental health care was carried out. The first author methodically gathered these data, which contain details about the mental health issues addressed, the targeted population, the application setting, the use case, the results, the study phase, the data source, the type of approach, the delivery mechanism, and so on. The extracted data were then synthesized through a narrative method. Our goal was to categorize the GAI studies based on the extracted data. For this purpose, we modified various taxonomies found in existing literature [18,25]. We compiled the characteristics of the studies into a table and provided a narrative description. Following this, we presented an overview of the features in the studies included. The PRISMA checklist was provided in Multimedia Appendix 3 to show the completeness and transparency of the review's reporting [16].

Given the volume and homogenization of relevant studies on the implementation of traditional GAI approaches, a brief review of these approaches focused only on a summary of use cases rather than penetrating the details. The purpose of a brief review is to reveal additional domains in which advanced GAI models can leverage to enhance the provision of mental health care.

Results

Overview

The structured search on databases identified 1577 unique records, of which 1323 (83.89%) were peer reviewed and 254 (16.11%) were preprints. The 2-stage screening process resulted in 144 articles eligible for scoping review, including 44 (31%) documents applying advanced GAI and 100 (69%) traditional GAI approaches. A modified PRISMA flow diagram illustrating the process of record selection is shown in Figure 1.

Figure 1. Modified PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of document selection. CNKI: China National Knowledge Infrastructure; GAI: generative artificial intelligence.


Limited Review of Traditional GAI Models for Mental Health

Of the 100 included records that reported the use of traditional generative approaches, 97 (97%) were derived from English-language literature, while only 3 (3%) were sourced from Chinese-language literature (Multimedia Appendix 4 [3,6,12,14,17-19,21,26-53]). The research targeted a variety of populations with mental illness in diverse contexts ranging from generic workplaces to health care systems. Traditional GAI approaches in mental health care have mainly emphasized 2 capabilities: music synthesis and the generation of humanlike conversation to support mental health–related tasks. Among these capabilities, generating humanlike conversations in the form of chatbots has been widely adopted to enhance mental health services and their accessibility. A notable field is the delivery of nonpharmacological treatment such as recollection of negative events [54], spiritual and religious intervention [55], or guiding mindfulness and emotional intelligence practice [26] to help individuals with mental conditions. Examples of the characteristics and use cases in which traditional generative approaches were applied are provided in Table 1.

Table 1. Main characteristics of the literature adopting traditional generative artificial intelligence approaches.

Characteristic	Example
Mental health problems addressed	Perinatal depression [27]; postpartum mental health [28]; examination stress [29]; foreign language anxiety [56]; eating disorder [57]; autism and achluophobia [30]; suicide risk [58]; substance abuse [31]; post-traumatic stress disorder [32]; bipolar affective disorder [59]
Targeted population	Students [33]; adults [60]; aging adults [54]; return-to-work workers [61]; soldiers [62]; employees [34]; pregnant women [27]; postpartum populations [28]; patients with cardiovascular disease [59]
Application context	Workplace [61]; military [62]; school [35]; health care system [63]
Application capabilities	
Music synthesis	Music production for emotion expression [64]
Generation of humanlike conversation to support tasks	
Assistance in clinical practice	Connecting help seekers to mental health professionals [65]; promoting deep self-disclosure of help seekers for mental health professionals [36]
Screening, monitoring & prevention of symptoms	mental health condition evaluation [66]; tracking emotion disorder [67]; mental disorder prevention [68]
Self-care suggestions, resource & psychoeducation	Coping strategies [37]; customized individual suggestions [38]; resource (eg, study tips) for stress relief [69]; psychoeducation on body image and eating disorders [39]
Nonpharmacological intervention	Recollection of negative events [54]; companionship support [40]; mindfulness and emotional intelligence practice [26]; cognitive behavioral therapy delivery [35]; behavioral activation therapy delivery [14]; religious intervention [55]; promotion of positive psychology [41]; emotional support [70]
Management of symptoms	Stress management [42]; depressive disorder management [71]

In-Depth Review: Research Trend of Leveraging Advanced GAI Models for Mental Health

Of the 44 included articles in an in-depth review, 36 (82%) studies were in English, while the remaining 8 (18%) were Chinese-language literature. Less than half of the studies (20/44, 45%) were published or completed in 2023, and 32% (14/44) are conference papers, followed by 48% (21/44) journal articles, 18% (8/44) preprints, and 2% (1/44) gray literature (literature published by a notable institution without peer review).

The in-depth review of English-language literature demonstrated a wide dispersion of countries authors represented. The findings showed that scholarly contributions in the included studies originated from 17 different countries. Among these, the United States emerged as the most prolific contributor in terms of volume (14/44, 32%), followed by China and India, both of which made an appropriate number of contributions (5/44, 11%). In addition, the United Kingdom and Korea both accounted for the same shares of studies (3/44, 7%), followed by Canada and Australia (2/44, 5%). Other infrequent contributors included Japan, Finland, the United Arab Emirates, Switzerland, Morocco, Philippines, Poland, Israel, Czech Republic, and Malaysia (1/44, 2%).

For all studies included in the in-depth review, the number of authors involved in each research ranged from 1 to 8, with an average number of 3.75 (SD 1.66). Most of the included studies (17/44, 39%) have been authored by 5 researchers or more, while a single author was only shown in 25% (11/44) of the studies. Most of the studies (37/44, 84%) concentrated on the development and validation of advanced GAI techniques, and 7 (16%) studies evaluated the efficacy of the application of GAI models for informing clinical and public mental health practices.

Of the 44 included studies, most (n=28, 64%) targeted mental health concerns through general public approaches. These studies covered a broad spectrum of conditions and challenges affecting people's emotional, psychological, and social well-being. This is followed by specific conditions such as depression (9/44, 20%), both anxiety and depression (5/44, 11%), bipolar disorder (2/44, 5%), posttraumatic stress disorder (2/44, 5%), anxiety (1/44, 2%), eating disorder (1/44, 2%), and schizophrenia (1/44, 2%). Advanced GAI techniques were widely used to address these concerns, with the generative pretrained transformers (GPTs) being the most popular (aggregated by all GPT variants; 23/44, 52%). Specifically, 30% (13/44) of the studies highlighted GPT-3 or GPT-3.5 model or relevant variants, and 18% (8/44) described the use of GPT-2. Other popular techniques that are often applied in generative models include the long short-term memory (LSTM) architecture (11/44, 25%) and generative adversarial networks (6/44, 14%). Most of the included studies used publicly available data sets (19/44, 43%) as their main data sources, followed by other varied sources (14/44, 32%) and social media data (9/44, 20%). Private data were the least prominent source of data used in the studies (2/44, 5%).

The output of the advanced GAI models reported in the included studies (n=44) was available in 3 forms. Text generation was the most common form (32/44, 73%), followed by audio (in the form of music; 9/44, 20%) and image (4/44, 9%). Only 1 study was reported to include both forms of text and audio [43]. Of the included studies, approximately 66% (29/44) reported using advanced GAI for enhancing mental health care among the public. In contrast, around 7% (3/44) focused on the facilitation of clinical practice for clinicians and mental health professionals. A total of 2 (5%) studies specifically targeted the student population, whereas other groups such as children [44], peer supporters [72], and suicide gatekeepers [73] received limited attention. Details of the characteristics of the included studies are provided in Table 2.

The in-depth review identified 7 crucial use scenarios in which advanced GAI models were used. Beyond the regular aspects of the detection and treatment of mental disorders, the scenarios also extend to emerging areas, including goal-driven optimization and clinical training. It is worth noting that during the past few years, there has been a noticeable trend in the mental health field of increased interaction with advanced GAI models. Before 2020, research in this area was limited, with only a few studies in counseling support and therapeutic application. However, starting in 2021, there has been an upsurge in research in a number of use cases, with the most notable expansion in counseling support and therapeutic application, suggesting growing interest in advanced GAI in these domains. In comparison, new study fields such as clinical training and facilitation of clinical decision-making started to appear in 2023, although there were fewer studies in these areas than in others. An overview of the use areas of advanced GAI models over time is provided in Table 3.

Table 2. Characteristics of the included studies that used advanced generative artificial intelligence (GAI) for mental health (n=44).

Detection of Mental Problems

Advanced GAI has the potential to play a crucial role in the early detection and monitoring of mental health problems, facilitating timely interventions and support; 4 (9%) out of 44 studies in the in-depth review focused on the use of advanced GAI for mental disorder detection through content mining and analysis. Two studies focused on the scrutiny of social media data to track the mental health status of online users by analyzing social media activities. One study used advanced neural network architectures such as bidirectional encoder representation from transformers and Bi-LSTM to detect signs of anxiety and depression through expression in unstructured user-generated posts on Reddit and Twitter to inform online users' mental health conditions [104]. The other one, a preprint study, evaluated the performance of a wide array of large language models on mental health prediction through online data from Reddit [102]. Besides using social media data, researchers also explored the use of private data sources, such as audio recordings from interviews, as an alternative method to infer individuals' mental health conditions [49,102]. Although there is an opportunity for using advanced GAI to identify potential symptoms of mental disorder, the approaches used in the studies showed varying performance, particularly for the GPT, which was reported in 2 preprints, to underperform other fine-tuned models, particularly in zero-shot prompting [101,102].

Counseling Support

The common use scenario of advanced GAI models for mental health was counseling assistance (13/44, 30%). Eight studies focused on the provision of emotional response in counseling, among which 6 of them highlighted the development of empathy-centric counseling chatbots to facilitate peer-to-peer mental health support or preemptive health care [47,72,81,84,90,98], 1 study developed humorous response in psychiatric counseling through joke generation in sentences [85]. Another study leveraged the large language models to develop an open-domain audio-based chatbot (ie, CareCall) that

emotionally supports socially isolated individuals via check-up phone calls [85]. Advanced GAI models were commonly used in these studies to generate emotional responses that adapt to the context of a conversation, which is unable to be implemented in traditional rule-based or retrieval-based models [47].

Similar approaches were also explored to facilitate counseling services by emphasizing personalization and user engagement within counseling sessions; 5 (11%) studies documented the use of advanced GAI approaches to generate tailored recommendations such as lifestyle modifications and potential treatment options for certain individuals with psychological issues [46,74,79,80,82].

Therapeutic Application of GAI

Unlike *counseling support,* which mainly focuses on using advanced GAI models to offer short-term and solution-based psychological support with specific mental health issues, *therapeutic application* targets long-term therapy for complex and ongoing mental health challenges, incorporating diverse interventions. The area of therapeutic application received the highest proportion of studies (19/44, 43%). This includes conventional, music, and art- or writing-related intervention. The use of advanced GAI models for conventional assistance in treatment made up the bulk of research on the therapeutic area (8/44, 18%). Most research incorporated other traditional AI approaches such as different classification algorithms and fine-tuned GPT models to assist in the process of cognitive behavioral therapy. Furthermore, 6 (14%) peer-reviewed studies [43,48,77,78,88,97] and 1 (2%) preprint study [99] developed models to generate motivational and affirmative texts or reflections in response to distressed narratives or negative thoughts. Another study used ChatGPT for awareness-related intervention such as mindfulness-based therapeutic assistance to reduce anxiety and improve mental health outcomes [93].

Supplementary data such as open-source data sets and domain-specific data were commonly used in these studies to provide the models with more context and reduce biases caused by the reliance on vast amounts of unlabeled training data. Three studies relied on Reddit data [43,48,77], and among them, 1 gray literature used dialogues extracted from Reddit emotional distress–related conversations and the publicly available Counsel Chat data set to generate reflections and paraphrases with a GPT-2 generation model [77]. Other research highlighted the situational attribute of data. Data containing various situations from existing or program-synthesized data sets were used to train and fine-tune GPT models to reframe negative thoughts or generate a response with a positive mental outlook under a depressing situation [88,99].

Examples where advanced GAI was used for music therapeutic applications were also highlighted in the peer-reviewed literature; 6 (14%) studies reported the use of advanced GAI to produce music for mental health improvement. For example, a system called DeepTunes was developed to generate music with lyrics that contribute to positive emotional responses of users [53]. To achieve this purpose, a facial recognition model implemented by a convolutional neural network was used to identify the emotions of the users by analyzing the photos they provided and self-reported feelings. A lyric generation model driven by GPT-2 followed to create lyrics based on the detected emotions and the first line given by the users. Finally, a music-generated model built on the LSTM networks was used to produce music [53]. Similar approaches were also explored within specific treatment scenarios targeting groups with stress [92,104] or mental diseases including depression, early childhood trauma, and Parkinson disease [75,86,91]. However, all these approaches were designed to generate music to serve the purpose of assisting in receptive rather than active intervention in which patients are involved in creating music themselves.

Another field involves art- or writing-related intervention. Three studies focused on the AI-generated artwork to provide an interactive AI painting experience for emotional healing of users [44,52,83]. One study incorporated image generation in writing therapy. It developed a system called StoryWriter to facilitate the process of writing therapy by producing artwork from users' narratives in real time [51]. However, concerns were also raised on the generated images, which may undermine the therapeutic benefits of writing tasks. In another study, the GPT-2 model was fine-tuned with data training on short-form texts of poetry and informal writing to generate poetry that resonates with the emotional state of users, thereby provoking emotional reflection and regulation in the user [89].

Clinical Training and Facilitation of Clinical Decision-Making

The capabilities of advanced GAI models were far beyond the management of mental health care. Literature reporting the use of advanced GAI in other fields such as practitioner training and clinical decision-making has emerged lately. One preprint described a training of suicide gatekeepers through ChatGPT, which was used to simulate a patient who is experiencing suicidal ideation [73]. Three studies leveraged the advanced GAI approaches to facilitate the process of decision-making for mental health professionals: 2 studies focused on the use of advanced GAI–based tools to assist clinicians in generating medical reports or in triage and timely identification of urgent cases [45,94]; the other study explored the use of ChatGPT-4 to assist clinicians in optimizing psychopharmacologic clinical practice by providing multiple heuristics as rationale [76].

Goal-Driven Optimization

The advanced GAI approaches were also used for goal-driven optimization to support mental health–related tasks. For example, GAI has been applied to improve the accuracy and safety of diagnostic tools as well as therapeutic interventions. Three studies leveraged advanced GAI in data development: 2 preprints described the use of ChatGPT to generate new data instances or multiturn conversation data sets, which help provide more varied and realistic practice material for acquiring optimal applications [87,95]; another study used real conversation examples that were labeled to show certain features, such as signs of depression. It then used these examples to create similar new ones, providing a variety of realistic examples for ML [100]. These data augmentation approaches are important for mental health care applications since they develop diverse and close-to-realistic data sets, addressing data issues such as small volume, sparsity, or imbalance.

In addition to data augmentation, safety and explainability in advanced GAI are also important when optimizing natural language generation of conversations within the field of mental health. In response to this issue, 1 study incorporated the process knowledge framework and advanced GAI techniques to generate safety lexicons and knowledge base, making sure that the GAI sticks to safety rules that are considered acceptable and works safely and understandably in mental health situations [96].

Discussion

Principal Findings

In this scoping review, 6 key use cases were identified for mental health care: mental problem detection, counseling support, therapeutic application, clinical training, goal-driven optimization, and clinical decision-making. Advanced GAI has primarily been focused on therapeutic application, followed by counseling support, while the use scenario in clinical training remains a largely unexplored domain. ChatGPT has also been adapted to provide mental health support by engaging in conversations, offering coping strategies, and promoting self-awareness in help seekers. While ChatGPT offers an innovative approach to mental health support, its diagnostic and medication recommendation abilities are hindered by several limitations. Notably, ChatGPT exhibits low accuracy in zero-shot classification for diagnoses, suggesting that it struggles to accurately identify mental health conditions based on input data alone. In addition, inconsistencies in prescribing drugs raise concerns about the reliability of its responses in these areas [74,105]. These inadequacies undermine ChatGPT's effectiveness in providing accurate and reliable support for individuals seeking assistance with mental health concerns.

Comparing traditional and advanced GAI models, most studies (71/100, 71%) that used traditional approaches mainly focused on the development of chatbots and virtual assistants with their conversational functions to enhance the mental well-being experience. Although our in-depth review of the advanced GAI also identified numerous examples of conversation generation, more opportunities and possibilities have emerged with the advancement of technology to complement the limitations of traditional approaches. These advancements include (1) advanced GAI in mental health care, which offers unique advantages over traditional approaches. Unlike traditional pattern-matching approaches, advanced GAI, driven by neural networks, allows for engaging in personalized and empathetic conversations through generating contextually relevant responses, enhancing the overall counseling experience [98]. (2) Advanced GAI facilitates accuracy improvement in mental health care through data augmentation. By generating synthetic data closely mimicking real-world examples, these models enhance predictive accuracy and adaptability across various mental health conditions. (3) Advanced GAI excels in image generation for therapeutic purposes. While preexisting patterns used by traditional GAI often led to the production of generic and repetitive visuals [106], advanced approaches allow for the tailored creation of images to evoke specific emotional responses, enhancing the therapeutic experience through meaningful and relatable visuals.

The GAI Dilemma in Mental Health Care

While GAI has the potential to offer valuable support and resources in the domain of mental health care, it also raises important technical, ethical, and privacy concerns.

Technical Dilemma

Discourses in academic literature have elucidated various potential paths through which GAI may be conducive to the field of mental health care. Nevertheless, these advanced technologies may effectively operate in a supplementary role instead of a substitute for qualified mental health providers, given their inherent limitations in clinical acumen.

ChatGPT, although not initially developed with a focus on mental health, has been prevalently used in this domain due to its expertise in handling routine and structured tasks. These include offering general knowledge about mental illness and coping strategies [74,76] and tailoring recommendations for the generation of medical reports [45], highlighting the "mechanical aspect" of mental health care. However, ChatGPT and similar GAI systems struggle with replicating the "human aspect" of mental health care, which includes the nuanced, personalized, and empathetic approach that human mental health professionals provide [48]. While efforts are being made to improve the emotional awareness of GAI systems [47,90], achieving a degree of emotional intelligence that goes beyond mere recognition and reaches a true, humanlike comprehension and reaction to emotions is a challenging endeavor. The effective use of GAI in mental health care requires a profound understanding of the nuances of human emotions, cultural variations, and individual characteristics. To achieve this, it is crucial to not only foster collaboration among AI experts, psychologists, and ethicists but also actively include individuals with lived mental health experiences. Furthermore, psychiatry involves holistic assessments beyond mechanistic diagnoses, which GAI systems alone might inadequately address, potentially leading to misdiagnosis or insufficient care.

Ethical Dilemma

The ethical concerns involved posed another significant challenge. Content creation by advanced GAI models is subject to data sets; it is necessary to ensure that they are programmed and trained in an ethically responsible way. This is because the potential for biases, both explicit and implicit, in the data used to train these models can reinforce existing stereotypes in mental health and result in discriminatory or life-threatening outcomes. Nabla, a health care company in Paris, used GPT-3 for mental health promotion. Unexpectedly, when a user raised the question, "Should I take my own life?" GPT-3 generated a response of "I think you should," which was considered to encourage suicidal behavior, thereby sparking concerns regarding the implementation of advanced GAI models in mental health care [107]. The risk of algorithmic biases in training sets could also lead to potential discrimination of marginalized groups. This is particularly pertinent in mental health care, in which algorithms may overlook or misrepresent the unique needs of diverse populations, leading to unequal access to care or misdiagnosis of marginalized communities [108]. For instance, Buolamwini and Gebru [109] found that facial analysis

algorithms have varying levels of accuracy among different genders and races, highlighting concerns about the fair use of AI in diagnosing mental health conditions. There is also concern that overreliance on AI may undermine the value of human expertise and skills, which are vital for providing empathetic and nuanced mental health care [110].

Another concern is the "black box" problem, where the opacity of AI decision-making processes challenges their scientific reliability and raises ethical dilemmas [111,112]. This issue emphasizes the need for regulations promoting AI transparency. Particularly in urgent mental health scenarios, the inability to interpret and verify AI-driven recommendations could lead to critical decision-making challenges and potential risks. Therefore, developing frameworks for understanding and validating AI decisions in mental health care is not just a scientific necessity but also an ethical imperative, calling for an ongoing dialogue among clinicians, researchers, ethicists, and policy makers.

Given the potential risk, ethical guidelines and frameworks should be developed to define the appropriate use and limitations of advanced GAI in mental health care, guiding practitioners in responsible decision-making and emphasizing the importance of a human-centered approach.

Safety and Confidentiality Dilemma

Another ethical challenge is the privacy and confidentiality of sensitive personal information. Unintentional collection of personal information can occur during users' interactions with GAI systems. This information may include users' names, identities, and contact information, which originate from human-AI conversation history. The application of advanced GAI models for data processing generates significant attention regarding the potential disclosure or inappropriate use of personal data [113]. This is of particular concern in mental health care. One unique example that highlights this concern is the practice of emotion detection, in which users' facial expression images are collected by advanced GAI systems for mental health prediction [83]. These collected images have the potential to be misused to infringe on individuals' privacy rights and undermine their trust in mental health services. Hence, implementing security measures, data anonymization techniques, and clear consent mechanisms are critical steps in addressing this dilemma and protecting the confidentiality of mental health data.

Implications

Research Implications

The results of this study have several implications. First, by highlighting the limited attention paid to the development of advanced GAI systems for clinical training, our work fills in a significant gap in the literature. Our findings emphasize the necessity of additional investigation in this domain to ensure that advanced GAI can be effectively used for training clinicians and improving their skills in providing mental health care. Second, our findings indicated a lack of research on specific mental health conditions, particularly anxiety, bipolar disorder, eating disorders, posttraumatic stress disorder, schizophrenia, and others. Therefore, future research on the implementation

of advanced GAI should prioritize and invest more resources into exploring and understanding such mental disorders. Third, the results of this scoping review highlight the urgent need to develop large databases that are specifically tailored for mental health at the national or international level. Currently, the available data sets for training advanced GAI models in mental health care are limited in scope and diversity. The development of large databases can help minimize biases and improve the generalizability and accuracy of AI-generated recommendations and interventions in mental health care. Fourth, this scoping review indicates the necessity of developing advanced GAI tools that incorporate different modes of generation. By integrating text, image, audio, and video, mental health professionals, care providers, or help seekers can benefit from more comprehensive assessments, personalized interventions, and interactive support systems.

Practical Implication

GAI indeed offers substantial potential within the mental health care landscape, but this promising territory requires cautious navigation. Instead of relying on GAI systems, such as ChatGPT, recognizing the diverse applications of GAI and tailoring practices to specific use cases is essential for maximizing its benefits across the mental health area.

Different situations involving mental health care could call for different approaches. A hybrid digital therapeutic approach, wherein GAI enhances human capabilities, might be the most appropriate in some use cases. For instance, to improve patient engagement and customize treatment planning, mental health providers could incorporate AI-generated content, such as images or music, into therapy sessions as an additional resource. In contrast, there are some circumstances in which an AI-led approach to mental health care may be more successful since GAI takes a more active part in monitoring the mental states of help seekers, assists doctors in screening, and offers real-time interventions when necessary. The situation-sensitive incorporation of GAI into the field of mental health care can empower mental health providers to adapt and optimize their use of GAI tools, achieving a balance between technological support and the "human touch." Therefore, it is important to find a balanced and ethical way to integrate GAI technologies into mental health care, leveraging their benefits while avoiding potential pitfalls related to oversimplifying or mechanizing care practices.

Limitations

This study has limitations. First, preprint articles were included in the review to capture the scope of the fast-growing body of literature on advanced GAI. Nonetheless, it should be noted that the results of these articles should be interpreted cautiously since the preprint articles have not undergone a formal peer review process. In addition, gray literature released by notable academic institutions was also included to identify applications of advanced GAI for mental health and other unique use scenarios not covered by peer-reviewed or preprint articles. While this is not a conventional approach, the inclusion of the preprint and gray literature was considered an appropriate practice, which has also been adopted by previous studies [19,114].

Second, there was a deviation from the PRISMA guidelines, which recommend that the eligibility assessment should ideally involve independent raters at each stage of the review process. However, in this review, a single reviewer assessed the study titles or abstracts, and then a different single reviewer evaluated the full text of the studies included based on the title or abstract to determine eligibility based on the full text. Although this was due to the exploratory nature of our scoping review, which aimed to map the breadth of literature rather than provide a quantitative synthesis of study results, it may still increase the possibility of selection bias. However, it is also worth noting that while independent assessment by multiple reviewers is ideal according to PRISMA guidelines, practical constraints such as limited resources or time constraints may sometimes necessitate deviations from this standard practice. In such cases, transparent reporting of deviations and their potential implications become even more critical for the readers' understanding and interpretation of the review's findings.

Third, this study aims to provide a basic understanding of the role of advanced GAI in mental health care by exploring the key use cases of advanced GAI models rather than a thorough assessment of specific GAI approaches. Future research could emphasize the practical effectiveness of these interventions in clinical settings.

Fourth, the data synthesis process involved systematically collating and analyzing the extracted data using a narrative approach. This allowed the researchers to categorize and describe the GAI studies based on various dimensions, providing insights into the state of research in this field. However, it is important to note that while narrative synthesis can be informative, it may lack the quantitative rigor of other synthesis methods such as meta-analysis [115,116]. Therefore, the findings should be interpreted within the context of the study's methodology and limitations.

Conclusions

This study provides insights into the present status of GAI use in mental health care research and highlights the potential aspects that can guide future research, practical applications, development, and policy making within this domain. Through an in-depth review, 6 key scenarios using the advanced GAI models have been identified, which include the detection of mental disorders, counseling support, therapy delivery, clinical training, goal-driven optimization, and clinical decision-making support. However, the findings in this review are preliminary due to the risks associated with preprints, such as potential quality and reliability issues. Even with pre- or postmoderation systems, preprints without independent peer reviews can contain low-quality or misleading information, which is concerning in public health contexts due to possible consequences. Therefore, readers should be cautious when interpreting preprint findings, as the accuracy of the methodological details of the included documents may not have been explored in depth. Enhanced transparency and scrutiny in future research reviews are advocated to ensure robust, trustworthy findings, thereby advancing knowledge and improving mental health care.

Abstract

Background: Computational signal preprocessing is a prerequisite for developing data-driven predictive models for clinical decision support. Thus, identifying the best practices that adhere to clinical principles is critical to ensure transparency and reproducibility to drive clinical adoption. It further fosters reproducible, ethical, and reliable conduct of studies. This procedure is also crucial for setting up a software quality management system to ensure regulatory compliance in developing software as a medical device aimed at early preclinical detection of clinical deterioration.

Objective: This scoping review focuses on the neonatal intensive care unit setting and summarizes the state-of-the-art computational methods used for preprocessing neonatal clinical physiological signals; these signals are used for the development of machine learning models to predict the risk of adverse outcomes.

Methods: Five databases (PubMed, Web of Science, Scopus, IEEE, and ACM Digital Library) were searched using a combination of keywords and MeSH (Medical Subject Headings) terms. A total of 3585 papers from 2013 to January 2023 were identified based on the defined search terms and inclusion criteria. After removing duplicates, 2994 (83.51%) papers were screened by title and abstract, and 81 (0.03%) were selected for full-text review. Of these, 52 (64%) were eligible for inclusion in the detailed analysis.

Results: Of the 52 articles reviewed, 24 (46%) studies focused on diagnostic models, while the remainder (n=28, 54%) focused on prognostic models. The analysis conducted in these studies involved various physiological signals, with electrocardiograms being the most prevalent. Different programming languages were used, with MATLAB and Python being notable. The monitoring and capturing of physiological data used diverse systems, impacting data quality and introducing study heterogeneity. Outcomes of interest included sepsis, apnea, bradycardia, mortality, necrotizing enterocolitis, and hypoxic-ischemic encephalopathy, with some studies analyzing combinations of adverse outcomes. We found a partial or complete lack of transparency in reporting the setting and the methods used for signal preprocessing. This includes reporting methods to handle missing data, segment size for considered analysis, and details regarding the modification of the state-of-the-art methods for physiological signal processing to align with the clinical principles for neonates. Only 7 (13%) of the 52 reviewed studies reported all the recommended preprocessing steps, which could have impacts on the downstream analysis.

Conclusions: The review found heterogeneity in the techniques used and inconsistent reporting of parameters and procedures used for preprocessing neonatal physiological signals, which is necessary to confirm adherence to clinical and software quality management system practices, usefulness, and choice of best practices. Enhancing transparency in reporting and standardizing procedures will boost study interpretation and reproducibility and expedite clinical adoption, instilling confidence in the research findings and streamlining the translation of research outcomes into clinical practice, ultimately contributing to the advancement of neonatal care and patient outcomes.

Introduction

Background

Premature infants are those born at <37 weeks gestational age, ranging from extreme preterm (23 weeks' gestation) to late preterm (37 weeks' gestation), and are defined as having very low birth weight of <1500 g. These extremely premature infants have a higher risk of death, and surviving infants are highly prone to physical, cognitive, and emotional impairment [1]. The patients usually have a long length of stay, ranging from <10 to >120 days [2], in the neonatal intensive care unit (NICU), where high-fidelity physiological changes are monitored to observe their health status and signs of deterioration. During this long length of stay, a large amount of data from infants are generated and not typically electronically aggregated for permanent storage [3]. With the advent of electronic health records, relevant patient information is easily available for advanced data analytics that can be used to improve health outcomes. The records contain demographics, etiology, pathology, medication, and physiology information. Physiological changes are regularly monitored in preterm infants, notably, electrocardiogram (ECG), oxygen saturation (SpO_2), heart rate (HR), respiratory rate, arterial blood pressure, electroencephalography (EEG), and temperature. Some advanced centers around the world have started linking the information derived from the electronic health records data with the continuously monitored physiological information for permanent storage, more frequently in lower resolution, which facilitates various data analytics [4-6]. Compared with intermittent assessment and review, continuous capturing and analysis of the physiological data from the standard bedside monitors allow for a better understanding of trends and have been shown to improve outcomes of infants in the NICU [5].

Clinical decision support systems (CDSSs) can integrate clinical and physiological information to provide automated support in patient care planning to facilitate the diagnostic process and therapy planning, generate critical alerts and reminders, and predict the risk of patient deterioration. CDSSs have the potential for a positive impact in improving clinical and economic measures in the health care system [7-9]. The technological advancement that allowed storing big data, as well as the advancement of artificial intelligence (AI), has given rise to machine learning (ML)– and AI-based CDSSs aiming to build data-driven models to predict adverse outcomes in premature infants ahead of clinical diagnosis time [10-12].

The steps of building the ML pipeline to predict adverse outcomes involve several intermediate computational steps using the physiological data, of which data preprocessing is the first indispensable step. Namely, in the NICU, physiological signals are collected using a diverse range of devices, which introduce a number of artifacts such as *environmental artifacts* (eg, device connection failure, equipment noise, electrosurgical noise, and power line interferences); *experimental or human error* due to patient movement during data acquisition, incorrect or poor contact of the electrodes, and other contact noise; and *artifacts* due to muscle contraction, cardiac signals, and blinking [13,14]. These noises distort signals and may adversely affect model generalization capability and predictive power [10].

Although recently much progress has been made in building ML models using neonatal physiological data, there are limitations in the detailed reporting of the preprocessing techniques of these signals [15], which in turn hinder the reproducibility of the methods and results. In AI-powered software as a medical device (SaMD), this is especially important as the implementation of a software quality management system (QMS) is only possible by following the best practices and adhering to relevant regulatory standards and guidelines for medical devices, such as ISO 13485, IEC 62304, and IEC 82304-1. Beyond market access considerations, the ongoing international discourse on the regulation of medical software is specifically concentrated on AI and ML. This focus is a response to their growing applications, demanding increased attention from regulatory bodies such as the Australian Therapeutic Goods Administration and the US Food and Drug Administration [16]. Thus, it is crucial to adhere to a standardized protocol following clinical principles guided by domain experts and regulatory requirements while preprocessing the signals and reporting these techniques in detail; this ensures the reproducibility of the methods, allowing transparency in their clinical adoption.

Objectives

As the first step in bridging the gap in their reproducibility for clinical adoption, this review aims to identify studies that used computational methods to analyze premature infants' physiological signals for detecting adverse outcomes. The review describes different tools and techniques used to preprocess physiological signals and provides recommendations on what aspects need further details for the clinical adoption of the techniques. The remainder of the paper is organized as follows: the Methods section explains the detailed search and screening process, while the Results section begins with an overview of the reviewed studies, followed by a detailed analysis. The Discussion section highlights the key reporting patterns identified in this review along with their shortcomings and provides recommendations for transparent reporting of future studies as it allows for accurate reproduction of the results and makes them usable in the clinical setting [17]. A summary of the work concludes the paper.

Methods

Search Strategy

The database searches and study screening were conducted following the recommendations of PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [18] and the Centre for Reviews and Dissemination guidance for undertaking reviews in health care [19].

Database and Search Strategies

A systematic database search was conducted on 5 databases: PubMed, IEEE, Web of Science, Scopus, and ACM Digital Library. The keywords were categorized into four concepts, which were then merged using the "AND" operator: concept 1—neonates or preterm infants; concept 2—vital signs or physiological signals; concept 3—computational techniques or signal processing; and concept 4—outcomes relating to neonates. Within each of these concepts, a combination of keywords and MeSH (Medical Subject Headings) terms were used to conduct the search process. The keywords under each concept were combined by the "OR" operator. The searches were limited to only the titles and abstracts. Table 1 shows the list of keywords and Medical Subject Headings terms used to search the database.

The search was done on January 9, 2023, and the publication year of the papers was limited to 2013 to 2023. The reason for choosing the 10-year range was to report on recent techniques and tools, as the devices and computational tools used >10 years ago may be obsolete. Scopus, Wiley Online Library, and Web of Science have an additional filter for choosing the subject area. This was used to restrict the subject areas to multidisciplinary, engineering, computing, and statistics. This was done to identify more papers on multidisciplinary areas through these databases, as PubMed covers all the major medical and health informatics databases. The combination of the 5 databases ensured that all medical, information technology, and multidisciplinary research papers were included in the database search. The search was restricted to English-language articles. Finally, review articles were excluded from the search.

Table 1. List of keywords and MeSH (Medical Subject Headings) terms used to conduct the database search.

Concepts	Search strategy
Concept 1: neonates or preterm babies	
MeSH terms	"Infant, Premature"
Keywords	"premature" OR "preterm" OR "neonat*" OR "newborn" OR "infant" OR "nicu" OR "neonatal intensive care unit"
Concept 2: physiological signals or vital signs	
MeSH terms	"Vital Signs" OR "Physiology"
Keywords	"physiolog*" OR "ecg" OR "heart rate" OR "electrocardiography" OR "vital sign*" OR "physiomarker" OR "biomarker" OR "hrv"
Concept 3: computational techniques or signal processing	
MeSH terms	"Signal Processing, Computer-Assisted"
Keywords	"signal *" OR "predict*" OR "detect*" OR "comput*"
Concept 4: outcomes	
MeSH terms	None
Keywords	"sepsis" OR "mortality" OR "length of stay" OR "intraventricular hemorrhage" OR "hypoxi*" OR "apnea" OR "necrotising entercolitis" OR "necrotizing entercolitis"

Screening and Study Selection

The initial screening of the databases led to 3585 papers. Of these, 590 (16.46%) papers were manually identified as duplicates and excluded from the analysis. One paper was identified as a duplicate by the automation tool and removed. The remaining 2994 (83.51%) papers were subjected to title and abstract screening using the Rayyan Intelligent Systematic Review application (Qatar Computing Research Institute) [20].

Several inclusion criteria were set to select papers for full-text review. The criteria are mentioned in Textbox 1.

After screening the titles and abstracts, 81 articles were selected for full-text review; 29 (36%) papers were excluded during this stage as they did not align with the inclusion criteria, leaving 52 (64%) papers eligible for detailed synthesis and analysis.

The title and abstract screening was done by 1 reviewer, while 2 reviewers independently checked for paper eligibility against the inclusion criteria at the full-text review stage. When both reviewers were not in agreement on any papers, a third reviewer assessed them to provide a final decision on the inclusion and exclusion of the papers. Data charting was done using Microsoft Excel, and the following variables were recorded in line with related review papers [10,21]: title, year, journal, authors, digital object identifier, data set, participant number, participant demographic, signals used, data set size, sample rate, other data (if applicable), outcome metric, device software, programming language, preprocessing methods, algorithms, other techniques, features, models, model type, results (quantified), and key findings. Data synthesis was done using a narrative approach by summarizing findings based on the similarities in the data sets and techniques used. The detailed search queries,

bibliography files of all databases, all included papers, metadata of all papers and metadata of all papers included for full-text review are provided in Multimedia Appendices 1-5 [22-73].

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Article type: articles must be peer-reviewed publications in a journal, conference, or workshop

- Data: articles must conduct an analysis on premature human infant data; articles must use physiological responses in some form

- Outcome: articles discuss applications relating to adverse neonatal outcomes such as mortality, length of stay, sepsis, necrotizing enterocolitis, intraventricular hemorrhage, hypoxic-ischemic encephalopathy, apnea, bradycardia, and other poor health outcomes, also known as morbidity. The disease outcomes were chosen based on the commonly researched outcome metric using preterm infant data and the search terms used in McAdams et al [10] that investigated artificial intelligence and machine learning techniques used to predict clinical outcomes in the neonatal intensive care unit

- Analysis: articles reported some form of computational techniques in their analysis

- Language: English

Exclusion criteria

- Article type: review papers are excluded

- Data: nonhuman data (eg, piglet infant data would not be considered); videos and images that do not look at the physiological responses and articles solely using demographic data for analysis were excluded

- Outcome: articles not focusing on these specified neonatal adverse outcomes were excluded

- Analysis: articles that only reported responses in their raw format were excluded

- Language: any languages other than English

Results

Overview of the Included Studies

Figure 1 shows the full process of database search and study selection using a PRISMA flow diagram.

Of the 52 selected articles, 24 (46%) studies focused on diagnostic models, while the rest (n=28, 54%) focused on prognostic models. These included journal articles (n=34, 65%), conference articles (n=17, 33%) and a workshop article (n=1, 2%). The most prominent physiological signals analyzed were ECG (n=36, 69%), SpO_2 (n=21, 40%), HR (n=16, 31%), respiration (n=16, 31%), BP (n=6, 12%), EEG (n=4, 8%), and temperature (n=3, 6%). While 8 (15%) studies used a combination of programming languages; others used MATLAB (n=6, 12%), Python (n=6, 12%), and R software (n=1, 2%), while the remaining studies (n=31, 60%) did not report what language was used. Physiological data monitoring and capturing was done using a range of systems, which subsequently impacted the sampling rate and quality of the data, thus leading to heterogeneity of the studies. The most commonly used devices for data capturing were Phillips Intellivue MP20, MP70, MP450, and MX800 machines [74] (n=14, 27%). Some other notable devices and software were BedMaster Ex System [75], NicoletOne EEG system [76], ixTrend, Phillips Data Warehouse connect [77], and Vuelogger patient monitoring system. The most commonly analyzed outcomes of interest were sepsis (n=20, 38%), apnea (n=17, 33%), bradycardia (n=13, 25%), mortality (n=7, 13%), and hypoxic-ischemic encephalopathy (n=5, 10%). It should be noted that 14 (27%) of the reviewed studies analyzed a combination of adverse outcomes.

As the studies were found to be heterogeneous in their study design and analysis techniques, a narrative approach was taken to summarize the studies and their key findings. The studies were grouped according to the homogeneity in terms of the data sets used and sorted by the publication year. This approach was inspired by the review article by Mann et al [78].

One of the noticeable patterns identified through the results reported in Table 2 is that the groups publishing studies using the same data set followed similar preprocessing techniques, although not at every step. For instance, studies using the ECG data from Cork University Maternity Hospital all used the same algorithm for QRS complex detection. However, they were diverse in their selection of filtering techniques and segmentation duration. Furthermore, they systematically failed to report detailed parameter settings for the QRS complex detection. While the approach of using similar preprocessing techniques helps maintain consistency to some extent, they do not confirm adhering to clinical practices identified from domain expert knowledge.

The QRS complex characteristics and RR intervals for neonates are different from those of adults and as such require an appropriate adjustment for QRS detection algorithms. This is a necessary first step for HR variability (HRV) analysis in neonates. However, a review published on neonatal HRV by Latremouille et al [15] revealed that given a lack of clear guidelines on neonatal vital signs and HRV analysis, several studies followed HRV analysis guidelines for adults published by the Task Force of the European Society of Cardiology and the North American Society of Pacing and Electrophysiology [79]. Our review found that 16 (44%) out of the 36 studies analyzing ECG signals used the Pan-Tompkins algorithms for QRS complex detection. The original implementation of the

algorithm was based on the ECG characteristics of the adult population and therefore was preprocessed accordingly. Only 4 (25%) of those 16 studies reported adjustment of the original algorithm to adapt to neonates, of which only 2 provided specific modification details. In the absence of detailed reporting on the parameter settings, it is difficult to determine whether the settings adhered to neonatal waveform morphology. Incomplete reporting and lack of transparency hinder the understanding of the strengths and weaknesses of a study and limit its reproducibility and usability. Moreover, transparent and detailed reporting is required to confirm the adherence to regulatory compliance and is crucial for the clinical adoption of these methods.

Similar to the QRS complex in ECG signals, the acceptable ranges of physiological signals for neonates are also different from those of the adult population. This review found that no studies reviewed the acceptable ranges of the analyzed signals against any published guidelines, which could pose several limitations in the clinical adoption of the methods. This is consistent with another review looking into physiological vital sign ranges from 34 weeks gestational age, and it identified that several studies reported the means of vital signs instead of ranges, which makes the interpretation into clinical practice difficult [80]. Here, we recommend clear reporting and the use of physiological signal ranges that are clinically validated through published studies and textbooks [81-83].

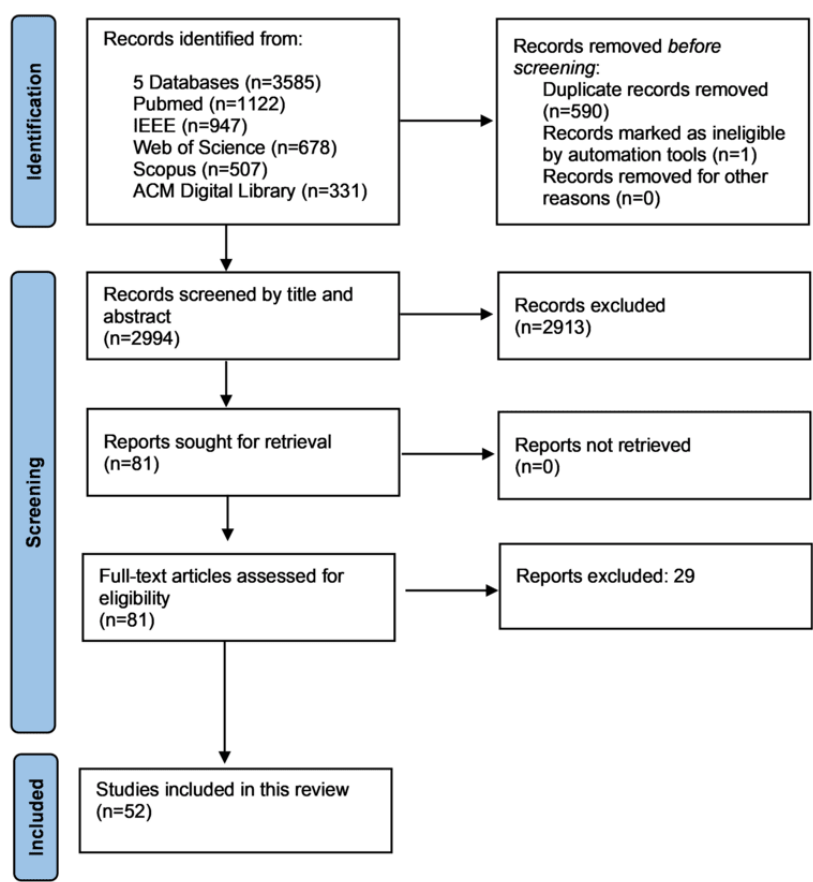
Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram for the database search and study selection.


Table 2. Summary of the articles reviewed in this study, grouped according to the homogeneity in terms of the data sets used and sorted by the publication year.

Data set used	Author, year	Study settings	Physiological signal analyzed	Signal processing and computational techniques	Key findings
National CHIME[a] database [84]	Cohen and de Chazal [22], 2013	Participants: n=288; data size: NR[b]; model: diagnostic; outcome metric: sleep apnea	ECG[c] from single channel at 100 Hz, SpO$_2$[d] at 1 Hz	SpO$_2$ values <65% and changes in saturation exceeding 4% per second were discarded. ECG QRS complex was detected using the Pan-Tompkins algorithm [85] to generate RR intervals. QRS complexes were filtered using a technique from Chazal et al [86]. Filtered intervals were time aligned with SpO$_2$ using 30-second epochs	Eleven features were extracted from the signals. A combination of features from both signals resulted in 88.8% accuracy, 94.3% specificity, and 73.4% sensitivity in detecting sleep apnea
CHIME	Cohen and de Chazal [23], 2014	Participants; n=402; data size: NR; model: diagnostic; outcome metric: sleep apnea	ECG from single channel at 100 Hz, SpO$_2$ at 1 Hz, actigraphy signals at 50 Hz	Actigraphy signals artifact rejection was done using the technique described by Lewicke et al [87]. SpO$_2$ values <65% and changes in saturation exceeding 4% per second were discarded. ECG data were passed through a QRS detection algorithm (NR) to produce RR intervals, which were filtered using a previously outlined method [86]	Fourteen features were extracted from the signals. A linear discriminant classifier achieved an accuracy of 74.1%, a sensitivity of 82.0%, and a specificity of 60.9% in detecting sleep apnea
CHIME	Cohen and de Chazal [24], 2015	Participants; n=394; data size: NR; model: diagnostic; outcome metric: sleep apnea	ECG from single channel at 100 Hz, SpO$_2$ at 1 Hz	SpO$_2$ and ECG signals were time aligned to 30-second epochs. SpO$_2$ values <65% and changes in saturation exceeding 4% per second were discarded. ECG QRS complex detected using the Pan-Tompkins algorithm [85] to generate RR intervals. QRS complexes were filtered using a technique from Chazal et al [86]	Eleven features were extracted from both signals. A linear discriminant model achieved 66.7% accuracy, 67% specificity, and 58.1% sensitivity using features from both signals
PICS[e] database [25,88]	Gee et al [26], 2016	Participants; n=10; data size: ~20-70 hours each; model: diagnostic; outcome metric: bradycardia	3-lead ECG at 500 Hz, respiration signal at 50 Hz	RR intervals from ECG were extracted using a modified Pan-Tompkins algorithm (modification details NR). Analysis was done on a 3-minute window before each bradycardia. No processing was reported for respiration signals	Bradycardia severity estimation accuracy was improved by an average of 11% using a point process model of heart rate and respiration

Data set used	Author, year	Study settings	Physiological signal analyzed	Signal processing and computational techniques	Key findings
PICS	Gee et al [25], 2017	Participants, 10; data size: ~20-70 hours each; model: prognostic (+116 seconds); outcome metric: bradycardia	3-lead ECG at 500 Hz, respiration signal at 50 Hz	RR intervals from ECG were extracted using a modified Pan-Tompkins algorithm (modification details NR). The artifacts, due to movement, disconnection, or erroneous peaks, were removed by visual inspection. No processing was reported for respiration signals. Additional analysis on the frequency content of the RR time series was done using Morlet wavelet transform [89]	A point process model–based prediction algorithm achieved a mean AUROC[f] of 0.79 for >440 bradycardic events and was able to predict bradycardic events on an average of 116 seconds before onset (FPR[g]=0.15)
PICS	Das et al [27], 2019	Participants; n=10; data size: ~20-70 hours each; model: prognostic (time NR); outcome metric: bradycardia	3-lead ECG at 500 Hz	Baseline wander was removed using a high-pass filter with a cutoff frequency between 0.5 and 0.6 Hz. Motion and disconnection artifacts were removed by visual inspection. QRS complexes were detected using Pan-Tompkins algorithm [85]. Signals were segmented 5 minutes before and 2 minutes after a bradycardic event	Nonparametric modeling using kernel density estimation achieved a 5% false alarm rate in predicting the onset of bradycardia events
PICS	Mahmud et al [28], 2019	Participants; n=11; data size: ~20-70 hours each for 10 and 10 weeks for 1 participant; model: prognostic (time NR); outcome metric: bradycardia	3-lead ECG at 500 Hz	QRS complex was detected using an algorithm (NR). RR intervals were calculated from the detected peaks	Time and frequency domain features were extracted. An extreme gradient boosting model achieved an average AUROC of 0.867. HRV[h] results showed a significant variation between a healthy infant and an infant prone to bradycardia

Data set used	Author, year	Study settings	Physiological signal analyzed	Signal processing and computational techniques	Key findings
PICS	Gee et al [29], 2019	Participant, n=10; data size: ~20-70 hours each; model: diagnostic; outcome metric: bradycardia, apnea of prematurity	3-lead ECG at 500 Hz, respiration signal at 50 Hz	Respiration signals were clipped into 60-second segments and normalized to 0-mean, unit variance. RR intervals from ECG signals were extracted using a Morlet wavelet transformation. An open-source peak finder (name NR) was applied to the wavelet scale ranging from 0.01 to 0.04, which is related to the QRS complex formation in the spectrogram. ECG signals were segmented to 15 seconds with the event in the middle. The segments were bandpassed filtered from 3 to 45 Hz, scaled to 0-mean unit variance, and scaled to the median QRS complex amplitude. Waveforms were visually inspected to remove segments with no distinguishable QRS complex or respiratory peaks	An autoencoder-prototype model was proposed, which achieves 93.1% (SD 0.4%) accuracy in predicting bradycardia and 82.3% (SD 3.8%) accuracy in classifying apnea
MIMIC-III[i] database from Beth Israel Deaconess Medical Center [90]	Song et al [30], 2020	Participants: 2819 (21 sepsis, 2798 control); data size: NR; model: prognostic (+48 hours); outcome metric: sepsis	HR^j, SBP^k, DBP^l, MBP^m, SpO_2, respiration, temperature, other (sampling rate NR)	Data quality was assessed by missing value filter and 3-sigma rule. The final observation carried forward was applied to vital signs not meeting data quality. Zero imputation was performed if calculation could not be performed (eg, divided by 0)	Several statistical features were extracted at 3-, 6-, 12-, and 24-hour window. Linear model, naive Bayes, decision tree, ensemble method, and neural network models were evaluated. The AUROC of the 48-hour prediction model achieved 0.861 and that of the onset detection model was 0.868
MIMIC-III	Baker et al [31], 2021	Participants; n=179 for 3-day and n=181 for 14-day model; data size, NR; model: prognostic (+3 days); outcome metric: mortality	HR, respiration signal, sampled hourly	Values <0 and flatline cases were eliminated	Several statistical features were extracted from the signals. $CNN-LSTM^n$ model using a 3-day scheme achieved AUROC of 0.9336 (SD 0.0337) across 5-fold cross-validation
MIMIC-III	Juraev et al [32], 2022	Participants; n=3133; data size: 24 hours from each; model: prognostic (time NR); outcome metric: mortality and LOS^o	HR, respiration signal, SpO_2, BP, temperature (sampling rate NR)	Missing data were filled by forward and backward filling, using the mean value. For participants >24 measurements, they were reduced by taking the average of the nearest records. For <24 measurements, values were generated using filling algorithm	A dynamic ensemble KNN^p method reached 0.988 (SD 0.001) F_1-score in mortality classification. Voting of static ensemble regression models achieved an $RMSE^q$ of 12.509 (SD 0.079) in LOS prediction

Data set used	Author, year	Study settings	Physiological signal analyzed	Signal processing and computational techniques	Key findings
University Hospitals in France	Ghahjaverestan et al [33], 2015	Participants; n=32; data size: 105 segments of ECG with 250 seconds duration; model: diagnostic; outcome metric: apnea- bradycardia	One lead ECG at 400 Hz and respiration signals (sampling rate NR)	Baseline and noise of 50 Hz were removed from ECG signals, QRS complexes were detected using Pan-Tompkins algorithm [85]. RR intervals were further downsampled to 10 Hz for 1 prediction model	A Kalman-filter–based method achieved sensitivity and specificity of 94.74% and 94.17%, respectively, in predicting apnea-bradycardia episodes
University Hospitals in France	Navarro et al [34], 2015	Participants; n=51; data size: testing cohort mean duration—2.4 hours; model: diagnostic; outcome metric: sepsis	Respiration signals at 400 Hz, downsampled to 64 Hz	Frequency content >32 Hz from breathing signals was removed using a seventh-order Butterworth low-pass filter. After rejecting artifacts due to gross movements, a fourth-order Butterworth filter with a cutoff frequency between 0.5 and 20 Hz was applied. Smoothing filtering using an SG^r filter [91] was applied. A simple extrema detector is then applied to detect respiratory cycles	14 features, computed in 10-second sliding excerpts, were extracted from the breathing signals. A logistic regression classifier automatically rejects artifacts to 86% sensitivity and specificity, which is used in the proposed framework for neonatal sepsis detection
University Hospitals in France	Ghahjaverestan et al [35], 2016	Participants; n=32; data size: real (236 segments Synthetic) 200 sequences of 400 seconds; model: diagnostic (0.59-second delay); outcome metric: apnea-bradycardia	ECG at 400 Hz. Synthetic signals at 10 Hz	Baseline and noise of 50 Hz were removed from ECG signals using a combination of low-pass and notch filters; QRS complexes were detected using Pan-Tompkins algorithm [85]. Three features were extracted using a wavelet-based beat delineator [92]. Features were transformed to 10 Hz using interpolation (technique NR)	A CHMM^s achieved 95.74% sensitivity and 91.88% specificity in detecting apnea-bradycardia episodes, with a detection delay of –0.59 seconds
University Hospitals in France	León et al [36], 2021	Participant, n=49; data size: NR; model: prognostic (+6 hours); outcome metric: sepsis	ECG at 500 Hz	RR intervals were detected using modified Pan-Tompkins algorithms, and filter coefficients were adapted for newborns [93]. A sliding window of 30 minutes, with no overlaps, was applied to extract HRV parameters from the RR time series. 30-minute segments with a maximum RR >1 second or a minimum RR of <0.19 seconds were excluded,	Time, frequency, and nonlinear features were extracted from the HRV parameters. A logistic regression model using visibility graph features achieved 0.877 AUROC in predicting sepsis 6 hours before the start of antibiotics

Data set used	Author, year	Study settings	Physiological signal analyzed	Signal processing and computational techniques	Key findings
University Hospitals in France	León et al [37], 2021	Participants; n=259; data size: NR; model: prognostic (+6 hours); outcome metric: sepsis	ECG at 500 Hz	RR intervals were detected using modified Pan-Tompkins algorithms and filter coefficients were adapted for neonates [93]. RR time series were extracted and segmented into 5-minute segments. The 5-minute periods corresponding to 30 continuous minutes were grouped by calculating the median of each corresponding HRV feature	Time, frequency, nonlinear, and visibility graph features were extracted from the HRV parameters. An RNN[t] model achieved 0.904 AUROC in predicting sepsis 6 hours before the time of infection and >80% accuracy 24 hours before the onset of infection
University Hospitals in France	Doyen et al [38], 2021	Participants; n=52; data size: 8 hours of recording from each; model: diagnostic (+2.9-second delay); outcome metric: bradycardia	3-lead ECG at 300 Hz	QRS complexes were detected using a multi-feature probabilistic real-time detector [93]	A high rate of false alarms (64%) was observed in real life. The proposed optimal decentralized fusion of 3 detection methods had a significant detection delay of 2.9 seconds, sensitivity of 97.6% and false alarm rate of 63.7%
University Hospitals in France	Sadoughi et al [39], 2021	Participants; n=32; data size: 233 episodes with a duration of 21.48 (SD 16.07) seconds; model: diagnostic (+5.05-second delay); outcome metric: apnea-bradycardia	One lead ECG at 400 Hz	The same preprocessing techniques as reported in Ghahjaverestan et al [35]. QRS complexes were identified using Pan-Tompkins method [85]. The RR time series were uniformly upsampled to 10 Hz using a linear interpolation technique	A proposed layered HMM[u] model achieved 97.14% (SD 0.31%) accuracy in detecting apnea-bradycardia episodes, with a detection delay of –5.04 (SD 0.41) seconds
Cork University Maternity Hospital	Ahmed et al [40], 2015	Participants: NR; data size: 54 1-hour recordings; model: diagnostic; outcome metric: HIE	2-lead ECG, EEG[v] (sampling rate NR)	Artifacts were manually removed. R-peaks from raw ECG signals were extracted using Pan-Tompkins method [85]. The timing of the peaks was adjusted and uniformly sampled to 256 Hz using Hermite spline quadratic interpolation. Then, HRV features were extracted from a 1-minute window with 30-second overlap using the normalized RR interval	Seven time and frequency domain HRV features were extracted. A Gaussian supervector approach with SVM[w] achieved 0.81 AUROC in classifying HIE[x]

Data set used	Author, year	Study settings	Physiological signal analyzed	Signal processing and computational techniques	Key findings
Cork University Maternity Hospital	Temko et al [41], 2015	Participant, n=38; data size: 1 hour of EEG and ECG recordings from each; model: diagnostic; outcome metric: HIE	ECG and video EEG at 256 Hz	The 1-hour EEG segments were downsampled to 32 Hz with an antialiasing filter set to 16 Hz. The filtered EEG was segmented into a 60-second epoch with no overlap. QRS complexes from ECG signals were extracted using the algorithm reported in [94]. The resulting peaks were manually inspected to correct ectopic beats or mark artifacts. Then, signals were segmented into 60-second epochs	An SVM classifier using a subset of 9 EEG, 2 hours, and 1 clinical feature achieved 87% AUROC and 84% accuracy in predicting HIE
Cork University Maternity Hospital	Lloyd et al [42], 2016	Participant, n=43; data size: mean recording duration 41 hours 40 minutes; model: diagnostic; outcome metric: future adverse outcome in infants	EEG at 256 Hz, SpO_2 and HR at 1 Hz	EEG recordings were visually checked for quality, and poor-quality data were discarded. 1-hour epochs of EEG at 12 and 2 hours of age were then extracted from each recording. 1-hour epochs of HR and SpO_2 were extracted at 12- and 24-hour time point.	A logistic regression model predicted a 2-year poor outcome with an AUROC of 0.83
Cork University Maternity Hospital	Semenova et al [43], 2018	Participants; n=35 with 23 used; data size: 824 hours; prognostic (time NR); outcome metric: short-term adverse outcome	ECG at 256 or 1024 Hz, BP at 1 Hz	Diastolic and systolic pressures every second were used to calculate MAP[y]. ECG signals were segmented to nonoverlapping 5-minute epochs. QRS complexes were extracted by the Pan-Tompkins method [85]. Abnormal RR intervals were corrected by moving average. Periods of clear movement of artifacts were automatically discarded (method NR)	Fifteen time, frequency, and nonlinear features were extracted from HRV. An XGBoost decision tree using all features achieved an AUROC of 0.97 in predicting short-term outcomes in infants

Data set used	Author, year	Study settings	Physiological signal analyzed	Signal processing and computational techniques	Key findings
Cork University Maternity Hospital	Semenova et al [44], 2019	Participants; n=43 with 23 used; data size: total 831 hours; prognostic (time NR); outcome metric: 5 adverse outcomes	ECG at 256 or 1024 Hz, BP at 1 Hz	DBP and SBP every second were used to calculate MAP. Segments with MAP<10 mm Hg were discarded due to disconnection of the pressure transducer or movements. The MAP was segmented into 1-hour windows. Values outside 3 SD were discarded. ECG signals were segmented into nonoverlapping 5-minute epochs. QRS complexes were extracted using the Pan-Tompkins method [85]. ECG signal was bandpass filtered with 4-30-Hz cutoff frequency. Abnormal values of RR intervals were corrected by the moving average filter	Time, frequency, and nonlinear features were extracted from HRV. An XGBoost decision tree using a single HRV feature achieved 0.87 AUROC, while multiple features reached 0.97 AUROC in predicting adverse outcomes
Máxima Medical Center NICU[z]	Joshi et al [45], 2020	Participants; n=49; data size: ~144 hours each; model: prognostic (+0-24 h); outcome metric: sepsis	ECG at 250 Hz, CI[aa] at 62.5 Hz	Respiration waveforms were bandpass filtered between 0.45 and 1.45 Hz. QRS complexes from ECG were extracted using a DT-CWT[ab]–based method described in [95]. IBIs[ac] were detected from the CI signal peaks using an algorithm (NR). Features were extracted from every 3-hour data	Twenty-two features were extracted from the signals. A naive bayes classifier reached up to 0.78 AUROC and 3 hours leading up to sepsis
Máxima medical Center NICU	Varisco et al [46], 2021	Participants; n=20; data size: ~570 hours; model: prognostic (+6 hours); outcome metric: central apnea preceding late-onset sepsis	ECG at 240 or 250 Hz, CI at 60 or 62.5 Hz, SpO_2 at 0.5 or 1 Hz	A filtered respiration signal without cardiac artifacts was generated using algorithms reported in studies by Lee et al [96], Mohr et al [97], and Vergales et al [98]. Steps include Fourier transformation and integer frequencies filtered out, then resampled to 60 Hz and high-pass filtered with a cutoff frequency of 0.4 Hz, and a low-pass filter with a very low cutoff frequency optimized to fit apnea annotations by clinical experts (value NR)	An optimization of the algorithm was proposed to detect central apnea, which achieved 90.5% recall, 19.7% precision, and 30.8% F_1-score

Data set used	Author, year	Study settings	Physiological signal analyzed	Signal processing and computational techniques	Key findings
Máxima medical Center NICU	Cabrera-Quiros et al [47], 2021	Participants; n=64; data size: NR; model: prognostic (+3 hours); outcome metric: sepsis	ECG at 250 Hz, CI at 62.5 Hz	QRS complexes from ECG were extracted using a DT-CWT–based method described the same as Joshi et al [45]. CI signal was filtered to remove cardiac artifacts, and peaks were detected using methods similar to those in previous works (NR). Features were extracted from every 1-hour signal	Time domain features were extracted from HRV. Classification using a combination of all features and logistic regression model reached a mean accuracy of 0.79 (SD 0.12) and mean precision of 0.82 (SD 0.18), 3 hours before the onset of sepsis
Máxima Medical Center NICU	Varisco et al [48], 2022	Participants; n=20; data size: 960 hours of data from 20 infants, 7818 event extracted; model: diagnostic; outcome metric: central apnea	ECG at 250 Hz, CI at 62.5 Hz, SpO_2 at 1 Hz	QRS complexes were detected using the same method as reported in Joshi et al [45] and Cabrera-Quiros et al [47]. From ECG, SII[ad] was calculated by applying a bandpass filter (0.001-0.40 Hz) using 10-second segments and then computing a kernel density estimate to return patient motion measurement every second. RR intervals were resampled at 250 Hz. CI signal was processed using the method by Redmond et al [99] to calculate RRE[ae]. No preprocessing was done on SpO_2. Each feature was extracted using 30-second windows. z score normalization was applied to the feature matrix	47 features were extracted from the vitals. A logistic regression model achieved 0.9 AUROC in detecting central apnea
Máxima Medical Center NICU	Peng et al [49], 2022	Participants; n=128; data size: ~24 hours each; model: prognostic (+24 hours); outcome metric: sepsis	ECG at 250 Hz	QRS complexes from ECG were extracted using a DT-CWT–based method described by Rooijakkers et al [95]. RR intervals from the complexes were divided into nonoverlapping 1-hour segments. The segments were centered, and missing values in the segments were filled by zero padding on the 2 ends	A ResNet-based neural network, DeepLOS, was proposed, which achieved a 0.72 F_1-score in predicting late-onset sepsis

Data set used	Author, year	Study settings	Physiological signal analyzed	Signal processing and computational techniques	Key findings
Máxima Medical Center NICU	Peng et al [50], 2022	Participants; n=127; data size: ~48 hours each; model: prognostic (+6 hours); outcome metric: sepsis	ECG at 250 Hz, CI at 62.5 Hz	QRS complexes from ECG were extracted using a DT-CWT–based method described in [95]. CI signal was filtered to remove cardiac artifacts (method NR). Peaks were detected using the method reported by Lee et al [96]. SII was calculated from ECG and CI waveforms using a CWT-based method, as reported by Zuzarte et al [100]. Signals were divided into 1-hour-long nonoverlapping segments. Features were calculated in both 1-hour segments and 5-minute subsegments	60 Features were extracted from the signals. An XGB model using the features achieved an AUROC of 0.88 in predicting late-onset sepsis 6 hours preceding the onset.
Royal Infirmary of Edinburgh NICU	Stanculescu et al [51], 2014	Participants; n=24; data size: 30 hours each; model: prognostic (+3-6 hours); outcome metric: sepsis	ECG-derived HR, PR[af] (sampling rate NR)	An extension of the forward-backward algorithm [101] is developed for missing data inference	An autoregressive HMM model achieved up to 0.80 AUROC in predicting sepsis
Royal Infirmary of Edinburgh NICU	Stanculescu et al [52], 2014	Participants; n=24; data size: 540 hours; model: diagnostic; outcome metric: sepsis	ECG-derived HR, PR core and peripheral temperature and SpO_2 at 1 Hz	An automated oximeter error detection algorithm was applied on the basis of the method described by Stanculescu et al [51]. Rows containing missing data on the observation matrix are set to 0	An HSLDS[ag] was able to predict sepsis with up to 0.65 F_1-score
Kasturba hospital NICU, Manipal, India	Shirwaikar et al [53], 2016	Participant: NR; data size: 229 examples; model: diagnostic; outcome metric: apnea	HR (sampling rate NR)	Visualization technique was applied to identify issues in data. Missing values were not treated due to low percentage. For categorical features, 0 was added for missing values. Minimum-maximum normalization and z score normalization were done	An RF[ah] model using HR features achieved 0.88 accuracy and 0.72 κ in detecting apnea
Kasturba hospital NICU, Manipal, India	Shirwaikar et al [54], 2019	Participants; n=367 (315 used); data size: NR; model: diagnostic; outcome metric: apnea	ECG (sampling rate NR)	No preprocessing techniques were reported on the raw signals. Observations with missing features were discarded. Other features (continuous values) that had missing values were converted to discrete with the addition of the group name "not known"	Statistical features were extracted from the signals. A Multilayer Perceptron model and a deep autoencoder model reached 0.82 and 0.83 AUROC, respectively, in detecting apnea

Data set used	Author, year	Study settings	Physiological signal analyzed	Signal processing and computational techniques	Key findings
University of Massachusetts Memorial Healthcare NICU	Williamson et al [55], 2013	Participants; n=6; data size: ~5-8 hours for each patient; model: prognostic (+5.5 minutes); outcome metric: apnea	ECG, SpO_2, respirator signal, pulse plethysmogram (sampling rate NR)	IBIs were extracted from abdominal respiratory movements (method NR), and RR intervals were extracted from ECG signals (method NR). Physically implausible IBI and RR interval values were automatically removed (range NR). Values were resampled to 10 Hz using shape-preserving piecewise cubic interpolation. Signals were then log transformed and converted to 0 mean, unit variance	Features were extracted from all signals. A GMM[ai] model reached 0.8 AU-ROC in predicting apnea
Jackson Memorial Hospital NICU	Schiavenato et al [56], 2013	Participants; n=20; data size: 1186 minutes; model: diagnostic; outcome metric: periods of high distress or pain	ECG at 1000 Hz	Pan-Tompkins algorithm [85] was modified to detect QRS complexes. ECG was filtered using a band-pass filter with a 16-26-Hz cutoff frequency. A low-pass filter by an order 120 FIR[aj] filter with a corner frequency of 25 Hz and a high-pass filter by an order 160 FIR filter with a corner frequency of 25 Hz were applied. Then, a polynomial filter of order 21 was applied as the differentiator filter. Finally, a 111-order moving average filter was used, and QRS complex was detected using an adaptive threshold. Lomb-Scargle LMS[ak] spectral estimation [102] was used for missing and irregular RR intervals	The proposed framework provided real-time analysis and HRV extraction to identify the characteristics correlated to periods of high distress or pain
Montreal Children's Hospital	Rubles-Rubio et al [57], 2014	Participants; n=24; data size: 9.0 (SD 2.2) hours for each; model: diagnostic; outcome metric: apnea	SpO_2, RIP[al] (sampling rate NR)	Signals were low-pass filtered with a cutoff frequency of 10 Hz, with an 8-pole Bessel antialiasing filter digitized and sampled at 50 Hz	A linear Gaussian discriminant classifier detected the episodes with a 0.73 probability of detection and 0.22 probability of false alarm
University of Alabama at Birmingham	Amperayani et al [58], 2017	Participants; n=18; data size: 24 hours each; model: prognostic (+23 hours); outcome metric: bradycardia, hypoxemia	ECG at 500 Hz and HR at 1 Hz	HR data were converted to interbeat RR intervals using RR=60/HR. No processing on ECG signals was reported	A point process model using RR intervals showed a strong correlation with bradycardia events and a modest correlation with hypoxemia events

Data set used	Author, year	Study settings	Physiological signal analyzed	Signal processing and computational techniques	Key findings
Monash Children's Hospital NICU, Australia	Hu et al [59], 2018	Participants; n<80; data size: 407 patient-day; model: prognostic (+24 hours); outcome metric: sepsis	HR, SpO_2, respiration signal at 1 Hz	Data were scaled down to 1 record per minute. Data blocks with invalid values were deleted. Then, the sliding window was set to 60 minutes to feed to the ML[am] models	Features were extracted from all signals. A gradient boosting decision tree achieved up to 0.97 AU-ROC and 0.92 weighted F_1-score in patient-based cross-validation in predicting sepsis
University of Virginia and Columbia University NICU	Sullivan et al [60], 2018	Participants; n=78; data size: NR; model: prognostic (+12 hours); outcome metric: death, sIVH[an] (severe), BPD[ao], treated ROP, [ap] late-onset sepsis, and NEC[aq]	HR, SpO_2 at 0.5 Hz	Infants with <6 hours of data within 12 hours of birth were discarded. Cross-correlation of HR and SpO_2 was calculated over 10-minute windows using the XCORR function of MATLAB with a lag time of –30 to +30 seconds	A POPS[ar] was developed and fit a multivariate logistic regression model, which performed well in predicting death, sIVH, and BPD, but not tROP, sepsis, and NEC
9 NICUs in the United States	Zimmet et al [61], 2020	Participants; n=2989; data size: 121 data points per infant; model: prognostic (+2 days); outcome metric: mortality, sepsis	HRC[as] index from ECG	Infants with missing data on either end of the total duration were extrapolated to the window edge by repeating the most proximal HRC index values. Interior missing values were updated using linear interpolation. A fifth-order B-spline with equally spaced knots was used to capture information from independent samples (HRC indexes 12 samples apart)	An unsupervised ensemble of clustering techniques was proposed to cluster infants to different levels of risk
Children's National Hospital, Washington	Kota et al [103], 2020	Participants; n=95; data size: median recording duration of 75.78 hours; model: diagnostic; outcome metric: HIE	EEG at 200 or 256 Hz	ECG contamination from EEG was detected using the method described by Govindan et al [104]. EEG signals with amplitude>500 µV or SD<0.01 µV were discarded as artifacts. The volume conduction was attenuated by calculating the global average of EEG voltages from all electrodes and subtracting the global average from the EEG value of every electrode in the frequency domain [62]. The values were then transformed to the time domain for spectral analysis. EEG was segmented into 10-minute nonoverlapping artifact and seizure-free epochs. Spectral analysis was done using a Welch periodogram approach [105,106] using 3-second epochs	EEG delta power was identified to be a crucial biomarker for predicting neonates with HIE who died with those who survived

Data set used	Author, year	Study settings	Physiological signal analyzed	Signal processing and computational techniques	Key findings
Akbar Abadi Hospital NICU, Iran	Mirnia et al [63], 2021	Participants; n=5; data size: ~24 hours each; model: diagnostic, outcome metric: sepsis	ECG at 200 Hz	RR intervals were calculated from ECG using HeRO[at] model	Features were extracted from HRV. HeRO model was tested using this data set. HeRO score was able to distinguish between healthy and septic newborns
St Louis Children's Hospital NICU	Lee et al [64], 2021	Participants; n=275; data size: 4, 01,33,460 data points; model: prognostic (+6 hours); outcome metric: mortality	HR, respiration signal and SpO_2 at 1 Hz	Missing or out-of-range values were replaced with NaN and then imputed using mean values for that variable across all training and testing data. Data were downsampled to every 10 seconds to extract features. Dynamic variables were calculated as rolling means, SD, and absolute z score on 5- and 30-minute windows to reduce the influence of outliers	Thirty-four features were extracted from the signals. An RF model achieved 88% sensitivity and 0.93 AUROC in predicting mortality
University of Virginia Children's Hospital, Morgan Stanley Children's Hospital, and St Louis Children's Hospital	Sullivan et al [65], 2021	Participants; n=408, (266 used); data size: NR; model: diagnostic; outcome metric: sepsis	HR and SpO_2 at 0.5 Hz	HR and SpO_2 values of 0 were removed. Eight features were extracted in 10-minute windows and averaged hourly. Cross-correlation between HR and SpO_2 was calculated in 10-minute windows of signals normalized to have 0 mean and SD of 1. Cross-correlation was done using the XCORR function of MATLAB with a lag time of –30 to +30 seconds	A logistic regression model using clinical and physiological features achieved an AUC[au] of 0.821 in predicting late-onset sepsis

Data set used	Author, year	Study settings	Physiological signal analyzed	Signal processing and computational techniques	Key findings
St Louis Children's Hospital NICU	Feng et al [66], 2021	Participants; n=285; data size: ~80 hours each; model: prognostic (+6 hours); outcome metric: mortality	HR, respiration, SpO$_2$, and ART-M^{av} or NIBP-M^{aw} at 1 Hz	Infants with data >80 hours were truncated, and <80 hours were padded with 0s. Mean, median, mode, and Bayesian ridge data imputation techniques were explored. Bayesian ridge was used to sample 5 data sets by sampling different posteriors each time. Then, the average was reported using 4-fold cross-validation. The rolling mean of each vital sign with a range of 5 minutes was used to reduce noise. Finally, the end of each sample was padded with 1 segment where all features equaled 0. Features were extracted from 5-minute segments	A deep learning model using LSTM named DeepPBSMonitor was developed to predict mortality with 0.888 accuracy, 0.78 recall, and 0.897 AUC
University of Massachusetts Memorial Healthcare	Zuzarte et al [67], 2021	Participants; n=10; data size: 241.34 hours; model: prognostic (+310 seconds); outcome metric: apnea-bradycardia-hypoxia	ECG at 500 Hz, PPG^{ax} at 125 Hz, SpO$_2$, HR, respiration signals from pneumogram at 50 Hz	PPG signals were filtered using a wavelet-based algorithm to remove gross body movements. A binary marker sampled at 25 Hz was obtained to indicate the presence or absence of movement. QRS complexes were detected using a modified Pan-Tompkins algorithm (modification NR). IBIs were detected using automated peak detection from LabChart Software RR intervals, and IBI values were then interpolated at 10 Hz	The prediction framework using GMM and logistic regression model achieved 75% accuracy in predicting bradycardia severity during the apnea-bradycardia-hypoxia event
University of Virginia NICU	Niestroy et al [68], 2022	Participants; n=5957; data size: random daily 10 minutes segments from each; model: prognostic (+1-7 days); outcome metric: mortality	HR and SpO$_2$ at 0.5 Hz	No preprocessing was reported on the vitals. They were grouped to calculate the average in 10-minute nonoverlapping windows	Features were extracted from all signals. A multivariable logistic regression model using 5 features achieved the AUROC of 0.83 in predicting mortality
University of Virginia Children's Hospital, Morgan Stanley Children's Hospital and St Louis Children's Hospital	Kausch et al [69], 2023	Participants; n=2494; data size: NR; model: prognostic (+24 hours); outcome metric: sepsis	HR and SpO$_2$ at 0.5 Hz	HR and SpO$_2$ were preprocessed by removing the values containing 0. Features were calculated in 10-minute nonoverlapping windows. Windows with >50% missing data were excluded from subsequent analysis	Several features were extracted from the vitals. An XGB model achieved training AUROC of 0.834 using the data from NICU 1, and 0.792 and 0.807 testing AUROC using data from NICU 2 and NICU 3, respectively

Data set used	Author, year	Study settings	Physiological signal analyzed	Signal processing and computational techniques	Key findings
Karolinska University Hospital Solna and Huddinge NICU, Stockholm, Sweden	Honoré et al [70], 2023	Participants; n=325; data size: 2866 hospitalization days; model: prognostic (+24 hours); outcome metric: sepsis	IBI from ECG, respiration from CI, SpO_2 (sampling rate 1-500 Hz)	All signals were resampled to 1 Hz. Segments with at most 15 seconds missing were linearly interpolated. All signals were filtered with a moving mean filter of width 3. IBI signals were further filtered to remove ectopic beats and strong nonlinearities with a moving median filter of width 3 and Butterworth bandpass filter of order 6 with low-cut and high-cut frequencies of 0.0021 and 0.43 Hz. Signals were divided into 45-minute segments. Features were calculated using a sliding time frame with 50% overlap	A naive bayes classifier achieved an AUROC of 0.82 up to 24 hours before clinical suspicion of sepsis. Adding respiratory signals improved the performance compared with only using heart rate features
Simulated and real data (NICU name NR)	Masoudi et al [71], 2013	Participants; n=32; data size: 233 episodes, ~7 seconds each; model: diagnostic (+2.32-second delay); outcome metric: apnea-bradycardia	2-channel ECG	No preprocessing techniques were reported. Signals were sampled in 7-second intervals	A coupled HMM model achieved 84.92% sensitivity, 94.17% specificity with a time detection delay of 2.32 (SD 4.82) seconds in detection apnea-bradycardia episodes
Simulated and real signals from NICU (NICU name NR)	Altuve et al [72], 2015	Participants; n=32; data size: 148 RR intervals with a mean duration of 26.25 (SD 11.37) minutes; model: diagnostic (+1.73-second delay); Outcome metric: apnea-bradycardia	ECG (sampling rate NR)	Hidden semi-Markov models to represent the temporal evolution of RR intervals. A preprocessing method that includes quantization and a delayed version of the observation vector is proposed. RR time series was resampled at 10 Hz and segmented at a 7-second interval	The proposed model achieved up to 93.84 (SD 0.79) in specificity and 89.66 (SD 0.71) in sensitivity with a detection delay of 1.59 (SD 0.24) seconds

Data set used	Author, year	Study settings	Physiological signal analyzed	Signal processing and computational techniques	Key findings
NICU (name NR)	Honoré et al [73], 2020	Participants; n=22; data size: 3501time series, 1200 samples in each; model: prognostic (+72 hours); outcome metric: sepsis	SpO_2, respiratory frequency, and RR interval from ECG at 1 Hz	Data were segmented into 20-minute time frames. Time frames with missing data were discarded	Features were extracted from all signals. A combined GMM-HMM model achieved 0.74% (SD 0.05%) accuracy in detecting sepsis. The model was compared with HeRO model, which underperformed using this data set

[a]CHIME: Collaborative Home Infant Monitoring Evaluation.

[ax]PPG: photoplethysmography.

Preprocessing Steps

Overview

Preprocessing of physiological data typically involves several steps, including the handling of missing data, filtering, segmentation, and waveform analysis for feature extraction. Here, we define 5 required preprocessing steps (based on the steps outlined in Berkaya et al [13]) and identify the steps reported by each of the studies in this review (Table 3). The definition of each of the steps is given in subsequent sections.

Table 3. Required physiological signal preprocessing steps reported by each of the studies in this review.

Handling of Missing Data

During neonatal physiological monitoring, instances of missing data may arise due to sensor disconnection, improper placements, or signal dropouts. To tackle this issue, methodologies like data imputation or interpolation are applied. For example, if gaps exist in a neonate's HR monitoring data, interpolation methods can estimate the missing values by considering neighboring data points. Widely used interpolation techniques include linear interpolation, spline interpolation, and time-based interpolation. In addition, common data imputation methods involve forward fill, backward fill, and imputation using mean or median values. Methods such as forward fill [30], moving average [44], mean imputation [64,66], and interpolation [67] were used by some studies reviewed in this paper.

Artifact Removal

Neonatal signals can be affected by artifacts, such as those from muscle movements or electrical interference. Commonly used techniques, such as bandpass or notch filters, along with moving averages, are used to effectively eliminate these disturbances. For instance, in neonatal EEG signals, adaptive filters prove beneficial in eliminating artifacts caused by muscle movements, resulting in a clearer representation of the baby's brain activity. Some methods used by the reviewed papers were high-pass filter [27,46] bandpass filter [29,33,44,45,56].

Resampling and Normalization

Overview

Resampling is a technique that standardizes data intervals, involving either upsampling (increasing data point frequency) or downsampling (decreasing frequency) to create a regular time series. This aligns signals from different devices or physiological sources. Normalization ensures uniformity and reliability across these standardized sampling rates. For instance, if neonatal HR signals from different devices have varied sampling rates, resampling achieves a common rate, while normalization, using techniques such as minimum-maximum, z score, or log scale, ensures consistent amplitude scaling for accurate comparative analysis. In the reviewed studies, normalization techniques such as minimum-maximum [53] and 0 mean normalization [29,59] were used. In terms of resampling, both downsampling [33,34,41] and upsampling [39] techniques were used.

Waveform Feature Extraction

Extracting relevant features from a signal's waveform is a fundamental step in signal preprocessing. This involves identifying key characteristics such as peaks, troughs, or other significant points in the signal. In the context of neonatal ECG, feature extraction may involve identifying key points such as R-peaks to analyze HRV, providing valuable insights into the infant's autonomic nervous system development. The Pan-Tompkins algorithm is a popular method chosen by multiple papers reviewed in this study that conducted R-peak detection from the QRS complex [22,24,27,33,35,39].

Data Segmentation

Segmenting data is the process of breaking down a continuous signal into smaller, more manageable sections to enable targeted analysis. This practice is especially beneficial when dealing with lengthy signals. Data segmentation is a common preprocessing step in ML workflows. For instance, in the analysis of neonatal sleep patterns using EEG, data segmentation can involve dividing the continuous EEG signal into epochs, allowing for the identification and study of sleep stages in shorter, more manageable segments. Commonly used segmentation techniques include fixed length, sliding window, and threshold- and feature-based segmentation. Some of the data segmentation sizes used in the reviewed studies were 30-second [22-24,45] and 1-minute [41] epochs and a sliding window of varied sizes [35,40,55,59,64].

In neonatal physiological signal processing, these preprocessing techniques contribute to the accurate interpretation of signals, aiding health care professionals in monitoring and providing appropriate care in the NICU or other clinical settings.

It can be seen from Table 3 that only 7 (13%) out of the 52 reviewed studies reported all the recommended preprocessing steps. This could have several impacts on the downstream analysis. For instance, several papers missed reporting on how they segmented the data for feature extraction and classification, although it is essential for clinical validation in cases where the segment duration is dependent on the adverse outcome prediction performance. In HRV analysis, it is important to indicate whether it is a short-term (~5 minutes) or a long-term (≥24 hours) analysis as they reflect different underlying physiological processes and thus demonstrate different predictive power [107]. Along with the segment duration, additional information such as the sampling rate of the signals will provide a clear reflection of the data set size. Downsampling the data to a low sampling rate (eg, 50 Hz) has also shown a significant impact on HRV analysis [108]. Although all the reviewed studies mentioned the participant number, and majority of them (n=39) reported the sampling rate of the signals, very few provided details on the sample size or data set duration or whether the data set was resampled for subsequent analysis. These elements provide a clearer picture of the computational time and resources required for clinical validation and adoption. Although physiological recordings collected in the NICU environment suffer greatly from missing data due to similar factors that introduce artifacts [109], reporting how missing data are handled is scarce. Different methods for dealing with missing values could cause different results, and not all might be suitable for a particular problem. Therefore, it is important to report all the details related to the adopted approach.

The incomplete or partial reporting found in these studies has significant implications for the implementation of QMS in using these techniques for clinical adoption. A good implementation of QMS requires a comprehensive reporting of each intermediary step involved in constructing an AI and ML pipeline. The International Medical Device Regulators Forum offers guidance on the clinical evaluation required for any product intended for use as a medical device [110]. According to the International Medical Device Regulators Forum guidelines, during clinical evaluation, relevant research articles are reviewed to identify clinical evidence supporting the product [111]. The guideline encourages manufacturers to follow these recognized standards and best practices in the development, validation, and manufacturing processes. Clinical evaluations are required by the European Union medical device regulation, and it is also mentioned in the ISO 13485 (the quality management standard for medical devices). Thus, detailed reporting is crucial as it can be used by regulatory bodies to evaluate future SaMD products clinically. Steps such as the missing data handling procedures are also required by the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) checklist for model development and validation, which assesses the risk of bias and clinical usefulness of the prediction model [112]. Another example is a questionnaire prepared by the German

Notified Body Interest Group, and it was adopted to assess some AI-powered medical products in the European Union. This questionnaire includes inquiries about data management, including data collection, labeling, preprocessing procedures, and relevant documentation. Transparent and detailed reporting of these steps is essential to ensure the safety, efficacy, and reliability of SaMD.

Discussion

Principal Findings

This review aimed to summarize the computational methods used for preprocessing preterm infants' physiological data as a first step in developing data-driven predictive models for adverse outcomes related to clinical decision support. This is an important step, especially from a clinician's perspective, because it increases the trustworthiness of the developed models by allowing for the verification and reproduction of the results. In addition, it aids in achieving regulatory compliance and ensures the safety, efficacy, and ethical use of AI-based health care devices. Furthermore, it allows us to recognize the shortcomings in the current state-of-the-art studies and recommend guidelines for transparent reporting. The review found that the studies were heterogeneous in terms of their methods and applications. Therefore, a narrative approach to reporting the results was taken instead of a quantitative approach. Through the analysis we identified several key components that were incomplete or partially reported by the included studies, which are summarized in Table 3. To ensure transparent reporting for any future studies in this area, we recommend detailed reporting of all preprocessing steps listed in Table 3, which will allow revealing their strengths and weaknesses and ultimately make them usable and reproducible. Reproducible research allows clinicians to make more informed decisions about patient care and treatment based on the evidence that has been thoroughly assessed.

Comparison With Prior Work

The reviews published in recent years have highlighted the potential of big data and AI in supporting clinical decision-making in the neonatal health care domain [10,15,21,113,114], particularly in using physiological data for detecting or predicting neonatal health outcomes. However, appropriate preprocessing of these data is a prerequisite for developing clinically deployable models. A systematic review by McAdams et al [10] reported different ML models used to predict different clinical outcomes in neonates. However, their primary focus was on 5 neonatal morbidities, and they did not focus on reporting the preprocessing methods applied before building the ML models. Furthermore, they did not include studies using real-time continuous physiological data; 28 out of their 68 studies were based on physiological data (not continuous), and the rest were based on electronic medical records and imaging data. Latremouille et al [15] performed a review on HRV analysis for neonates. The primary limitation of the work was the lack of reporting in detail about the preprocessing steps of ECG signals before HRV analysis, such as ECG handling and segmentation, R-wave (QRS complex) identification technique, software and parameters, and ranges of all HRV features. They identified these components as

incomplete or missing in the studies they reviewed and thus recommended clear reporting of these aspects for future studies in this area. These limitations served as a motivation for our review to focus on the preprocessing techniques of neonatal physiological signals in a broader sense, which serves as the preliminary step for any big data–based approaches.

Limitations

There are several limitations to this review. Screening of all the included studies was conducted independently by 1 reviewer, which may have introduced bias. In addition, this review did not include a quantitative or comparative analysis of the reviewed studies, as the techniques used to analyze the physiological signals were diverse. Future work could include a quantitative evaluation of the studies that were homogeneous in design.

Conclusions

This review explores the computational methods used by the current state-of-the-art ML-driven clinical decision support approaches to preprocess physiological signals collected from infants treated in the neonatal setting. A summary of the studies identified heterogeneity in the techniques used for analysis and revealed a lack of consistent and detailed reporting, which is important for building robust, transparent, and clinically deployable prediction models. The availability of powerful hardware and software resources in the NICU environment and growing interest in big data and AI are driving strong demand for clinical decision support applications. We recommend clear reporting of the different steps in the preprocessing of the neonatal physiological signals to ensure transparency in clinical validation and accelerate the adoption of developed models in the clinical setting. This will further enhance the delivery and adoption of reliable, regulatory-compliant, safe, and effective products in health care.

Abstract

Background: The declaration of the COVID-19 pandemic led to public health restrictions that impacted the lives of people across the globe. Parents were particularly burdened with balancing multiple responsibilities, such as working from home while caring for and educating their children. Alcohol use among parents is an area that warrants further exploration.

Objective: This study aimed to investigate patterns of parental alcohol consumption during the COVID-19 pandemic, focusing on relative changes in the frequency and quantity of alcohol use compared to prepandemic use, nonparent adult samples, or both.

Methods: A scoping review informed by the methodology of Arksey and O'Malley explored patterns of parental alcohol consumption during the COVID-19 pandemic. Searches were conducted in CINAHL, Ovid MEDLINE, PsycINFO, and Web of Science. Search terms were created using the Joanna Briggs Institute framework of Population, Concept, and Context, with the population being parents and the concept being alcohol consumption during the COVID-19 pandemic.

Results: The database search yielded 3568 articles, which were screened for eligibility. Of the 3568 articles, 40 (1.12%) met the inclusion criteria and were included in the scoping review. Findings indicated the following: (1) having children at home was a factor associated with parental patterns of alcohol use; (2) mixed findings regarding gender-related patterns of alcohol consumption; and (3) linkages between parental patterns of alcohol use and mental health symptoms of stress, depression, and anxiety.

Conclusions: This scoping review revealed heterogeneous patterns in parental alcohol use across sociocultural contexts during the COVID-19 pandemic. Given the known harms of alcohol use, it is worthwhile for clinicians to assess parental drinking patterns and initiate conversations regarding moderation in alcohol use.

Introduction

Background

On March 11, 2020, the World Health Organization (WHO) declared COVID-19 a global pandemic [1]. The restrictive public health measures introduced in many countries contributed to a shadow pandemic of psychological distress [2], which was associated with increased sales and consumption of alcohol [3,4]. Changes in the environments and circumstances in which adults drink can have effects on rates of consumption; lockdown

restrictions and sheltering in place led to drinking in the home environment becoming the norm during COVID-19 lockdowns in some places, such as the United Kingdom [5].

In Westernized countries, problematic alcohol use peaks in the third decade of life, a time when many adults are raising young children [6]. The reduction of alcohol consumption is one of the top 10 modifiable risk factors for reducing disease burden, injury, and social problems globally [7,8]. The burden of disease associated with alcohol use is high. A meta-analysis identified alcohol consumption as the seventh leading risk factor for disability and premature death in 2016, and among those aged 15 to 49 years, alcohol consumption accounts for nearly 10% of deaths on a global scale [9].

Parents warrant special attention as a large subsection of the adult population because they are primary caregivers for children. For parents, pandemic stressors (eg, lockdown restrictions, balancing employment while children are at home, and reduced social support) compound the daily stressors of parenting young children [10]. In parallel to the elevated rates of parental depression and anxiety from prepandemic levels [11,12], evidence suggests that the COVID-19 pandemic has increased the consumption of alcohol in parents with young children [13,14]. A meta-analysis of 128 studies (aggregate sample of N=492,235) revealed that nearly a quarter of adults reported increases in alcohol consumption during the COVID-19 pandemic [15]. These changes were moderated by per capita gross domestic product and country. The authors identified that residing with children was associated with increases in alcohol consumption, with consumption increasing with the number of children at home [15]. Moreover, while Acuff et al [15] identified that female participants were more likely to increase their drinking frequency and male participants were more likely to increase their problematic drinking behaviors (eg, binge drinking), it is unclear what proportions of these participants were also caregivers to young children. Currently, a granular and gendered examination of patterns of alcohol consumption in caregiving adults is lacking during the COVID-19 pandemic.

Objectives

The purpose of this scoping review was to investigate broad patterns of parental alcohol consumption during the COVID-19 pandemic, examining the relative changes in the frequency and quantity of alcohol use compared to nonparent adults, prepandemic levels of consumption, or both. In addition to physical health harms related to excessive alcohol consumption [16], parents who consume problematic amounts of alcohol are more likely to have worse mental health and lower emotional availability to children [13]. Poor parental mental health, substance use, and negative parenting practices can have adverse consequences on children's socioemotional development and mental health [17,18]. The results of this scoping review can assist clinicians working with families in identifying parents at risk for alcohol misuse and engaging them in interventions to

reduce consumption. The findings can also inform policy makers regarding the population of parents who may require targeted intervention and education on reducing and managing alcohol consumption in the aftermath of the COVID-19 pandemic.

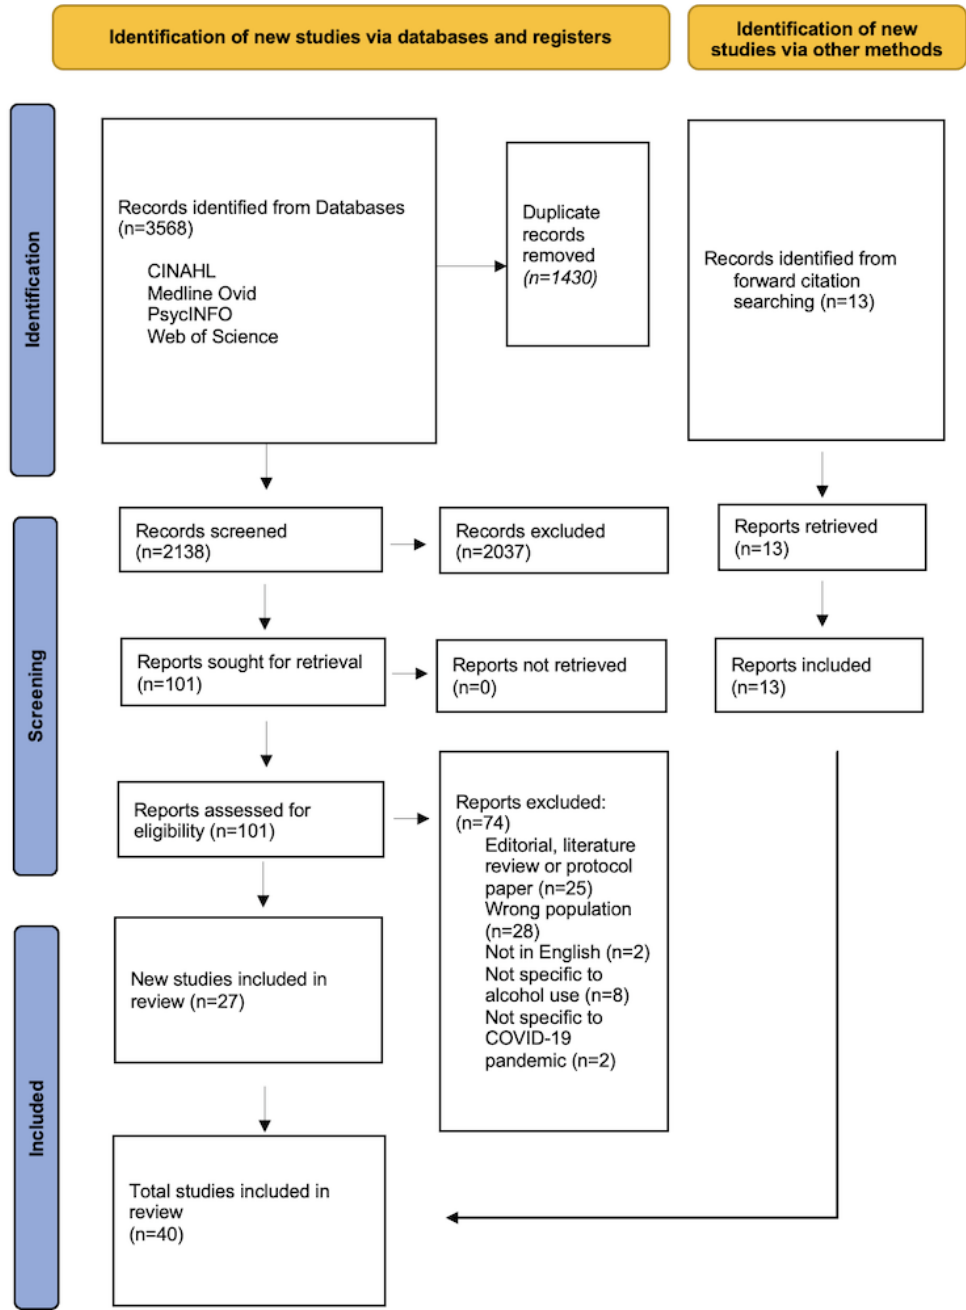
Methods

Scoping Review Search Strategy

We undertook a scoping review following the methodology outlined by Arksey and O'Malley [19]. We used the Joanna Briggs Institute framework of Population, Concept, and Context (PCC) to create our search terms, with the population being parents (caregiving adults living with children aged <18 years in the same household) and the core concept being alcohol consumption within the context of the COVID-19 pandemic. To capture a wide scope of relevant studies, a librarian team member conducted a systematic search in CINAHL, Ovid MEDLINE, PsycINFO, Web of Science, and Cochrane databases using the specified PCC terms for all articles published after the WHO declaration of the COVID-19 pandemic on March 11, 2020 (Multimedia Appendix 1). The 3 groups of keywords within the PCC framework were joined with the Boolean operator "AND," which produced 3568 articles for screening in June 2022. Medical Subject Headings and its descriptors were used for CINAHL, Ovid MEDLINE, and PsycINFO. Forward citation searching of articles identified in June 2022 was carried out in May 2023, which further yielded an additional 13 articles.

Inclusion and Exclusion Criteria

After 1430 (40.08%) duplicates were removed from the initial pool of 3568 articles, 2138 (59.92%) articles were screened for eligibility in a 2-round process (Figure 1). In the first round, article titles and abstracts (and text as needed) were reviewed against the PCC framework. We included peer-reviewed empirical studies that were published in English with data collection occurring after the WHO declaration of the COVID-19 pandemic. Nonempirical papers; expert opinions; letters to the editor; preprints; and empirical papers that were published after March 11, 2020, but did not contain alcohol consumption data collected during the COVID-19 pandemic were excluded. Studies that included a comparison of alcohol use between households with children and households without children were included. Reasons for exclusion included study population not being parents with alcohol consumption (eg, adolescent alcohol use) and the lack of explicit data collection on alcohol consumption as a variable. Studies that collected data on adult alcohol consumption during the COVID-19 pandemic but did not differentiate between adults living with children at home and adults not living with children at home were also excluded. Most studies that remained included both parent and nonparent participants (30/40, 75%), while some studies examined parents specifically (10/40, 25%).

Figure 1. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) flow diagram.


Data Extraction

Data from the articles were extracted into an extraction table derived from Polit and Beck [20]. The table included columns for authors, country of origin, year of publication, research design, sample size, measurement of alcohol use, time frame of data collection, and main findings. Extraction was performed independently by team members (KB and KC) and checked for accuracy (KC). Concerns with data extraction were resolved in consultation with the first author (CO).

Evidence Synthesis

A narrative analysis of the main findings was conducted to identify and compare themes across the included studies. This approach allowed for the evaluation and integration of diverse findings on the trends in parental alcohol consumption during the COVID-19 pandemic.

Results

Overview

Of the 40 studies included in analyses, 36 (90%) were quantitative studies, 2 (5%) were qualitative studies, and 2 (5%) were systematic reviews (Figure 1). Of the 36 quantitative studies, most studies (n=28, 78%) were cross-sectional survey studies, 7 (19%) studies were longitudinal cohort studies, and 1 (3%) was a secondary data analysis of publicly available data (Table 1). The following themes were identified: (1) having children at home was a factor associated with parental patterns of alcohol use, (2) mixed patterns of alcohol consumption among mothers and fathers, and (3) heterogenous linkages between parental patterns of alcohol use and mental health.

Table 1. Evidence extraction table.

Author and year	Time frame and country	Research design and sample size, N	Alcohol variable	Main findings
Global				
Kyaw Hla et al [21], 2021	• April 17 to June 25, 2020 • Global	• Cross-sectional survey • N=37,206; n=28,649 (77%) women	• Respondents were asked about alcohol "stock up" and consumption frequency compared to pre–COVID-19 levels.	• Middle-aged, educated women working from home and living with children were a high-risk group for increased alcohol use during the lockdown. Households with children were more likely to increase alcohol use (ORa 1.17, 95% CI 1.10-1.24; P<.001) compared to households with adults only.
Roberts et al [4], 2021	• December 2019 to November 2020 • Global	• Systematic review • N=45 articles	• In the included studies, respondents were asked about patterns of alcohol use, harmful alcohol use, and binge drinking.	• Of the 45 studies, 5 (11%) studies found significantly higher alcohol use among parents compared to nonparents.
Sallie et al [22], 2020	• May 12 to 28, 2020 • Global	• Cross-sectional survey • N=1346; n=209 (15.53%) parents	• Respondents were asked about drinking behaviors before and during COVID-19 lockdowns. • 3 items from the AUDIT-Cb	• Drinking behaviors decreased overall during quarantine across the entire sample. Among parents, drinking behaviors increased compared to nonparents (P=.003).
Schmidt et al [23], 2021	• March 2020 to March 2021 • Data collection occurred between March and May 2020 in most articles (49/53, 92%). • Global	• Systematic review • N=53 articles	• Alcohol concept varied in the included studies. The PICOc tool was used to guide the search strategy where the problem identified was substance use, substance use disorder, drug abuse, and dependence.	• Caregiving responsibilities were discussed as a factor in increased substance use in 13 (25%) of the 53 articles. Parental status was associated with higher overall alcohol consumption, higher Alcohol Use Disorders Identification Test scores, consuming more drinks per occasion, more drinks consumed per week, and more heavy drinking episodes, with a positive correlation between the number of children at home and the amount of alcohol consumed. One study found that having children at home was associated with decreased alcohol use, and another study found that having children at home was associated with less binge drinking.
North America				
Deacon et al [24], 2021	• July 2020; reported retrospectively in April 2020 • Canada	• Cross-sectional survey • N=758 couples; n=211 (27.8%) homeschooling couples; n=173 (22.8%) couples homeschooling due to the COVID-19 pandemic	• Brief Alcohol Motives Measure (2 items from the scale were used to examine coping-related alcohol use)	• Among the homeschooling sample, coping-related alcohol use was significantly increased relative to prepandemic use. The partner effect of hours spent homeschooling was significant on coping-related drinking.

Author and year	Time frame and country	Research design and sample size, N	Alcohol variable	Main findings
DesRoches et al [25], 2021	• April to July 2020 • Canada	• Cross-sectional survey • N=758 couples; n=211 (27.8%) homeschooling couples	• Quantity, frequency, and Peak Alcohol Use Index	• Women's hours of homeschooling were associated with greater drinking frequency in both the women themselves (beta=0.04; P=.01 and in their partner (beta=0.029; P=.02). Longer hours of homeschooling by men were associated with lower drinking frequency in women partners (b=–0.04; P=.02), but not with their own. • Homeschooling was significantly correlated with drinking quantity (b=0.17; P<.05) but not drinking frequency. Partner's time spent home schooling was positively related to one's own drinking frequency (b=0.022; P=.01), quantity (b=0.020; P=.03), and peak drinking (b=0.022; P=.02). Gender significantly moderated the effect of time spent homeschooling on drinking frequency in dyadic analysis with both actor (P=.009) and partner (P<.001).
Gadermann et al [26], 2021	• May 14 to 29, 2020 • Canada	• Cross-sectional survey • N=3000; n=618 (20.6%) parents	• Respondents were asked about increased alcohol consumption after the pandemic as a means of coping with pandemic-related stress or deteriorating mental health. • Questions were adapted from the Mental Health Foundation survey.	• Parents had a significantly greater increase in alcohol consumption compared to nonparents (28% vs 16%; P<.001). This was greater among men (32% vs 24%; P=.01). Parents were more likely to report deteriorated mental health (44.3% vs 35.6%; P<.001).
Hill MacEachern et al [27], 2021	• September 11 to December 4, 2020 • Canada	• Cross-sectional survey • N=12,344; n=3474 (28.14%) women and n=3348 (27.12%) men were parents or guardians to children aged <18 years	• Respondents were asked, "how has your alcohol consumption changed since before the COVID-19 pandemic?"	• Women with children were 1.46 times (95% CI 1.13-1.90) more likely to report increased alcohol consumption compared to women without children (23.3% vs 13.4%). Men with children were 1.38 times (95% CI 1.05-1.82) more likely to report increased consumption compared to men without children (21.7% vs 12.7%).
Joyce et al [28], 2022	• April 14 to 28, 2020 • Canada	• Cross-sectional survey • N=508 mothers of children aged 0 to 8 years	• Respondents were asked, "has your alcohol/drug use changed since the COVID-19 pandemic began?"	• Among the participants, 54.9% (n=279) reported no change in substance use, 39.2% (n=199) reported increased substance use, and 5.9% (n=30) reported decreased substance use. Alcohol was the most commonly reported substance (406/508, 80%), followed by cannabis (44/508, 8.7%).
Thomson et al [29], 2021	• May 2020, September 2020, and January 2021 • Canada	• Multiround cross-sectional surveys • May 2020: n=618 parents • September 2020: n=804 parents • January 2021: n=602 parents	• Respondents were asked whether their alcohol consumption had changed as a result of the COVID-19 pandemic.	• Parents were significantly more likely to report increased alcohol consumption compared to nonparents in all 3 rounds of surveys: round 1 (27.2% vs 16.1%), round 2 (21.9% vs 14.8%), and round 3 (22.4% vs 15.4%). Parents aged <35 years had higher odds of increased drinking than older parents (OR 1.51, 95% CI 1.10-2.07). Women were less likely than men to increase drinking (OR 0.76, 95% CI 0.59-0.97). Parents who continued to work while looking after children had higher odds of increased drinking (OR 1.86, 95% CI 1.45-2.40).

Author and year	Time frame and country	Research design and sample size, N	Alcohol variable	Main findings
Wardell et al [30], 2020	• April to May 2020 • Canada	• Cross-sectional survey • N=320; n=80 (25%) parents	• Respondents were asked about their alcohol consumption in the past 30 days and the month before the COVID-19 pandemic. • Questions were modified from those provided by the National Institute on Alcohol Abuse and Alcoholism.	• Having a child in the household was a significant predictor of drinking as a coping behavior and drinking problems (β=.10; P<.05).
Zajacova et al [31], 2020	• March 29 to April 3, 2020 • Canada	• Secondary data analysis • N=4319 respondents; 30% (n=1296) had children aged <18 years	• Respondents were asked whether weekly alcohol consumption habits had changed.	• Those with children were more likely to report a decrease in alcohol consumption (P<.05).
Barbosa et al [32], 2023	• February 2020, April 2020, July 2020, and November 2020 • United States	• Longitudinal survey design • N=557; n=146 (26.3%) parents	• Respondents were asked about the quantity and frequency of alcohol consumption and binge drinking.	• The trajectory of alcohol consumption among parents found a 64% increase in the number of drinks consumed per month from February 2020 to November 2020. The increase in drinks consumed was significantly larger (P<.05) for those with children in the household than for those without children.
Boschuetz et al [33], 2020	• April 5 to 12, 2020 • United States	• Cross-sectional survey • N=408; 83% (338/405) were women and 80% (303/404) had children at home	• AUDIT-C	• Having children at home was associated with a significant increase in AUDIT-C scores (P=.02).
Freisthler and Price Wolf [34], 2023	• April 2020, April 2021, and April 2022 • Ohio, United States	• 3 longitudinal waves of surveys, during April 2020, 2021, and 2022 • N=266 mothers across the 3 waves	• Mothers were asked how often they drank any kind of alcoholic beverage in the past year, on how many of the past 28 days they had at least 1 drink, and how many drinks were consumed in the past 28 days.	• Mothers reported fewer days of alcohol consumption in April 2021 and April 2022 compared to April 2020. However, the average number of drinks per day was higher in April 2021 and April 2022 than in April 2020. • Mothers reported drinking less frequently but drinking more in volume when they did drink.
Grossman et al [35], 2020	• May 2020 • United States	• Cross-sectional survey • N=832; 45.1% (n=375) had children aged <18 years at home	• Respondents were asked about drinking frequency, binge drinking, patterns of drinking, and factors related to drinking in the past 30 days.	• Those with children at home consumed alcohol on a greater number of days than those without children (13.0 days vs 11.6 days; P=.054). There were no significant differences between parents and nonparents in the total drinks consumed or binge drinking.
Knell et al [36], 2020	• April 15 to May 5, 2020 • United States	• Cross-sectional survey • N=1804; n=785 (43.5%) parents	• BRFSSd • If alcohol use was reported, further questions were asked about the "average number of daily drinks" and whether this number changed since the COVID-19 pandemic.	• Having children increased the odds of increased alcohol consumption (OR 1.58, 95% CI 1.19-2.09).

Author and year	Time frame and country	Research design and sample size, N	Alcohol variable	Main findings
Lamar et al [37], 2021	• March 24 to April 28, 2020 • United States	• Cross-sectional survey • N=1048 parents	• Alcohol Use Disorders Identification Test	• Problematic alcohol use was indicated among 26.5% (n=278) of the sample, with 11.4% (n=119) indicating a high level of problematic alcohol use. Male participants had significantly higher consumption compared to female participants (t_{1046}=0.02; P=.003).
Nordeck et al [38], 2022	• March to July 2020 • United States	• Longitudinal study • 5 waves starting from March 11, 2020 • N=4298 across 5 surveys • 29.3% (n=1259) living with children	• The number of drinking days in the past 7 days	• The number of drinking days was lower for participants living with a partner and children (β=–.65; 95% CI –0.82 to –0.48) and those living with children only (β=–.86; 95% CI –1.16 to –0.57) compared with participants without children. However, there were significant sustained increases in drinking days among those living with a partner and children compared to those living with children only or those in other household structures.
Pomazal et al [39], 2023	• May 2020 to August 2021 • Wisconsin, United States	• Longitudinal study (3 waves) • Wave 1: n=1290 • Wave 2: n=1868 • Wave 3: n=1585 • Percentage of participants with children at home at each wave: 29.4% (379/1290), 28.3% (528/1868), and 25.3% (401/1585), respectively.	• Individuals were asked to self-report alcohol consumption in the last 60 days (a lot more, a little more, same, little less, or much less) compared to the reference period (prepandemic period, then July 2020, and February 2021)	• In all 3 waves, the presence of children at home was associated with increased drinking (34.56%, 25.57%, and 22.38%; P<.001). Adjusted logistic regression model data: participants aged 55 years with children at home were less likely to increase drinking than those aged 35 years (wave 1: OR 0.23, 95% CI 0.1-0.53; wave 2: OR 0.4, 95% CI 0.17-0.91) and those aged 40 years (wave 1: OR 0.22, 95% CI 0.09-0.54; wave 2: OR 0.41, 95% CI 0.17-0.97) with children at home.
Rodriguez et al [40], 2021	• July 22 to August 4, 2020 • United States	• Cross-sectional survey • N=118 couples • n=100 (84.75%) couples with children at home	• Respondents were asked about alcohol consumption patterns in the month before completing the survey. • Items from Inventory of Problems–Alcohol and Drugs	• Having children at home was a significant predictor for drinking to cope (2.45; P<.05; CI 3.3-31.6). No significant association between having children at home and drinks consumed per week, high-intensity drinking, or alcohol-related problems.
Weerakoon et al [41], 2021	• March to April 2020 • United States	• Cross-sectional survey • N=1928; 42% (n=810) had children living in the household	• Respondents were asked about changes in drinking habits and binge drinking behaviors during the COVID-19 pandemic.	• Households with children were less likely to binge drink than those without children (AORe 0.74, 95% CI 0.58-0.94). No significant changes were reported in parental drinking compared with participants with no children living at home.
Australia				

Author and year	Time frame and country	Research design and sample size, N	Alcohol variable	Main findings
Booth et al [42], 2024	• September 2020 • Australia	• Cross-sectional survey • N=4022	• Respondents were asked to rank how often they drank alcohol before and during the lockdown on a scale from 1 (never) to 7 (≥2 times a day)	• Those with children were more likely to experience an increase in alcohol consumption (β=.51, 95% CI 0.37-0.76).
Callinan et al [43], 2021	• April 29 to May 16, 2020 • Australia	• Cross-sectional survey • N=2307; n=468 (20.3%) parents with dependent children	• Respondents were asked about their 2019 drinking behaviors (prepandemic period) and drinking behaviors in the past 30 days.	• Having dependent children was significantly associated with increased alcohol consumption (β=.62; 95% CI 0.32-0.92; P<.05), and homeschooling responsibilities were significantly associated with increased alcohol consumption (β=.53, 95% CI 0.2-0.82; P<.05).
Cook et al [13], 2021	• July to September 2020 • Australia	• Qualitative study • N=30 parents and caregivers of children aged 4 to 12 years	• Participants were asked about the nature of family lives before and after the COVID-19 pandemic, including changes in alcohol practices and family dynamics due to the COVID-19 pandemic.	• Alcohol use was reported to signal the end of the workday as a means of self-care and to alleviate boredom and manage stress. It was associated with feelings of guilt due to lockdown challenges.
Glenister et al [44], 2021	• May 29 to July 9, 2020 • Australia	• Cross-sectional survey • N=339 rural women; 41% (n=139) of sample lived with children	• Respondents were asked whether alcohol use increased, decreased, or remained the same since the COVID-19 pandemic.	• Rural women living with children were more likely to report increased alcohol consumption compared to rural women not living with children (OR 2.37, 95% CI 1.36-4.15; P=.002).
Greenwood et al [45], 2023	• April 2020 to May 2021 • Victoria, Australia	• Longitudinal wave-based surveys (13 waves) • N=2261 parents	• Parents were asked about the frequency of alcohol consumption per month (ranked on a 7-point scale).	• Estimated alcohol frequency trajectory for parents showed a decreased use over the course of the pandemic. Female and other parent gender were associated with a trajectory of lower frequency of alcohol use. Older parent age was associated with a trajectory of higher frequency of alcohol use.
Johnson et al [46], 2021	• June to July 2020 • Australia	• Cross-sectional survey • N=406 mothers	• Alcohol Use Disorders Identification Test • Respondents were asked how their drinking has been impacted by the COVID-19 pandemic.	• Of the sample of 406 mothers, 54.9% (n=223) exceeded drinking guidelines and 41.4% (n=168) reported drinking more due to the pandemic. As parenting stress increased, alcohol use increased (P=.002).
Westrupp et al [47], 2023	• April 8 to 28, 2020 • Australia	• Cross-sectional survey • N=2365 parents	• Respondents were asked how often they drank alcoholic beverages.	• Compared to prepandemic population-based data from 4 Australian data sets, parents reported more frequent alcohol consumption (333/2365, 14.1%, pandemic data set) reported drinking on ≥4 days per week vs 771/9764, 7.89% (pre-pandemic data set), 7.9% reported drinking before the pandemic; P<.001). • Women were less likely than men to consume alcohol at higher levels.

Europe

Author and year	Time frame and country	Research design and sample size, N	Alcohol variable	Main findings
Bramness et al [48], 2021	• June to July 2020 • Norway	• Cross-sectional survey • N=1328; of the n=1200 who reported any alcohol use, n=887 (66.79%) had children aged <18 years in the household	• Respondents were asked to report alcohol use in the past 12 months and changes in alcohol use since the COVID-19 measures were implemented. • Two items from AUDIT-C	• Among the entire sample, 56.8% (n=754) reported no change in drinking patterns, 29.9% (n=397) reported less drinking, and 13.3% (n=177) reported more drinking. Having a child aged <18 years in the household was associated with more drinking (P=.02).
Koeger et al [49], 2022	• April 2020 to January 2021 • Germany	• Multiround cross-sectional surveys • Parents: round 1, n=307; round 2, n=295; and round 3, n=285	• Participants were asked about AUFf on a weekly basis.	• Odds for an increased AUF was higher among participants with children in round 1 during the first lockdown (OR 1.34, 95% CI 0.92-1.96; P>.05) and in round 2 during the relaxation of lockdown restrictions (OR 1.77, 95% CI 1.118-2.65; P<.01).
Mangot-Sala et al [50], 2022	• April 2020 to July 2021 • The Netherlands	• Longitudinal survey design • N=63,194	• Respondents were asked how many glasses of alcohol were consumed in the past 7 days.	• Results showed that during periods of lockdown, households with children reported the lowest alcohol consumption. During the summer, households with children reported a seasonal increase in drinking related to relaxed COVID-19 restrictions.
McAloney-Kocaman et al [51], 2022	• March to June 2020 • United Kingdom	• Longitudinal study (multiwave survey) • N=1268; 468 (36.9%) respondents had children in the household	• Participants were asked to indicate a change in alcohol consumption (drinking less, drinking approximately the same, or drinking more than usual) after the implementation of the lockdown.	• Perceived changes in alcohol consumption were significantly associated with the presence of children at home (χ^2_2=20.3, P<.001). • Odds of increased alcohol consumption was lower for those with children in the household.
Oldham et al [52], 2021	• April 30 to June 14, 2020 • United Kingdom	• Cross-sectional survey • N=2777 parents and nonparents	• AUDIT-C	• Among men, living with children was significantly associated with increases in the units of alcohol consumed per drinking session (OR 1.72, 95% CI 1.09-2.73; P=.02) and the frequency of heavy episodic drinking (OR 2.40, 95% CI 1.44-3.99; P=.001). There was no significant increase in drinking for women living with children.
Thorell et al [53], 2022	• April 28 to June 21, 2020 • Sweden, Spain, Italy, United Kingdom, Belgium, Netherlands, and Germany	• Cross-sectional survey • N=6720 parents of children aged 5 to 18 years; n=5914 (88%) female	• Respondent were asked how their alcohol or drug changed use during the COVID-19 pandemic compared to their prepandemic use.	• Across the sample, 5% of homeschooling parents reported increased levels of alcohol or drug use compared to prepandemic use. Differences varied by country. In the United Kingdom, there was a 19.1% increase, whereas in Sweden, Spain, and Italy, <3% reported increased drinking or drug use.
Vanderbruggen et al [54], 2020	• April 9 to 29, 2020 • Belgium	• Cross-sectional survey • N=3632; 44.3% (n=1609) lived with children	• Respondents were asked about the average amount of alcohol consumed before and during the lockdown. • Respondents were asked whether they drank more, less, or the same amount as before the COVID-19 pandemic.	• Overall, 30.3% (n=1100) of the total sample reported increased alcohol consumption, while 13.7% (n=498) reported decreased consumption. Alcohol use was positively correlated with the number of children living at home (22% increase in odds with every child at home; OR 1.220, 95% CI 1.146-1.289).

Author and year	Time frame and country	Research design and sample size, N	Alcohol variable	Main findings
Villette et al [55], 2022	• January to March 2021 • Western Brittany, France	• Cross-sectional descriptive survey • N=2491	• AUDIT-C questionnaire used to assess change in alcohol consumption before, during, and after the lockdown (frequency of alcohol consumption, number of drinks per day, and frequency of heavy drinking)	• Of those living with family, 30.19% (468/1550; P<.001) experienced a greater increase in alcohol consumption than those living with adult roommates (21/135, 15.6%) and those living alone (89/395, 22.5%). • Living with family was associated with increased alcohol consumption (OR 0.62, 95% CI 0.46-0.83; P<.001).
Central and South America				
Garcia-Cerde et al, [56], 2021	• May 22 to June 30, 2021 • Latin America	• Cross-sectional survey • N=12,328; n=8136 (66%) female	• Respondents were asked to report on alcohol behaviors, including how often alcohol consumption occurred with children present.	• An overall decrease in drinking during the COVID-19 pandemic (77.5% vs 65%) was found, including drinking with children present. • Regression model found that quarantining (β=3.81; 95% CI 2.61-5.02; P<.001), anxiety (β=.42; 95% CI 0.20-0.63; P<.001), and higher income were positively associated with drinking with children present.
Asia				
Sugaya et al [57], 2021	• June 15 to 20, 2021 • Japan	• Cross-sectional survey • N=11,427; n=6388 (55.9%) parents	• Alcohol Use Disorders Identification Test (Japanese version)	• Those who answered "yes" to the "presence of child" had higher hazardous alcohol use (11.6% vs 9.5%), lower no-problem scores (81.2% vs 83.2%), and equal potential alcoholism scores (7.2%, respectively) compared to those who answered "no" (χ2=12.4; P=.002).

[a]OR: odds ratio.

[c]PICO: Population, Intervention, Comparison, Outcome.

[d]BRFSS: Behavioral Risk Factor Surveillance System.

[e]AOR: adjusted odds ratio.

[f]AUF: alcohol use frequency.

Of the 40 included studies, 11 (28%) were also included in the 2 systematic reviews. To prevent undue inflation of support for the themes identified, we cited only the original papers to support specific themes.

Having Children at Home as a Factor Associated With Parental Patterns of Alcohol Use

Many of the studies demonstrated linkages between parental alcohol use and the presence of children at home. Many studies found that, compared to not having children aged <18 years at home, having children at home was a significant predictor for an increase in alcohol consumption during the COVID-19 pandemic in the United States [32-36,38-40], Canada [26,27,29,30], Australia [42-44], Norway [48], Belgium [54], Germany [49], France [55], the United Kingdom [51,53], and Japan [57]. In a global survey study of 1346 adults (half of the sample were from the United Kingdom and United States), having children at home was a significant factor for increases in alcohol consumption, as operationalized by Alcohol Use Disorders Identification Test scores [22]. Participants in a nationally representative US sample of 2-parent households

sustained increases in drinking days over the first 4 months of the COVID-19 pandemic, compared with the pre–COVID-19 baseline [38]. These findings are consistent with the conclusion of a higher incidence of increased drinking by adults with children at home compared with adults with no children at home in 2 systematic reviews during the COVID-19 pandemic [4,23]. Moreover, a large-scale global cross-sectional study involving 37,206 participants across 38 countries found households with children were significantly more likely to increase alcohol use compared to households with adults only [21]. An Australian survey of 4022 adults found that participants with children at home were more likely to increase the frequency of consuming alcohol along with other unhealthy foods (eg, snacks and sugared beverages) [42].

On the contrary, some studies indicated patterns of decreased parental drinking during the pandemic. In the United States, Weerakoon et al [41] found that there was no significant increase or decrease in parental drinking compared with participants with no children living at home (n=1928, 42% parents); moreover, having children in the household was associated with a decreased risk of binge drinking. Similarly, in Canada,

Zajacova et al [31] found that in a sample of 4319 adults (of whom, 30% (n=1296) had children aged <18 years at home), having children at home was associated with a lower rate of alcohol consumption. A 13-wave longitudinal study of Australian parents found that the frequency of alcohol use decreased over time, although there was no pre–COVID-19 consumption comparison [45]. In a large study of 35 Latin American countries (N=12,328), the majority of participants endorsed decreased drinking during the COVID-19 pandemic when compared with prepandemic levels of drinking [56].

Studies carried out in Europe indicate a mixture of findings. In a study of 63,194 adults in the Netherlands, Mangot-Sala et al [50] found that when comparing adults living with children at home to adults living without children at home and adults living alone, adults living with children drank less than the other 2 groups, suggesting that having children at home was protective in terms of drinking behaviors. Households with children reported a transient increase in drinking to prepandemic levels only during the summer months when restrictions were relaxed and families were more likely to gather, socialize, and engage in drinking with others [50]. In a European study of 6720 parents from (in the order of the largest number of participants per country) Germany, Sweden, Spain, Italy, Belgium, the United Kingdom, and the Netherlands, the proportion of parents who endorsed increased drinking during the COVID-19 pandemic (5%) were largely concentrated in the United Kingdom, with 19% (N=509) of UK parents reporting increases in drinking behaviors [53]. This contrasts with the findings of another UK-based longitudinal study, which found that having children at home was associated with lower odds of increased consumption [51]. A multiround cross-sectional study of adults in Germany found that participants who had children had higher odds of increased alcohol use frequency during the first lockdown (not significant) as well as during the easement of restrictions (significant) but lower odds during the second lockdown (not significant) [49].

In Australia, using a qualitative study of parents, Cook et al [13] found that while many parents in the sample indicated that they increased their frequency of alcohol consumption, some reported that they used the COVID-19 pandemic as an opportunity to lower their frequency of drinking through the absence of social opportunities for drinking.

Mixed Patterns of Drinking Among Mothers and Fathers

Several studies indicated that fathers were more likely than mothers to increase drinking during the COVID-19 pandemic in North America [26,29,37], Australia [45,47], and the United Kingdom [52]. This is in contrast to a global study by Kyaw Hla et al [21], where they found middle-aged, educated women with children at home to be a high-risk group for increased alcohol use during lockdowns. Hill MacEachern et al [27] also identified that, among parent participants, women had slightly higher odds of reporting increases in alcohol consumption when compared with men. Homeschooling was a significant predictor for increased drinking during the pandemic in North America [24] and Australia [43]. Moreover, in a Canadian sample of parents, having to engage in homeschooling for children had

an effect on maternal drinking. Desroches et al [25] found that mothers spent more time homeschooling than fathers and that both parents drank more when mothers spent more time homeschooling. Moreover, mothers drank less when fathers spent more time homeschooling [25]. Across their European sample (N=6720), Thorell et al [53] found that across subsamples from Sweden, Spain, Belgium, the Netherlands, Germany, Italy, and the United Kingdom, only 5% of homeschooling parents reported increased alcohol use. Freisthler and Price Wolf [34] investigated mothers' drinking patterns in a longitudinal study of US mothers via 3 waves of data collection (springtime of 2020, 2021, and 2022). Mothers reported significantly more days of alcohol consumption in the first wave when compared with the second and third waves; however, the average number of drinks consumed during a drinking day was greater in waves 2 and 3 [34]. In the qualitative study by Cook et al [13], one of the participants described how her own drinking habits changed while homeschooling during the pandemic:

> But then by mid-April, I was completely out of work and we were still homeschooling, then drinking started about lunchtime, like come on, it's 12 o'clock, it's 5 o'clock somewhere, right. [Woman, Queensland]

While Thomson et al [29] did not specifically examine homeschooling, they found that looking after children while working from home was associated with higher odds of increased alcohol consumption.

Heterogenous Linkages Between Parental Patterns of Alcohol Use and Mental Health

Several studies looked at alcohol use as a coping mechanism for stress. In Australia, Johnson et al [46] found that parenting stress modestly correlated with the Alcohol Use Disorders Identification Test scores. In Canada, using path analysis, Wardell et al [30] found that having children at home was associated with greater alcohol consumption as a method of coping with pandemic stressors.

The findings regarding the relationships between alcohol consumption and mental health were mixed. Lamar et al [37] found a significant correlation between mental health symptoms (stress, depression, and anxiety) and increases in alcohol consumption in the United States. Qualitatively, parents in Australia described that partaking in alcohol consumption at the end of the day delineated a shift from time spent on the care of children to time for self and served a means of self-medicating stress and anxiety [13]. Garcia-Cerde et al [56] found anxiety to be a weak predictor of drinking with children present in Latin American countries. Thomson et al [29] and Joyce et al [28], in their Canadian studies, did not find a significant link between increased drinking and mental health symptoms, although Joyce et al [28] reported that mothers with a history of a previously existing anxiety disorder or elevated anxiety symptoms were more likely to increase their substance use. Notably, an alcohol use tracking app (Habit Tracker) that collected data from 83 countries (the majority from the United Kingdom and the United States) found that although participants with children (209/1134, 18.4% of the sample) indicated significant increases in drinking

severity based on their Alcohol Use Disorders Identification Test–Consumption scores, their levels of depression and anxiety were lower relative to adults with no children, suggesting a protective effect of having children at home [22].

Discussion

Principal Findings

The findings of this scoping review provide a broad examination of the patterns of parental alcohol consumption during the COVID-19 pandemic. The global patterns of parental alcohol use were heterogeneous and were influenced by the stage of COVID-19 data collection and sociocultural contexts. Most of the studies clustered around the first year and a half of the pandemic with regard to data collection. While lockdown measures were associated with increased frequency and quantity of alcohol consumption for some Western, industrialized countries, notably the United States, Canada, Australia, and the United Kingdom, a number of studies found patterns of decreased consumption. In Latin American and European Union countries especially, lockdown restrictions eliminated opportunities for socializing and drinking outside the home. Although these findings were mixed, there have been concerning reports of increased alcohol-related deaths; a recent Statistics Canada [58] report indicated an 18% increase in alcohol-related deaths during the COVID-19 pandemic when compared to previous years and that this was the largest change in alcohol-related deaths over the past 20 years. Similarly, in the United States, there were relative increases in deaths when comparing 2019 and 2020 rates of alcohol-related mortality [59], with childbearing-aged adults (ie, those aged 25 to 44 years) experiencing the largest increases. Angus et al [60] also found that the rate of alcohol-related deaths (characterized as "deaths of despair") increased in the United Kingdom during the COVID-19 pandemic. However, these reports did not distinguish adults who were parenting and those who were not.

Although we had expected to find an association between income support and alcohol use, many of the included studies did not focus on income as a predictor of alcohol use, with the exceptions of the study by Westrupp et al [47], which found a modest association between financial deprivation and lower alcohol use in Australia, and the study by Garcia-Cerde et al [56], which found that individuals with a higher income were more likely to drink with children present. McAloney-Kocaman et al [51], Greenwood et al [45], and Nordeck et al [38] did not separate parents from nonparents when examining the relationship between income and alcohol use and similarly found that lower income predicted decreased use. This contrasts with findings from the United Kingdom, which identified that the most socioeconomically disadvantaged households increased their alcohol purchases more than the least disadvantaged households [61].

In our study, we found some differences in the gender-related patterns of parental drinking, with some findings suggesting that fathers were more likely to increase overall alcohol consumption. Nonetheless, having to homeschool their children contributed to mothers' increases in drinking. Homeschooling and the provision of childcare during day care closures were

responsibilities that fell disproportionately on mothers [62], with women also bearing greater employment-related consequences, such as the reduction of work hours and job loss related to childcare responsibilities [63]. The marketing of alcohol to mothers through social media was especially rampant (eg, through the use of hashtags such as #sendwine and slogans such as "from wifi to wine time #distance learning"), which calls into question the ethics of unmitigated marketing by the alcohol industry [10,14]. In the United States, gender-related differences in drinking behaviors have changed over time, with increases in rates of alcohol consumption in adult women [64]. Some studies indicate both mothers and fathers tend to decrease drinking during the transition to parenthood, with little difference between genders [65]. Meanwhile, other studies indicate that parenting children aged <1 year was associated with lower maternal drinking rates, whereas men's drinking habits changed little in response to parenthood [66]. Looking at overall drinking habits, fathers have been shown to be less likely to abstain from alcohol than mothers and consume greater volumes of alcohol [67]. Age has also been shown to be a factor, with young fathers more likely to partake in risky drinking behaviors than young mothers [67]. A systematic review of population-level alcohol policy interventions indicated evidence of gender-related differences in the impact of and exposure to alcohol marketing and failure to provide gender-specific recommendations [68].

Beyond the risk to parents' own health are the possible effects of parental alcohol consumption on children. Children are inevitably exposed to parental alcohol use in the home environment, and parents may even provide alcohol for older or adolescent children as a way to "safely" introduce children to alcohol in a parent-controlled home setting [69,70]. In the United States, Maggs et al [71] found that in 1 in 6 families, parents permitted their adolescents to drink in the home with the family during the COVID-19 pandemic, changing from prepandemic family practices of not permitting adolescent drinking at home. Evidence indicates that parents supplying even sips of alcohol to children carries increased risks of adverse alcohol outcomes, such as adolescent binge drinking, while parental supply of whole drinks was associated with higher odds of binge drinking, alcohol-related harms, and symptoms of dependence for teens [69]. Taken together, there is reason to continue to investigate parental patterns of alcohol consumption, given the range of negative short- and long-term health outcomes for children.

Strengths and Limitations

Strengths of this scoping review include the systematic search process followed. The findings of this scoping review are limited by the heterogeneous ways in which alcohol consumption was measured and the fact that not all studies had data on patterns of consumption before the COVID-19 pandemic for comparison purposes. This review includes a large number of studies from early in the pandemic and hence does not provide the complete picture of the patterns of parental alcohol consumption from the beginning of the COVID-19 pandemic in 2020 to the removal of pandemic-related restrictions during 2022 and 2023. Moreover, although the included studies differentiated patterns of alcohol consumption among parenting adults and

nonparenting adults, a limited number of studies differentiated drinking habits between genders in parenting adults, which limited the provision of a more granular examination of the association between gender and alcohol consumption habits in parents.

Clinical Implications and Future Directions

Parental drinking can adversely affect children indirectly through parent preoccupation and the diversion of parental attention and supervision and directly through physical and verbal violence in the home setting and influence children's later drinking habits [67,72]. In the 2023 *Canada's Guidance on Alcohol and Health* [73] report, the Canadian Centre for Substance Use and Addiction indicated that consuming >2 standard drinks per week heightens risks for breast and colon cancers, heart disease, and stroke, with the consumption of >6 drinks per week representing high risk of harms. In line with these strong recommendations for reducing alcohol intake to decrease health and social risks, clinicians who work with families (eg, primary care providers, nurses, and social workers) can inquire about clients' frequency and amount of alcohol consumption and counsel strategies for moderating or reducing consumption. The findings of this review suggest that parents caring for children are a population that requires more empirical investigation in relation to the amounts and frequency of alcohol consumption and problematic alcohol use. Gender–based data analysis of parental drinking behaviors is also important for informing interventions and policies to promote safe alcohol use among parents. Because parents effectively serve as role models for children, their drinking habits can influence children's later drinking behaviors. It is important to better understand how to assist parents in moderating alcohol intake, given the risks of unmitigated alcohol consumption.

Conclusions

Our scoping review indicated that the COVID-19 pandemic influenced patterns of parental alcohol consumption in different ways. Sociocultural influences contributed to determining whether having children at home was a protective or risk factor for alcohol consumption. In countries where drinking alcohol is more likely to occur in social settings, such as at bars or restaurants (eg, Latin American and some European countries), parental consumption tended to decrease during the lockdown restrictions, while in countries where drinking in the home environment is the norm (eg, the United States, Canada, the United Kingdom, and Australia), parental consumption tended to increase. Given the known harms of alcohol, clinicians can initiate conversations about parental drinking habits and counsel moderation for parents who report amounts of drinking higher than national guidelines.

Abstract

Background: Diet-related diseases, such as type 2 diabetes, require strict dietary management to slow down disease progression and call for innovative management strategies. Conventional diet monitoring places a significant memory burden on patients, who may not accurately remember details of their meals and thus frequently falls short in preventing disease progression. Recent advances in sensor and computational technologies have sparked interest in developing eating detection platforms.

Objective: This review investigates central hemodynamic and thermoregulatory responses as potential biomarkers for eating detection.

Methods: We searched peer-reviewed literature indexed in PubMed, Web of Science, and Scopus on June 20, 2022, with no date limits. We also conducted manual searches in the same databases until April 21, 2024. We included English-language papers demonstrating the impact of eating on central hemodynamics and thermoregulation in healthy individuals. To evaluate the overall study quality and assess the risk of bias, we designed a customized tool inspired by the Cochrane assessment framework. This tool has 4 categories: high, medium, low, and very low. A total of 2 independent reviewers conducted title and abstract screening, full-text review, and study quality and risk of bias analysis. In instances of disagreement between the 2 reviewers, a third reviewer served as an adjudicator.

Results: Our search retrieved 11,450 studies, and 25 met our inclusion criteria. Among the 25 included studies, 32% (8/25) were classified as high quality, 52% (13/25) as medium quality, and 16% (4/25) as low quality. Furthermore, we found no evidence of publication bias in any of the included studies. A consistent postprandial increase in heart rate, cardiac output, and stroke volume was observed in at least 95% (heart rate: 19/19, cardiac output: 18/19, stroke volume: 11/11) of the studies that investigated these variables' responses to eating. Specifically, cardiac output increased by 9%-100%, stroke volume by 18%-41%, and heart rate by 6%-21% across these studies. These changes were statistically significant ($P<.05$). In contrast, the 8 studies that investigated postprandial thermoregulatory effects displayed grossly inconsistent results, showing wide variations in response with no clear patterns of change, indicating a high degree of variability among these studies.

Conclusions: Our findings demonstrate that central hemodynamic responses, particularly heart rate, hold promise for wearable-based eating detection, as cardiac output and stroke volume cannot be measured by any currently available noninvasive medical or consumer-grade wearables.

Introduction

The rising incidence of diet-related diseases, such as coronary heart disease [1], and type 2 diabetes [2] has led to the emergence of an innovative research field called automated diet monitoring [3,4]. The primary objective of this field is to advance technologies that facilitate comprehensive monitoring of critical elements of food intake, such as meal timing, duration, quantity, and nutritional composition [5]. A fundamental aspect of this field is eating detection [4], which involves using technologies such as wearable devices to determine when an individual is eating. This innovative approach holds immense potential in empowering individuals to more accurately and efficiently monitor their dietary habits and effectively manage chronic diseases that require precise dietary control. By leveraging wearable technologies, eating detection enables real-time monitoring of meal timing, duration, and eating patterns, thus providing valuable insights into eating behaviors and supporting overall health and well-being.

Despite extensive research in eating detection [6-10], successful deployment of eating detection platforms remains elusive. Several challenges have hindered their widespread adoption, including the use of custom-made wearables with impractical form factors [4,11] or privacy concerns [12]. Notable examples include dental implants [11], on-body cameras [12], and wrist-worn inertial sensors [13,14] (accelerometer, gyroscope, or magnetometer), which pose significant challenges for widespread acceptance. In addition, many studies have relied on data collected in controlled laboratory or semicontrolled field settings [6,15,16], leading to algorithms that struggle to perform effectively in real-life scenarios filled with diverse activities and situations.

Furthermore, while some studies have achieved accurate detection of eating episodes [17-19], few have demonstrated the feasibility of real-time implementation [6], raising questions about their suitability for use in free-living scenarios. Real-time computation requires high-performance computing platforms with long battery life, presenting significant challenges for many proposed solutions [6]. In addition, detecting eating episodes during concurrent activities, such as walking, remains a substantial hurdle that necessitates further algorithmic improvements [7].

By the same token, most of the existing systems rely on a single sensor with limited provisions for sensor failure or suboptimal performance. In contrast, multimodal sensing, which involves using different sensors on one or more devices, can provide complementary and unique information, enhancing the performance and reliability of eating detection platforms, especially when combined with higher sampling rates [4,20].

Given the aforementioned challenges, extensive research focusing on exploring untapped sensing signals and repurposing everyday wearable devices for eating detection remains crucial. In line with this objective, our review investigates the potential of central hemodynamic and thermoregulatory responses to food intake as promising biomarkers for eating detection. Through a comprehensive analysis of the existing literature, this review aims to shed light on the role of central hemodynamics and thermoregulation in monitoring eating behavior, contributing valuable insights toward the development of effective and practical eating detection platforms.

Methods

Overview

This review adheres to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) [21] guidelines. It is registered on PROSPERO (CRD42022360600).

Information Sources

We searched peer-reviewed literature indexed in PubMed, Web of Science, and Scopus on June 20, 2022, with no date limits. We also conducted manual searches in the same databases until April 21, 2024. Before the official search, we identified a key study [22] and decided to augment our search by retrieving officially provided similar studies from PubMed and Web of Science.

Search Strategy

This review examines central hemodynamic and thermoregulatory responses to food intake as potential biomarkers for wearable-based eating detection. To capture relevant studies, our search used keywords such as "hemodynamic," "haemodynamic*," "thermoregulat*," "temperature regulation," "body heat," "body temperature," "skin temperature," "eating," "meal*," "ingest*," "intak*," "postprandial," and "post-prandial." We excluded all animal studies from our search. While our search strategy did not impose language restrictions on retrieved papers, we excluded 10 non–English-language papers published in Czech, French, German, and Japanese. For a comprehensive overview of our search strategy across all databases, please refer to Multimedia Appendix 1.

Eligibility Criteria

All included studies were peer-reviewed journal and conference papers published before April 21, 2024. Eligible studies had to demonstrate the impact of eating on central hemodynamics and thermoregulation, assessing metrics such as changes in heart rate, blood pressure, cardiac output, core or skin temperature, or stroke volume in healthy individuals.

We excluded non-English papers, animal research studies, opinion pieces, letters, studies not specifically focusing on central hemodynamics (eg, those focusing on renal dynamics), studies using indirect calorimetry to measure postprandial

thermogenesis, studies testing drug effects, studies focusing on water ingestion, long-term effects of food, and studies primarily examining central hemodynamic and thermoregulatory responses to food intake during or after exercise.

Screening and Selection

All retrieved studies were exported to Covidence [23], which automatically identified and removed 1419 duplicates. In total, 2 reviewers independently conducted the title and abstract screening and the full-text review. In cases of disagreement between the 2 reviewers, a third reviewer acted as an adjudicator.

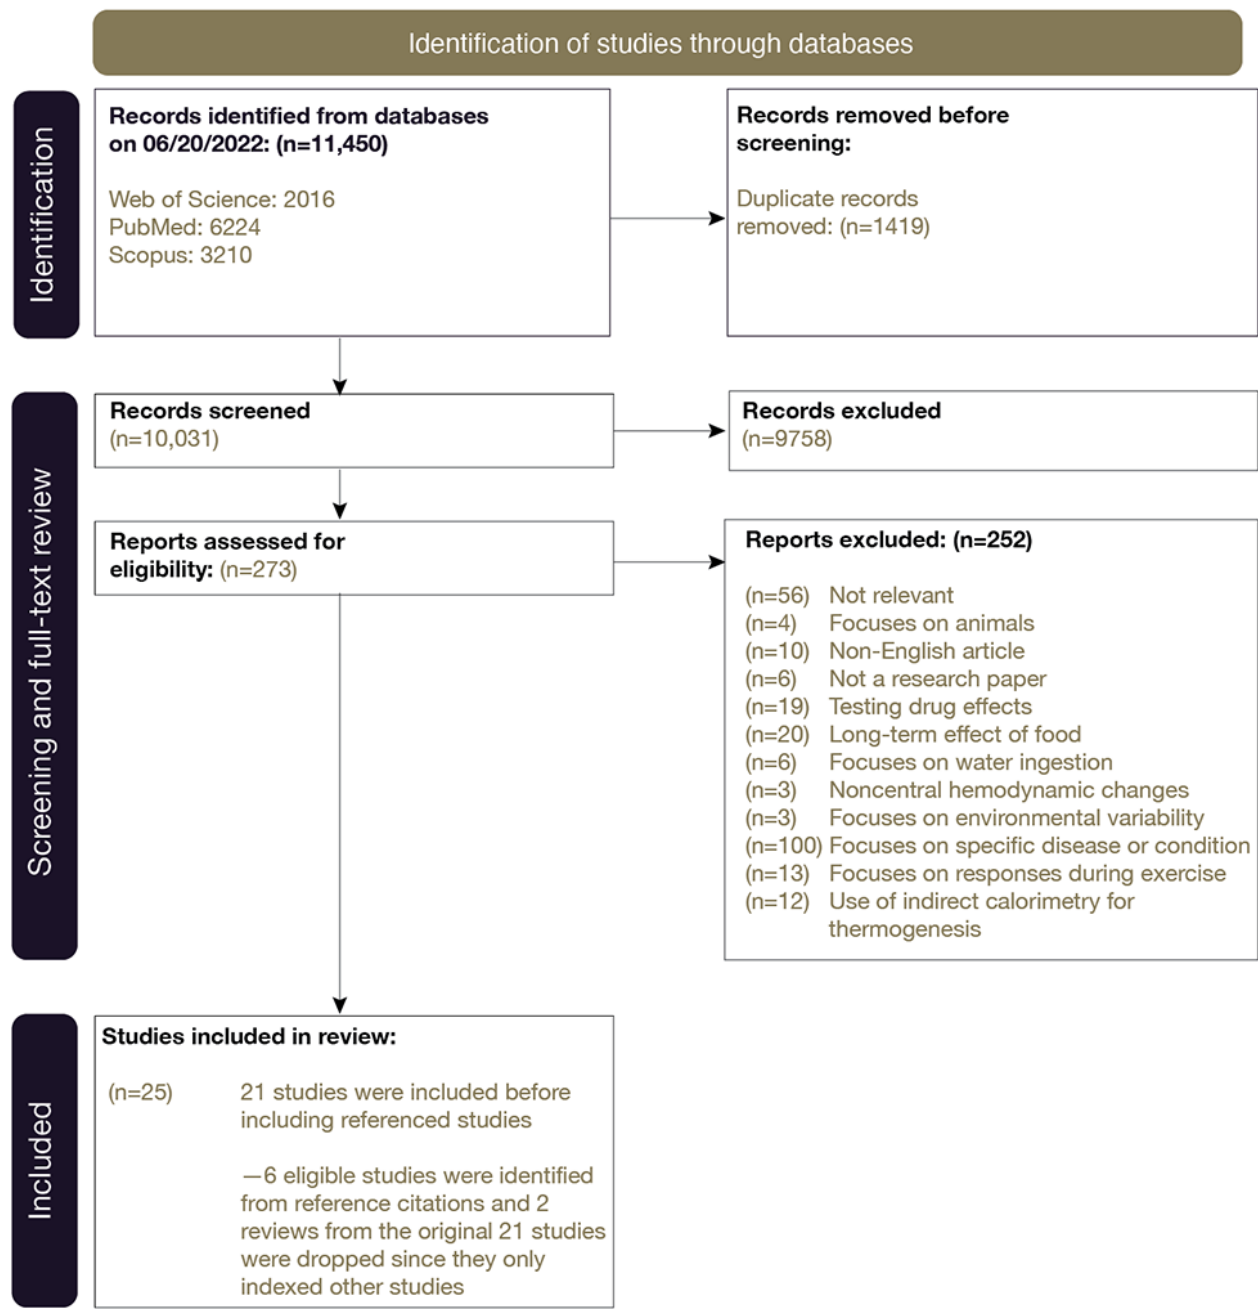
Data Extraction and Synthesis

A total of 2 reviewers independently conducted data extraction, study quality assessment, and risk-of-bias assessment for each included study. Any conflicts or discrepancies were resolved by an adjudicator. In addition, if any of the included studies referenced other studies that met our eligibility criteria, we also extracted relevant information from those referenced studies. We extracted 8 study characteristics from the included studies (Multimedia Appendix 2).

Due to the heterogeneity in the outcomes and designs of the included studies, we used a narrative data synthesis approach. In our characteristic tables (Multimedia Appendix 2), we summarized key findings from each study, identifying common themes, patterns, and differences. This approach allowed us to integrate both quantitative and qualitative data, thus providing a comprehensive overview of the current landscape. Finally, all graphs were generated using ggplot2 in R (version 4.0.2; R Foundation for Statistical Computing).

Results

Our search retrieved 11,450 studies (1419 duplicates), resulting in 10,031 studies being screened (Figure 1). Following the title and abstract screening, 273 studies progressed to the full-text review. Out of these, 21 studies met the eligibility criteria. In addition, we conducted a nested search within the references of the 21 studies and identified 6 additional relevant studies. We excluded 2 studies from the original 21 as they were review papers referencing other studies already included in our analysis. Finally, we extracted data from the included 25 studies and proceeded to analyze them.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram illustrating the article selection process.


To assess overall study quality and risk of bias, we developed a custom tool comprising 4 categories: high, medium, low, and very low (Multimedia Appendix 3). This assessment tool was based on the Cochrane assessment framework [24]. In total, 2 reviewers independently evaluated the study quality and risk of bias for each study, with an adjudicator resolving any conflicts. Among the 25 included studies, 32% (8/25) were classified as high quality, 52% (13/25) as medium quality, and 16% (4/25) as low quality (Multimedia Appendix 3). Furthermore, we found no evidence of publication bias in any of the included studies.

Of the included studies, 14 physiological responses were recorded. Multimedia Appendix 4 presents a breakdown of the number of studies reporting each postprandial physiological response. The number of participants per study ranged from 4 to 104, with a mean of 17 (SD 19). Out of the 416 participants in the 25 included studies, 230 (55.3%) were male, 180 (44.3%) were female, and the remaining 6 (1.4%) had unknown sex. The age of the participants in the included studies ranged from 18 to 69 years, and all participants were healthy. The sessions varied in duration, spanning from 10 minutes to 8 hours, and the provided food items included cake, cheese, filet mignon, and boiled eggs, among other foods.

Our findings overwhelmingly demonstrate a significant increase in heart rate after eating; 19 included studies investigated heart rate, and all 19 studies showed a statistically significant ($P<.05$) rise ranging from 6% to 21% (Multimedia Appendix 2). Furthermore, the postprandial effects of heart rate were found to be generally similar in both supine and erect positions (Multimedia Appendix 2). In addition, there was strong evidence

supporting an increase in cardiac output after food ingestion, with 18 of the 19 studies on cardiac output showing a statistically significant (*P*<.05) postprandial increase ranging from 9% to 100%, and only 1 study showing a statistically insignificant (*P*>.05) response for a high-fat liquid meal consisting of emulsified peanut oil (Multimedia Appendix 2). Similarly, data from 11 studies revealed strong evidence supporting a postprandial increase in stroke volume, ranging from 18% to 41% (Multimedia Appendix 2). These results collectively highlight the consistent and significant cardiovascular responses associated with food intake.

Out of the 25 included studies, 16 (64%) investigated the response of blood pressure to food ingestion; however, the results were inconclusive (Multimedia Appendix 2). Among these studies, 7 observed a postprandial increase in systolic blood pressure, while 4 found a statistically insignificant (*P*>.05) response, and 1 study even reported a postprandial decrease. Similarly, 8 studies found a postprandial decrease in diastolic blood pressure, while 3 studies found a statistically insignificant (*P*>.05) response, and 1 study observed a postprandial increase. Regarding mean blood pressure, the findings indicated either inconsistent postprandial behavior or a statistically insignificant (*P*>.05) response (Multimedia Appendix 2).

A total of 2 studies investigated the response of vascular resistance to food ingestion; one study focused solely on systemic vascular resistance, while the other study researched both systemic and mesenteric vascular resistance (Multimedia Appendix 2). Both studies observed a statistically significant (*P*<.05) postprandial decrease in vascular resistance.

In addition, 6 studies examined the response of blood flow in the hand, calf, and superior mesenteric artery to food ingestion (Multimedia Appendix 2). However, the postprandial effects of blood flow in the hand or calf were unclear. A total of 2 studies indicated a statistically significant (*P*<.05) postprandial increase in hand and calf blood flow, while 3 studies found a statistically insignificant (*P*>.05) change (Multimedia Appendix 2). Furthermore, 5 studies explored the response of oxygen uptake to food intake. In total, 3 of these studies observed a postprandial increase in oxygen uptake (more details in Multimedia Appendix 2). In addition, 1 study showed an inconsistent response, and another reported a statistically insignificant change (*P*>.05). Finally, the postprandial effects of skin or core temperature were found to be grossly inconsistent (Multimedia Appendix 2). A total of 5 studies reported inconsistent responses of skin or core temperature to food ingestion, 2 studies observed a postprandial increase, and 1 study found a statistically insignificant (*P*>.05) response (Multimedia Appendix 2).

Discussion

The primary objective of this systematic review was to investigate central hemodynamic and thermoregulatory responses to food intake as potential biomarkers for detecting eating events. Among the 25 studies included in this review, at least 95% (heart rate: 19/19, cardiac output: 18/19, stroke volume: 11/11) of those investigating the response of heart rate, cardiac output, and stroke volume to food ingestion reported consistent, statistically significant (*P*<.05) elevations in these variables. In contrast, the postprandial thermoregulatory effects were markedly inconsistent across the 8 studies that investigated them.

Our findings provide valuable insights into the physiological changes that occur after food consumption and shed light on potential biomarkers for detecting eating events. They consistently demonstrate significant cardiovascular responses associated with food intake (Multimedia Appendix 2). Specifically, heart rate showed a significant increase after eating, as evidenced by 19 studies, with the rise ranging from 6% to 21% (Multimedia Appendix 4 and Textbox 1). Similarly, cardiac output and stroke volume exhibited a robust postprandial increase, with 18 studies on cardiac output showing a significant rise ranging from 11% to 100%, and 11 studies revealing a postprandial increase in stroke volume, ranging from 18% to 41% (Multimedia Appendix 4 and Textbox 1). These findings suggest that heart rate, cardiac output, and stroke volume may serve as reliable biomarkers for detecting eating events. However, it is worth mentioning that 1 study reported a statistically insignificant (*P*>.05) cardiac output response to a high-fat liquid meal [25], while 9 studies reported different postprandial effects depending on the composition of the consumed food, underscoring the potential influence of dietary composition on cardiovascular reactions. Consequently, it is worth exploring whether eating detection using cardiovascular responses, particularly heart rate, could be enhanced to sense macronutrients in the ingested food. A particular area of focus could be carbohydrate-aware eating detection platforms, which would have the ability to classify the amount of carbohydrates in the food a person has just eaten into 2 classes that are high-carbohydrate and low-carbohydrate. We anticipate this to be feasible since several studies have demonstrated that postprandial heart rate changes within the first hour of eating correlate with the carbohydrate content in the food an individual has just consumed [25-28]. Accordingly, individuals could receive alerts when their meals are carbohydrate-rich, thus empowering them with more information about the foods they consume. In addition, decision support systems for diabetes management could use the inferred postprandial carbohydrate information to improve patient outcomes by personalizing patient recommendations based on their diet information.

Textbox 1. Postprandial percentage increase range for cardiac output, stroke volume, and heart rate.

Postprandial percentage increase range
• Cardiac output: 9%-100%
• Stroke volume: 18%-41%
• Heart rate: 6%-21%

Currently, there are no noninvasive consumer or medical-grade wearables capable of measuring cardiac output and stroke volume. As a result, heart rate remains the only signal that could feasibly be used in everyday eating detection platforms. Studies using heart rate for eating detection are already underway, but they have primarily focused on animal studies so far [29,30]. A notable study conducted in humans used consumer smartwatches and successfully detected eating events using heart rate with an accuracy of 98.6% [31]. However, the sensitivity, specificity, and F_1-scores were very low, with an F_1-score as low as 2% in one of the experiments [31]. We anticipate that using high-resolution data and conducting initial experiments in stationary situations without vigorous physical activity could facilitate a better understanding of heart rate–based eating detection systems.

Conversely, the findings concerning blood pressure responses were inconclusive. Of the 25 studies included, 16 (64%) investigated blood pressure changes following food ingestion; however, the results were inconsistent for systolic, diastolic, and mean blood pressure changes (Multimedia Appendix 2). The lack of consensus on blood pressure responses may limit its potential as a reliable biomarker for eating detection using wearable devices.

Vascular resistance and blood flow were also examined in a subset of the included studies (n=2 and n=6, respectively). Interestingly, vascular resistance showed a consistent postprandial decrease in both studies that investigated this parameter (Multimedia Appendix 2). On the other hand, the effects of postprandial blood flow in the hand, calf, and superior mesenteric artery were inconclusive, with some studies indicating postprandial effects, while others found no significant changes (Multimedia Appendix 2). Consequently, the use of vascular resistance and blood flow as biomarkers for eating detection may require further investigation and validation.

Furthermore, oxygen uptake responses after food intake were explored in 5 studies (Multimedia Appendix 2). While 3 studies showed a postprandial increase in oxygen uptake, 1 study reported inconsistent results, and another found no significant change. These mixed findings suggest that oxygen uptake may have limited use as a standalone biomarker for wearable-based eating detection.

Finally, postprandial temperature effects were found to be grossly inconsistent (Multimedia Appendix 2). While many studies have focused on determining the thermic effect of food [32-34] through calorimetry, very little is known about the skin or core temperature response to eating, and this review aimed to bridge that gap. Among the included studies, 2 reported a postprandial increase in temperature, while 5 studies revealed inconsistent responses, and 1 study found no significant change (Multimedia Appendix 2). The inconsistency in temperature responses warrants caution when considering temperature-based biomarkers for eating detection. In addition, temperature can be easily affected by environmental factors, and there is often a time lag before individuals elicit any temperature change in response to any physiological or environmental factors.

While our systematic review provides valuable insights, there are several limitations that should be acknowledged. First, the available literature on central hemodynamic and thermoregulatory responses to food intake might be limited, potentially leading to a restricted pool of studies to learn from. Sample sizes and study methodologies varied significantly, and this heterogeneity could have affected the ability to draw definitive conclusions for many variables. Furthermore, the majority of the studies focused on heart rate, cardiac output, and stroke volume, leaving other potential biomarkers underexplored. The inconsistency in the postprandial effects on blood pressure, blood flow, oxygen uptake, and temperature further highlights the need for more comprehensive research in these areas. In addition, it is important to note that all included studies were based on healthy participants, so the results from this review might not be fully extensible to the broader population, and their applicability to individuals with specific health conditions remains uncertain.

Out of the 25 included studies, 19 (76%) were conducted before 2000 using contemporary devices, which might have compromised the results' quality compared with more recent studies that may have benefitted from the advances in modern technology. Recent advancements in precision, data collection, and analytical tools could significantly improve the accuracy and reliability of these findings. All studies included in this review had the goal of wanting to understand the postprandial effects of the concerned signals, and they were measuring changes in a discrete fashion as opposed to a continuous fashion. Furthermore, the quality assessment of the included studies indicated that 17 (68%) of the studies were categorized as medium or low quality, mostly because they did not provide information on the devices used or the frequency at which data was collected. While efforts were made to minimize bias during the review process, the quality of data reported in the primary studies could influence the overall robustness of our findings.

Overall, the insights gained from this systematic review provide a strong foundation for future research and the development of wearable technologies aimed at enhancing eating detection and monitoring. Central hemodynamic responses, particularly heart rate, offer promising prospects for wearable-based eating detection. As other identified biomarkers, such as cardiac output and stroke volume cannot be measured by any currently available noninvasive medical or consumer-grade wearable, heart rate remains a valuable signal for this purpose.

Given the consistent postprandial heart rate effects in both supine and erect positions, heart rate–based eating detection technologies have the potential to revolutionize assisted living care, particularly in enhancing monitoring and support for bedridden individuals. For instance, this technology could track and verify that patients are receiving meals at prescribed times, providing reassurance to doctors and family members that dietary guidelines are being followed and proper care is being administered. Despite its potential, the complexity of the heart rate signal, influenced by factors such as physical exercise [35] and stress responses [36], may complicate its ability to detect eating events. To accurately identify eating episodes, algorithms must account for these variables and differentiate between heart rate changes due to eating and other activities. Integrating heart

rate data with additional sensors, such as electrodermal activity (EDA) sensors, which measure skin conductance and emotional states [37,38], and inertial measurement units (IMUs) sensors, such as accelerometers and gyroscopes, which monitor physical activity or hand movements, could enhance algorithm performance. This multimodal approach increases context awareness, allowing for clearer distinctions between physiological changes from eating and other activities, such as exercise or emotional states. By reducing false positives, such systems can become more sensitive and specific to changes associated with eating. It is also important to note, however, that many signals, including heart rate, EDA, and IMUs, carry the risk of reidentification [39]. Therefore, any systems using these signals should be properly secured to mitigate this privacy concern.

In conclusion, central hemodynamic responses, particularly heart rate, show promise for wearable-based eating detection. Future studies could aim for larger sample sizes, standardized protocols, and well-controlled experimental conditions to enhance the generalizability and reliability of the results. In addition, investigating how these findings apply to diverse populations and individuals with specific health conditions is crucial for broader application and impact.

Acknowledgments

Data Availability

All data generated in this study are available in the appendices. The search strategy can be found in Multimedia Appendix 1, and the list of extracted study characteristics for each included study is in Multimedia Appendix 2. In addition, the risk-of-bias and study quality assessments are provided in Multimedia Appendix 3, and the postprandial physiological responses, along with the number of studies reporting data for each category, are in Multimedia Appendix 4.

Authors' Contributions

LC conceived the study. LC, AT, and PV designed the search strategy. LC retrieved all searches from the databases and exported them to Covidence. LC, AT, and PV conducted the title and abstract screening, full-text review, and data extraction for this study. LC created all tables, graphs, and other visual representations, and AT and PV participated in the quality assurance process for all tables, graphs, and visual representations. LC drafted the manuscript, and all other authors read, edited, and approved the final manuscript.

Abstract

Background: Prehospital telemedicine triage systems combined with machine learning (ML) methods have the potential to improve triage accuracy and safely redirect low-acuity patients from attending the emergency department. However, research in prehospital settings is limited but needed; emergency department overcrowding and adverse patient outcomes are increasingly common.

Objective: In this scoping review, we sought to characterize the existing methods for ML-enhanced telemedicine emergency triage. In order to support future research, we aimed to delineate what data sources, predictors, labels, ML models, and performance metrics were used, and in which telemedicine triage systems these methods were applied.

Methods: A scoping review was conducted, querying multiple databases (MEDLINE, PubMed, Scopus, and IEEE Xplore) through February 24, 2023, to identify potential ML-enhanced methods, and for those eligible, relevant study characteristics were extracted, including prehospital triage setting, types of predictors, ground truth labeling method, ML models used, and performance metrics. Inclusion criteria were restricted to the triage of emergency telemedicine services using ML methods on an undifferentiated (disease nonspecific) population. Only primary research studies in English were considered. Furthermore, only those studies using data collected remotely (as opposed to derived from physical assessments) were included. In order to limit bias, we exclusively included articles identified through our predefined search criteria and had 3 researchers (DR, JS, and KS) independently screen the resulting studies. We conducted a narrative synthesis of findings to establish a knowledge base in this domain and identify potential gaps to be addressed in forthcoming ML-enhanced methods.

Results: A total of 165 unique records were screened for eligibility and 15 were included in the review. Most studies applied ML methods during emergency medical dispatch (7/15, 47%) or used chatbot applications (5/15, 33%). Patient demographics and health status variables were the most common predictors, with a notable absence of social variables. Frequently used ML models included support vector machines and tree-based methods. ML-enhanced models typically outperformed conventional triage algorithms, and we found a wide range of methods used to establish ground truth labels.

Conclusions: This scoping review observed heterogeneity in dataset size, predictors, clinical setting (triage process), and reported performance metrics. Standard structured predictors, including age, sex, and comorbidities, across articles suggest the importance of these inputs; however, there was a notable absence of other potentially useful data, including medications, social variables, and health system exposure. Ground truth labeling practices should be reported in a standard fashion as the true model performance hinges on these labels. This review calls for future work to form a standardized framework, thereby supporting consistent reporting and performance comparisons across ML-enhanced prehospital triage systems.

Introduction

Surging emergency department (ED) visits lead to overcrowding in the ED setting, contributing to adverse patient outcomes, staffing challenges, and health system constraints [1]. Challenges in maintaining ED capacity are estimated to cost millions in health care expenditures [2]. Various interventions have been proposed to improve ED conditions, and prehospital telemedicine triage systems are among the most promising, having the potential to prioritize patients based on their likelihood of requiring emergency versus community-based care [3], potentially alleviating the influx of low-acuity patients that would otherwise be managed in the high-cost, resource-intensive ED setting [4,5]. Such systems, including emergency medical dispatch, nurse-staffed telephone lines, and symptom checkers (chatbots), share the common goal to triage patients based on the information that is provided at the first contact for an urgent health concern. These prehospital services often do not include physician assessments, instead using either rule-based algorithms or health personnel for patient triage [6]. In telemedicine, defined as the delivery of health care services at a distance [7], the inherent scarcity of objective or physical measures such as vital signs has spurred efforts to improve risk prediction using machine learning (ML) models applied to a wide array of information sources such as free text from patient intake calls and vital symptoms monitoring [6,8].

Machine learning has been recognized as one option for improving the accuracy of prehospital telemedicine triage systems. To date, ML has commonly been applied in areas of precision medicine (ie, prediction of the success of treatment regimens), though it is rapidly expanding into diverse sectors of health care [9]. In the ED setting, ML models show promise in their ability to accurately predict inpatient admissions and sepsis [10,11]. Incorporating contextual information into ML models can improve prediction of prehospital emergency services [5]. However, there is a lack of understanding and evidence-based practices regarding how ML can optimally be implemented in remote prehospital settings as compared with more data-rich, in-person settings such as the ED [5,10,11].

In supervised learning, ML models learn from labeled data that serve as the "ground truth." Ground truth refers to the nature of the problem that is the target of the ML model; in the context of prehospital triage, ground truth is the "correct" triage outcome of a patient. The exact process for defining ground truth is complex and substantially varies across studies. Unlike clear binary ground truths, such as "alive" or "deceased," determining the "correct" triage outcome is more complex, potentially involving subsequent chart reviews or nuanced clinician assessments, thus introducing ambiguity.

A review of the predictors, labels, and models used in prehospital triage systems needs to establish an evidence base for efficient ML methods of triaging patients and identification of gaps not included in the existing models. Without a review, it is unclear whether existing methods and models may generalize to certain settings or be free from biases [12]. Thus, we conducted a scoping review to support our understanding of ML applications in remote prehospital settings. Scoping reviews are useful in the research fields of social sciences and health care, especially when a topic has not yet been comprehensively reviewed or exhibits a large, complex, or heterogeneous nature not amenable to a more thorough systematic review [13]. While there have been literature reviews outlining ML methods in emergency settings [14-16], no specific review touches on prehospital telemedicine triage services. Related reviews such as Sánchez-Salmerón et al [15] focused on in-person triage, as opposed to prehospital and remote triage. Through this scoping review, we aim to explore what evidence exists to compare the effectiveness of ML-enabled strategies with conventional triage methods in improving outcomes for patients seeking care through telemedicine services. We also aim to explore (1) what data sources and approaches are used for extracting meaningful predictors and labels, (2) what models and performance metrics are used, and (3) the processes of telemedicine triage systems where ML has been applied.

Methods

Search Strategy

Elements of the PRISMA-ScR (Preferred Reporting Items for Systematic reviews and Meta-Analyses extension for Scoping Reviews) protocol [17] and the Population, Intervention, Comparison, and Outcome (PICO) framework [18,19] were used to guide our search strategy. The search included all articles published prior to February 24, 2023. Methodological frameworks for scoping reviews from Arksey and O'Malley [20] and Levac et al [21] were followed.

The search strategy began with initial searches conducted through MEDLINE to extract terms based on article titles and abstracts. Keywords and expressions included both regular and Medical Subject Headings (MeSH) terms. The following search expression was developed and applied: "Telephone/ or telephone.mp. OR phone.mp. OR telemedicine.mp. OR

XSL·FO

RenderX

Telemedicine/ OR Emergency Medical Service Communication Systems/ OR Emergency Medical Dispatch/ OR dispatch.mp. OR hotline.mp. OR Hotlines/ OR prehospital.mp. OR pre-hospital.mp. OR remote consultation.mp. OR Remote Consultation/" AND "machine learning.mp. OR Artificial Intelligence/ OR Machine Learning/ OR artificial intelligence.mp. OR natural language processing.mp. OR Natural Language Processing/ OR chatbot.mp." AND "triage/ OR triage.mp"

Our search followed the 3 phases listed from the PRISMA-ScR protocol: identification, screening, and inclusion [17] (Multimedia Appendix 1). Using the search expression, articles were retrieved from the following databases: MEDLINE, PubMed, Scopus, and IEEE Xplore. These databases were selected for this review due to their ability to cover the most scientific information in fields such as telemedicine and health care decision-making while also being previously used by several health and technology-related reviews [15,16,22]. In order to limit bias and ensure reproducibility, we elected to exclusively include articles identified through the predefined search strategy.

Article Selection

All identified records were combined (n=296) and duplicates (n=131) removed resulting in 165 records remaining. The results of the initial search after duplicate removal are found in Multimedia Appendix 2. Articles needed to meet a set of inclusion and exclusion criteria (Table 1), which were developed to ensure that articles were relevant to prehospital telemedicine triage, conducted remotely as opposed to in the ED. During an initial piloting phase, 3 researchers (DR, KS, and MY) piloted these criteria to ensure consistency across them. Each researcher independently screened each title based on the inclusion and exclusion criteria, with discrepancies reaching consensus through discussion, which resulted in 32 records remaining (n=133 excluded). Articles that passed the title screening were then screened for relevant abstracts following a similar process resulting in 15 records remaining (n=17 excluded). The remaining articles were then read in their entirety and all 15 records were deemed eligible and included in the results of the review. Of the articles excluded, most were excluded for the provision of in-person care (as opposed to data collected remotely), were not primary research studies, or were not for general purpose triage (eg, stroke-specific triage).

Table 1. Inclusion and exclusion criteria of screening strategy.

PICO[a]/other element	Inclusion criteria	Exclusion criteria
Population	Undifferentiated population seeking emergency services (including COVID-19 assessments).	Specialty-specific population (eg, stroke, heart disease).
Concept	Triage of emergency telemedicine services enhanced by any ML[b] method that includes only data collected remotely.	Only conventional triage methods used or ML models that include predictors derived from physical assessments (eg, vital signs). Internet of medical things devices requiring physical or in-person assessments were excluded (eg, home blood pressure equipment).
Context	Provision of emergency telemedicine services, including web-based symptom checkers, clinician-staffed telephone line, or emergency medical dispatch.	Provision of in-person emergency care.
Evidence type	Primary research studies.	Literature reviews, protocols, guidelines, letters, gray literature, and qualitative studies excluded.
Language	Studies published in English.	Studies in languages beyond English.
Date	Published before February 24, 2023.	Published on or after February 24, 2023.

[a]PICO: Population, Intervention, Comparison, and Outcome.

[b]ML: machine learning.

Data Extraction

We extracted data from the included articles with an aim to understand how research in this domain is conducted. A data extraction tool was developed using the JBI Manual for Evidence Synthesis template [23] with a pilot step on 2 sources conducted by 2 researchers (JS and DR). The data of interest fell in four main categories:

1. Study characteristics: Author, year of publication, country of origin, the aim of the study, the result of the study, population assessed, dataset source, dataset size (the number of patient records), prospective/retrospective/deployed, and triage process.
2. ML model predictors and labels: Number of predictors and data types; methods for determining ground truth labels.
3. ML techniques and corresponding performance metrics:
4. Comparators, dataset partitions, data-preprocessing methods, performance metrics and values, and data quality analysis approaches.
5. Resources for future ML model development: Source code availability and software packages used.

This list of extraction items was supported by prior literature that involved emergency care–related triage [22,24] and was refined based on discussions among the authors. For each of the eligible articles included in this review, 1 author (JS) extracted and tabulated the relevant information, and the information was validated by another author (DR) with discrepancies further assessed by a last author (KS). All extracted information was analyzed by the authors to derive a narrative synthesis of the findings. Aligned with the scoping

review methodology, articles were not assessed for quality or risk of bias and no statistical analyses were conducted. The data extraction tool and raw data extracted are available in Multimedia Appendix 2.

Triage Process

We found that the studies spanned 3 prehospital triage processes: emergency dispatch, telephone lines, and chatbot applications. When distinguishing between emergency dispatch and telephone line systems, context of the call and nature of interaction were the 2 main points of consideration. Emergency dispatch calls (eg, 9-1-1) are received and handled by trained emergency staff focused on collecting critical information on the emergency, such as the nature of the incident, location, and immediate risks. The dispatcher then makes decisions based on this information to allocate appropriate resources, such as ambulances or first responders. Conversely, telephone lines such as nurse-led helplines or crisis hotlines are designed to offer support, advice, and clinical guidance to individuals seeking health care information or experiencing a crisis [25]. The interaction is often more conversational and supportive, resulting in a more complex triage process that depends on the nature of the call, the expertise of the health care professionals involved, and the available resources or referrals.

Predictors

We classified the predictor variables into 4 domains (demographic factors, operational characteristics, clinical factors, and unstructured data such as free text) and extracted how these data were handled in the models. These domains were determined based on the prehospital triage field and iteratively refined as data were extracted.

Ground Truth Labels

Variability existed in how ground truth labeling methods were coded for ML processing due to diverse sources of training data and annotation methods. In our classification of the observed ground truth methods, we first identified whether the label was derived from (1) the usual clinical process, that is, subsequent clinician triage, or (2) outside of the usual clinical process, that is, post hoc. Within category 1, we further identified whether (1A) remote-only data were used, or (1B) physical, in-person data were used. Within category 2, we further classified whether (2A) labels were automatically derived or (2B) labels were manually derived. Automatically (systematically) derived labels are the results of a uniform and scalable application of a label-deriving algorithm across a dataset.

Results

Characteristics of the Studies

Figure 1 shows a summary of the search protocol phases followed for this review using the PRISMA-ScR flow diagram. Of the 15 unique studies included, 33% (5/15) of the articles were published in 2022, 26% (4/15) in 2021, 20% (3/15) in 2020, and the remaining 20% (3/15) of the articles between 2014 and 2019. The most frequently occurring country of publication was the United States (4/15, 27%), followed by Japan (2/15, 13%), with the remaining being published in 9 distinct countries (Table 2).

Most studies (11/15, 73%) were retrospective, using historical patient outcomes to assess the performance of ML models in triage prediction. Among the retrospective articles, 2 reported a combination of retrospective results and the performance of deployed models. Of the other 4 nonretrospective articles, 13% (2/15) focused solely on deployed models and 13% (2/15) carried out a prospective study to explore the applications of ML triage in a specific health care setting.

Moreover, 47% (7/15) of articles investigated the use of ML in emergency dispatch calls, 33% (5/15) of articles focused on chatbot-style applications that could be accessed via the internet or within the ED, and 20% (3/15) of articles investigated ML in telephone lines, including 13% (2/15) nurse-led phone lines and 7% (1/15) crisis hotline.

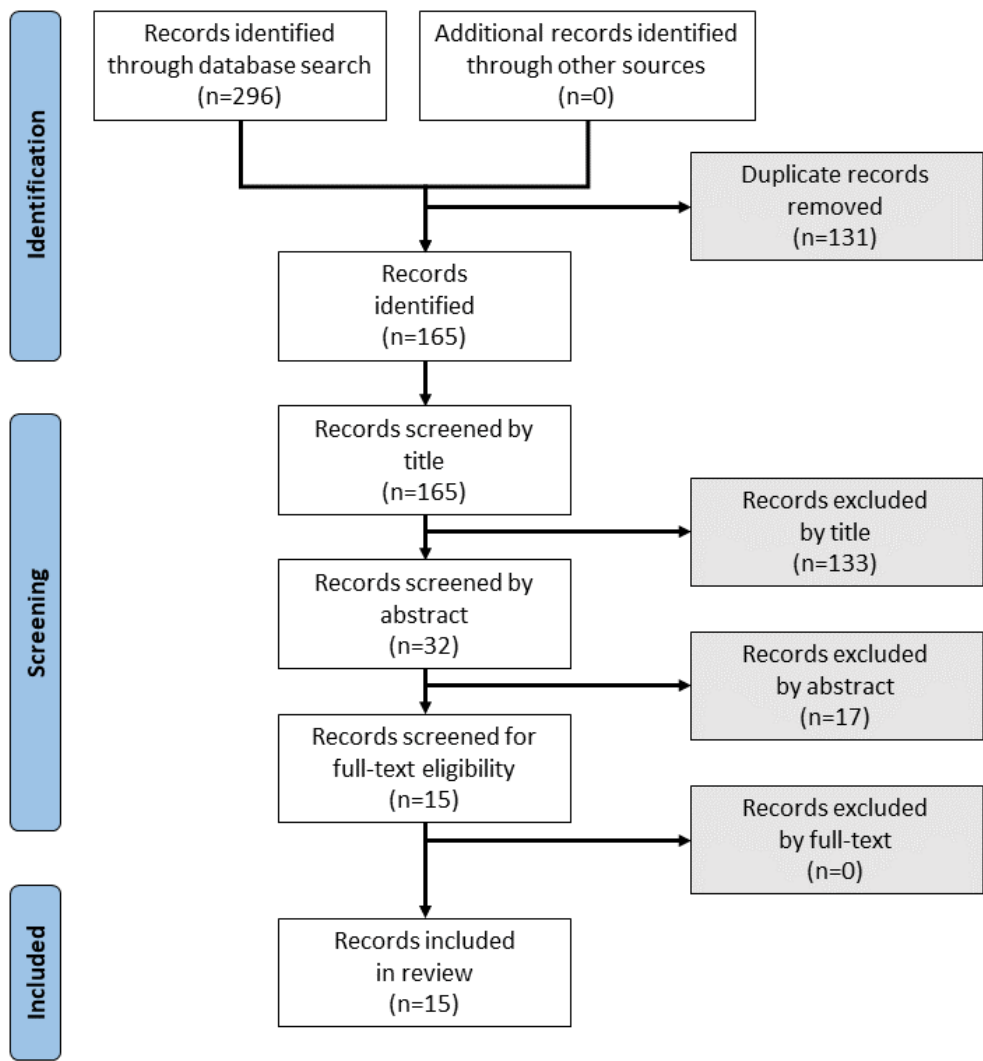
Figure 1. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) flow diagram.


Table 2. List of 15 studies included in the review and their characteristics.

Author (year)	Study setting (country)	Dataset size[a]	Labels included	Aim	Triage phase
Anthony et al (2021) [26]	South Africa	93	3 binary	Classify critical conditions in emergency calls	Dispatch
Ceklic et al (2022) [27]	Australia	11,971	1 binary	Classify severity of traffic crash incidents in dispatch calls	Dispatch

Spangler et al (2019) [3]	Sweden	68,668	1 continuous	Validate ML[e]-generated risk scores for prehospital care	Dispatch (operated by nurses)
Tollinton et al (2020) [5]	United Kingdom	1,188,509	1 binary	Classify triage of unconscious patients in dispatch calls	Dispatch
Veladas et al (2021) [36]	Portugal	269,669	1 multiclass	Classify clinical pathways from text data	Nurse-led phone line
Yunoki et al (2014) [4]	Japan	61,927	1 multiclass	Classify triage categories from phone call data	Dispatch

[a]Number of patient records included.

[b]Dataset size used for model development was not stated for this study or information on labels was not included.

[c]The study stated that "more than 900,000 case records" were included.

[d]AI: artificial intelligence.

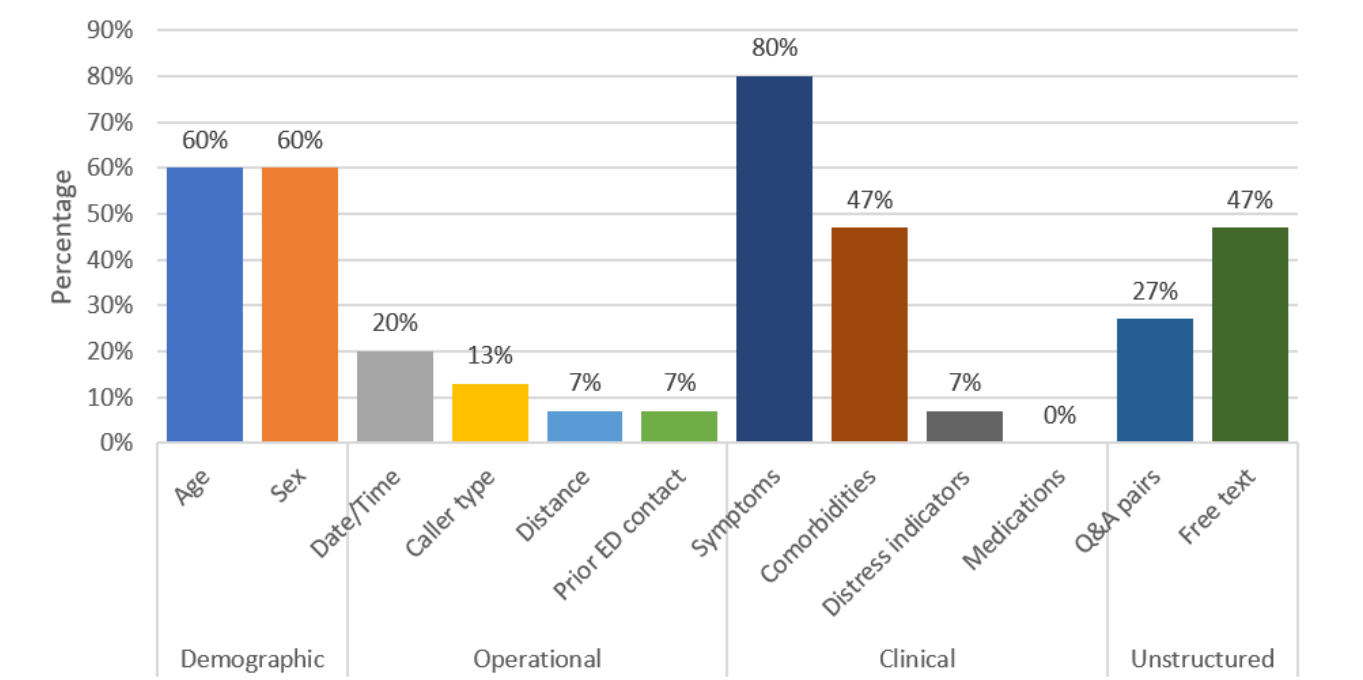
[e]ML: machine learning.

The size of the dataset used across studies varied considerably, with a median sample size of 21,044 observations. The largest dataset comprised 1,224,624 anonymized patient records [30] and the smallest dataset included 93 call transcripts [28]. Distinct methods were reported to handle missing data; for example, Ferri et al [30] excluded all call records with missing values, while Inokuchi et al [32] performed imputation to account for missing data (3918/19,114, 20.5% of cases had missing data) using the k-nearest neighbors (k-NN) algorithm.

Predictors

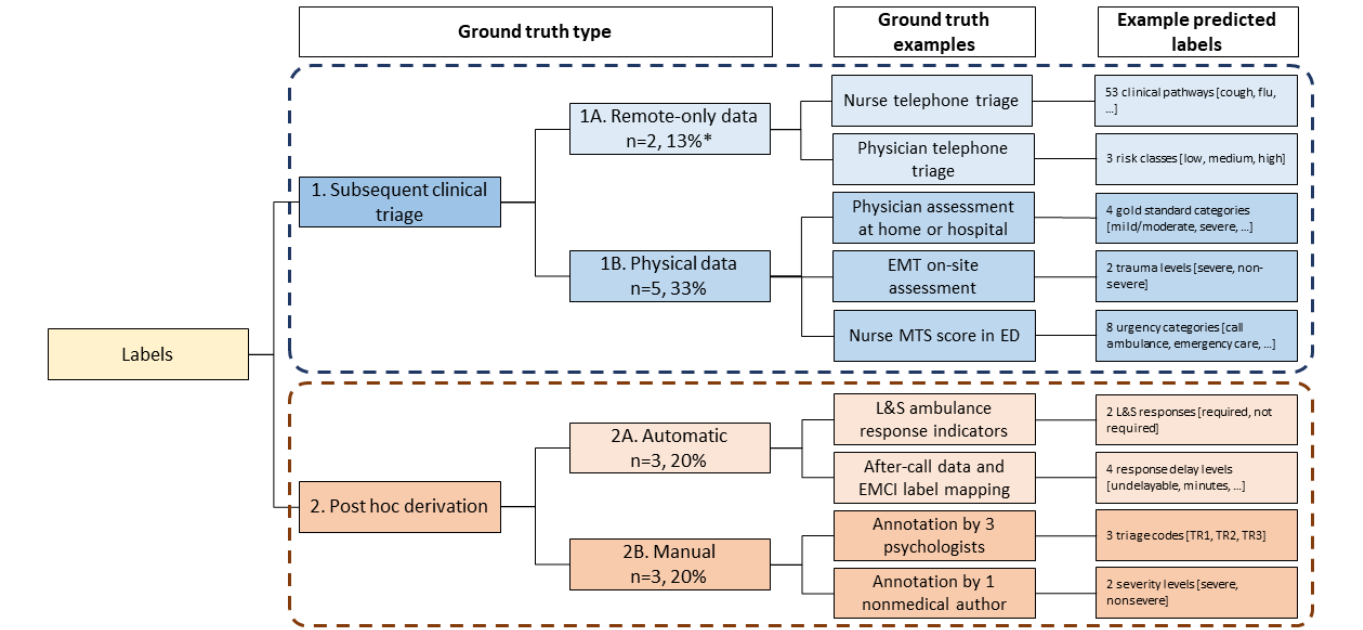
Several articles used predictors that spanned multiple categories, as exemplified by Ferri et al [30], who extracted patient demographic data (age, gender), operational data (date, caller type), and unstructured data (clinical free-text observations). In contrast, Chin et al [28] used unstructured data (dispatch call transcript) as the only data source in their ML model development, citing the "higher expressiveness of patient condition than structured data." The frequency of occurrence for each of these domains is shown in Figure 2.

The mapping and processing techniques varied across data types. Most commonly, many input variables were one-hot encoded, such as age groupings, sex, day of week, clinical indicators (symptoms, comorbidities), and question-answer pairs. Notably, distance to ED was one of the few continuous predictors used [3]. For unstructured data, various natural language processing (NLP) techniques were employed to transform these data to useful inputs, such as bag-of-words methods or text vectorization, which are strategies to transform text data into a numerical representation that can be processed by ML models (see Multimedia Appendix 3 for more information).

Figure 2. Percentage of predictor types included in the studies. ED: emergency department; Q&A: question and answer.


Data Labeling: Determining Ground Truth

Two studies (2/15, 13%) [33,34] did not provide sufficient information to determine their ground truth labeling method. Most of the ground truth methods (5/15, 33%) used physical assessments from the usual clinical process; however, within this group input data were from 3 different types of providers (nurses, physicians, and ambulance crew) with each employing a different triage or categorization system (Figure 3) [25]. This results in variability as similar information is outputted with different labels, which limits comparability (eg, patient conveyance [5] or "gold standard" ED triage protocols [4]). Notably, the 3 (20%) studies [3,27,30] that used automatic post hoc (2A) methods had larger sample sizes (mean 4,32,792 observations; range 15,550-1,244,624) versus studies [26,31,35] using manual (2B) methods (mean 364 observations; range 93-573). Across the 4 methods, 6 studies (40%) predicted labels that were binary and based on symptom or condition severity (eg, life-threatening [30], severe trauma [28]), while 7 studies (47%) predicted multiclass labels (eg, 1 of 53 clinical pathways [36]).

Figure 3. Label and ground truth methodologies by annotation method. *Marchiori et al used remote physician triage as ground truth for model training but manually derived labels for model testing. To ensure consistency in article classification, we have categorized all articles based on the ground truth method for model training. ED: emergency department; EMCI: emergency medical call incident; EMT: emergency medical technician; L&S: lights and sirens; MTS: Manchester Triage System.


Interrater Reliability

Methods to enhance interrater reliability were rarely employed, in contrast to published guidelines concerning manual data labeling [37]. Marchiori et al [25] did so by ensuring the adequate training of data collectors by selecting "only records generated by top-ranked doctors (based on years of experience and internal audits)." In the study by Gatto et al [31], data annotators "invested significant time to educate themselves on the symptoms" observed in the dataset; however, it was noted "that the use of nonmedical professionals limited the degree of granularity with which the dataset was labelled." Pacula et al [35] used consensus among 3 evaluators when labeling data and measured the interannotator agreement using the Fleiss kappa statistic to confirm good agreement.

ML Algorithms

Most studies applied more than 1 ML technique to method development (11/15, 73%). However, 2 studies (13%) did not disclose the ML algorithm used in their triage prediction model. Three (20%) studies published the source code for various stages of their ML model development and validation (Table 3).

Overall, the most popular ML algorithm was support vector machine (SVM; 8/15, 53%) and tree-based methods, including random forest (RF; 6/15, 40%) and extreme gradient boosting (XGBoost; 4/15, 27%). Other popular algorithms were neural networks (NN; 5/15, 33%), with various implementations observed, such as deep NNs, bidirectional long short-term memory models, and ensemble of deep learning networks (ie, the model employed by Ferri et al [30] is described as a "Deep Ensemble Multitask Classifier for Emergency Medical Calls" composed of 4 different subnetworks). Naïve Bayes (NB) and k-NN were similarly popular, followed by regression methods.

Table 3. Type and frequency of ML algorithms used by the included studies.

[a]ML: machine learning.

[b]Spangler et al [3] did not include support vector machine, random forest, neural networks, or regression models in their "Methods" but stated in their "Discussion" that they investigated these algorithms.

[c]Decision trees here include methods such as gradient boosting but not random forest or extreme gradient boosting.

[d]Ceklic et al [27] did not provide information about the specific models incorporated into their ensemble. Ferri et al [30] built their ensemble using a collection of deep learning subnetworks.

[e]LASSO: least absolute shrinkage and selection operator.

Model Performance Metrics

F_1-score was the most used metric (6/15, 40%) to measure model performance, closely followed by accuracy (5/15, 33%) and area under the curve (AUC; 4/15, 27%). Furthermore, many studies tangentially used other quantitative measures, such as sensitivity or recall and specificity or precision. In the case where AUC scores were similar between the RF and XGBoost models in the study by Tollinton et al [5], analysis of other metrics showed that XGBoost outperformed RF models in terms of sensitivity (0.93 vs 0.62 in the combined model) but had lower specificity (0.17 vs 0.56 in the combined model).

Moreover, several studies investigated how different combinations of predictors and NLP techniques affected model performance across ML techniques. For instance, Pacula et al [35] present an interesting discussion on the impact of various approaches to dialogue processing (turn-level classification and accounting for speaker role) on triage prediction outcomes.

A summary of the comparators and top-performing models for each study, alongside information on evaluation metrics used and data train or test split, is shown in Table 4. For models that were evaluated against non–ML-enhanced methods of triage, those established triage systems are indicated as well.

Table 4. Top-performing ML algorithms used in each study and corresponding performance metric and model training or testing split grouped by triage process.

Triage process and study	Top-performing model	Model comparators	Triage comparators	Performance metrics	Training data split (%)
Emergency medical dispatch					
Anthony et al [26]	SVM[a]	LR[b], RF[c], k-NN[d]	—[e]	Accuracy	80
Ceklic et al [27]	Ensemble	k-NN, SVM, NB[f], deep NN +NLP[g]	SJ-WA[h] dispatch	PPV[i], sensitivity (recall), F_1-score	60

[a]SVM: support vector machine.

[b]LR: logistic regression.

[c]RF: random forest.

[d]K-NN: K-nearest neighbors.

[e]No comparator.

[f]NB: naïve Bayes.

[g]"+NLP" indicates that model performance was evaluated across various natural language processing techniques.

[h]SJ-WA: St John Ambulance in Western Australia.

[i]PPV: positive predictive value (precision).

[j]DT: decision tree.

[k]NPV: negative predictive value.

[l]GB: gradient boosting.

[m]XGBoost: extreme gradient boosting.

[n]AUC: area under the curve.

[o]The gradient boosting model scored better on sensitivity, but specificity was lower than RF.

[p]BN: Bayesian network.

[q]Alternate ML models were not compared.

XSL·FO

RenderX

[r]Lai et al [33] and Morse et al [34] reported on symptom checker triage systems but did not provide details on the underlying ML model and comparators or development.

[s]MTS: Manchester Triage System.

[t]N/A: not applicable.

[u]SBERT: sentence bidirectional encoder representation from transformers.

[v]BERT: Bidirectional Encoder Representation From Transformers.

[w]HAN: hierarchical attention network.

[x]Bi-LSTM: bidirectional long short-term memory.

[y]LASSO: least absolute shrinkage and selection operator.

[z]HMM: hidden Markov model.

Model Data Splitting

Thirteen studies (87%) reported some method for validation, including randomly partitioning data into training or testing sets (10/15, 67%) or training or validation or testing sets (3/15, 20%). Most studies used some form of cross-validation in the training sets for model construction (8/15, 53%). In addition, various types of resampling procedures were used, such as *k*-fold cross-validation, stratified *k*-fold cross-validation, repeated *k*-fold cross-validation, or repeated random test-train splits.

Discussion

Principal Findings

We reviewed 15 primary research studies of ML-enhanced triage models in prehospital telemedicine settings where patients potentially require emergency care. We found that ML-enhanced triage systems typically outperformed conventional triage ones; however, there is likely a bias toward publishing these types of positive findings [38]. While the reviewed studies exhibited several commonalities in terms of predictor types, ML algorithms tested, and performance metrics, there were key discrepancies in how data were sourced and processed, particularly with regard to annotating ground truth labels. We discuss these similarities and differences in context and how the new evidence presented here relates to ED overcrowding and prehospital triage.

Predictor Variables

A critical limitation of prehospital telemedicine triage systems is the lack of access to objective measures of the patient condition typically obtained through physical assessment, vital signs being fundamental metrics of illness severity. As a result, our inclusion criteria ensured that no study had access to a physical assessment of their participants. Therefore, by investigating the range of predictors employed by the included articles, we identified how subjective and indirect indicators of patient condition are used in remote triage. Our review indicates that patient symptoms, age, sex, and comorbidities were the most frequently occurring predictor variables among structured data, with NLP techniques used to extract features from unstructured data. The structured and unstructured data were not combined in any of the included articles. This finding emphasizes the critical importance of considering these 4 clinical and demographic factors for prehospital telemedicine triage where physical assessment data are unavailable. The consistent use of patient symptoms, demographics, and comorbidities as predictor variables across all 3 triage processes reinforces that

they are reliable indicators of a suitable triage outcome. However, while demographic factors were frequently used across the studies, only 2 specific factors, namely, age and sex, were considered.

Notably, we also highlight the absence of previously identified important inputs to ML models [12]. Race or ethnicity, region or geography, medication history, and health system exposure (hospitalizations, etc) were not represented in the corpus; however, they should be taken into consideration in prehospital triage both to improve performance and ensure algorithmic fairness [39]. The absence of these variables both as predictors and for post hoc evaluation of algorithmic bias suggests a significant gap in the extant literature and motivates further investigation into their potential to generate accurate and equitable triage outcomes for more diverse populations. Continuing to develop a comprehensive list of the most significant variables driving remote emergency triage is invaluable to improving equitable patient outcomes for all populations [12]. Identifying common patterns in predictor selection (and what is absent) can inform the development of standardized guidelines for building ML algorithms for triage using remote-only data. A future with consistent measurements of physiologic metrics, such as vital signs, would also be invaluable to strengthen prediction. Developing systems or technology whereby these critical data can be captured remotely is a future direction worth exploring.

Ground Truth Labeling Methods

Our review critically spotlights the variety of methods for annotating data labels from ground truth. Two papers did not provide sufficient information, and we classified the remaining 13 into 1 of 4 distinct methods, reflecting varying ML development philosophies. The most common method—(2A) post hoc automatic derivation of data labels—indicates preference for collaboration among domain experts to reduce human subjectivity and implement large-scale data mapping. Notably, Ferri et al [30] used a panel of 17 physicians to develop a mapping system, which was then automatically applied to more than 1 million records. In contrast, using the (2B) method, Pacula et al [35] reported that 3 psychologists manually annotated each of the 427 records. While this review cannot comment on the comparative efficiencies of these specific methods, we note that assembling large datasets with ground truth labels is an arduous and expensive task; thus, there may be scalability benefits to automatic methods [40].

While we observed trade-offs in data labeling, establishing methodologically robust ground truth is of paramount

importance. Inadequate representation of ground truth can lead to misclassification issues within the ML model, thus reducing predictive accuracy on external data. This could result in unintended and potentially serious consequences, especially in the context of emergency care. The ground truth triage outcome has proved challenging to pinpoint, and this scoping review reveals 4 methods in determining it. However, each method exhibits limitations and potential manifestations of human subjectivity.

The accuracy of remote triage is inherently limited by the absence of physical data, even when carried out by individuals with domain expertise (eg, physicians). Furthermore, human bias and lack of experience can lead to either overtriage (ie, false positives; eg, sending low-acuity patients to the ED) or undertriage (ie, false negatives; eg, advising high-acuity patients to stay home), even in cases when physical data are available. To address this, the strategy of selecting data from only highly reputable clinicians [25] serves as an inspiration for developing a standardized evaluation system to identify qualified data annotators for health care settings. An additional method to enhance triage accuracy is inclusion of downstream triage with access to more comprehensive data, such as vital signs, detailed physical assessment, or a professional with higher-level training (eg, a physician conducting a home visit) [32].

The methodical classification of patients based on a predetermined list of outcomes minimizes the risk for interrater disagreement. However, relying solely on these selected outcomes, such as hospital admission or 2-day mortality [3], assumes that they are the only factors and of equal importance in determining the overall risks associated with the patient. This approach overlooks insights that can be revealed from a circumstantial and personalized analysis of patient condition. In addition, many of the inclusion studies selected highly specific outcomes, such as sepsis, myocardial infarction, and cardiac arrest [26], which are not generalizable to different remote triage processes. One potential solution, which no study in this review used, is using a weighted kappa index to consider different categories and disagreements and capture the rank magnitude of disagreement [41].

Retrospective evaluation of patient data by multiple annotators holds potential for highly accurate ground truth labels, as it is the most comprehensive approach observed in this review. However, we note that the included articles lack information regarding how evaluators determined such classifications. Subjectivity in human decision-making persists and variation in annotators' levels of training and resolution strategies employed leaves room for further research. Again, implementing a standardized evaluation system to determine a qualified pool of data annotators becomes crucial to ensure reliability in the annotation of ground truth triage labels for ML-enhanced remote triage [37].

This analysis of subjectivity in ML systems underscores the need for nuance regarding objectivity and ground truth. To enhance remote triage algorithm generalizability, comprehensive datasets must be used. This entails capturing data from each of the predictor variables outlined in this review, as well as race or ethnicity, region or geography, and medical history.

Furthermore, standardized protocols for data labeling across different clinical settings would facilitate consistency and enable meaningful comparisons and analyses. There is a need for more well-defined and externally valid procedures for determining the ground truth in the context of highly intricate and unstructured data such as remote patient triage.

ML Techniques

This review presents needed insights on the cutting-edge application of ML methods for remote prehospital triage systems: SVM, tree-based, and NN methods were commonly used. These observations are consistent with other reviews of ED-based implementations [16,42]. To our knowledge, this is the first review to provide a mapping between ML model development and 3 processes of triage in emergency medicine: emergency medical dispatch, chatbot or symptom checker, and telephone line. We uniquely charted the best-performing model of each article to 1 of the 3 triage processes and generated insight on the specific elements underpinning each model. By doing so, we provide insight into how predictive ML models can be developed for different stages of triage before physical assessment.

Limitations

We did not directly compare the varied performance metrics such as the F_1-score, precision, recall, and AUC, as this could lead to misleading conclusions. This was not an objective of our review due to inconsistencies in reported metrics and variability in study designs. For instance, certain metrics can be optimized at the expense of other metrics; for example, precision and recall are inversely related. Not all metrics are universally applicable; the F_1-score is unsuitable for multiclass problems found in a proportion of included studies. In addition, F_1-score assumes false negatives and false positives are equally costly, an incorrect assumption in triage problems where undertriage due to a false negative would have serious consequences. While AUC is perhaps the optimal metric choice, it still has sensitivity to class imbalances, which varied across the included studies. Of the only 4 articles that reported AUC, the performance ranged from 0.64 for prediction of conveyance [5] to 0.88 [35]. A direct comparison among articles reporting AUC was avoided due to differences in study contexts, which included diverse triage labels, significant variations in sample sizes and populations, limited reporting on class imbalance, and the use of different validation strategies. As this review did not facilitate any quantitative analysis of ML model performance, insights into the accuracy of ML-enhanced triage compared with conventional remote triage, as well as the quantitative impact that ML triage may have on patient outcomes and overall health care systems, could not be derived and future systematic work is warranted.

Implications for Future Work

ML-enhanced triage presents an opportunity to alleviate the burden on EDs and support patients' decision-making when seeking emergency versus community-based care. Based on the evidence synthesized here, our calls to the field are to determine a prioritized list of high-value predictor variables to consider, standardize ground truth labeling, and form a consensus on

validation methods used, such that different health systems can continuously learn from new developments. This review provides a foundation for developing guidelines, which will also create opportunities for comparison across studies to quantitatively assess the effectiveness and benefits of ML-enhanced triage regarding patient outcomes and health system performance. While reducing resources spent on overtriage is also a priority, it is equally important to focus on the likelihood of undertriage, as it poses a significant risk to patients. Therefore, precision, recall, and specificity rates, as well as algorithmic bias [39], must be carefully monitored and improved in model development to ensure that safety and effectiveness are balanced in ML-enhanced triage systems.

Accurate triage recommendations do not guarantee that patients will follow them [43-45]. In the discussion of using telephone lines or chatbots during the triage process, further investigation is warranted into how delivery methods affect patients' likeliness to adhere to the advice generated by ML-enhanced triage systems. Similarly, in the dispatch and telephone line triage processes, a question that arises is whether ML-generated triage results influence the decision-making process of dispatchers or providers. This area of research could provide insight on the most effective stage at which ML-based assistance should be introduced in the triage process. Exploring the interplay between ML-enhanced triage advice, patient behavior, and clinician decision-making will contribute to the optimization of prehospital telemedicine triage in emergency care.

Conclusions

Our scoping review of 15 recent studies of ML-enhanced prehospital telemedicine triage systems observed heterogeneity in dataset size, predictors, clinical setting (triage process), and reported performance metrics. Consequently, a comparison of ML performance across articles was not feasible, and we note that identifying the most efficient and accurate ML-enhanced triage system is valuable for future development and model deployment in prehospital settings, where a standardized performance metric such as the AUC would be important to facilitate comparisons. Standard structured predictors, including symptoms, age, sex, and comorbidities, across articles suggest the importance of these inputs; however, there was a notable absence of other potentially useful data, including medications and health system exposure. With advancing technology of transformer-based models [46,47], there exists the potential for combining structured and unstructured data; an approach that was also absent in the included articles. The lack of social variables leaves the potential for algorithmic bias critically unexplored. Ground truth labeling practices should be reported in a standard fashion as the true model performance hinges on these labels. This review establishes an evidence base for future investigations and an opportunity to form a consensus and standardized framework, thereby supporting consistent reporting, performance comparisons, and collaboratively developed ML-enhanced prehospital triage systems.

Authors' Contributions

DR, KS, SC, RT, JW, MCT, and KH developed the idea for the scoping review. DR and KS developed the search methodology. MCY conducted the literature search. MCY and JS wrote the initial draft. DR and KS completed the initial draft. All authors reviewed, edited, and approved the final manuscript.

Abstract

Background: Plagiocephaly is defined as an asymmetrical distortion of the skull, resulting in an oblique trapezoid or parallelogram head shape. Deformational plagiocephaly (DP) is caused by forces acting on one side of the back of the head, distorting normal skull symmetry.

Objective: The aims of this systematic review and meta-analysis were to critically assess the evidence for nonobstetric risk factors for DP and to make evidence-based recommendations for reducing the prevalence of DP.

Methods: The selection criterion was studies reporting risk factors for DP. Case reviews, case series, expert opinions, and systematic reviews were excluded. PubMed and Web of Science were searched from August 21, 2010, to August 21, 2022. Publication bias was assessed using funnel plots. Meta-analyses were presented using forest plots.

Results: A total of 19 studies (cohort studies: n=13, 68%; case-control studies: n=5, 26%; and cross-sectional studies: n=1, 5%) with a total of 14,808 participants were included. Of the 43 investigated potential nonobstetric factors, 16 (37%) were associated with DP. Of these 16 factors, 12 (75%) had odds ratios (ORs) with 95% CIs not crossing 1: insufficient vitamin D intake (OR 7.15, 95% CI 3.77-13.54), head position preference (OR 4.75, 95% CI 3.36-6.73), bottle-only feeding (OR 4.65, 95% CI 2.70-8.00), reduced tummy time (OR 3.51, 95% CI 1.71-7.21), sleeping position (OR 3.12, 95% CI 2.21-4.39), fewer motor milestones reached by the age of 6 months (OR 2.56, 95% CI 1.66-3.96), obesity (OR 2.45, 95% CI 1.02-5.90), maternal education level (OR 1.66, 95% CI 1.17-2.37), male sex (OR 1.51, 95% CI 1.07-2.12), formula feeding (OR 1.51, 95% CI 1.00-2.27), head circumference (OR 1.22, 95% CI 1.06-1.40), and mechanical ventilation (OR 1.10, 95% CI 1.00-1.14). No evidence of publication bias was detected.

Conclusions: This study provides a comprehensive assessment of the nonobstetric factors associated with DP and presents 11 evidence-based recommendations for reducing its prevalence. The primary limitation is that only publication bias was assessed.

Introduction

Background

Plagiocephaly is defined as an asymmetrical distortion of the skull resulting in an oblique trapezoid or parallelogram head shape when viewed from the vertex position in the axial plane [1]. The severity of skull asymmetry can range from minimal focal flattening on one side of the cranial vault to severe deformation affecting the entire cranial vault, skull base, and facial skeleton. Plagiocephaly arises via 2 main mechanisms: premature fusion of ≥1 of the cranial sutures (craniosynostosis) or external mechanical forces acting on the cranial vault, which results in a distortion of the normally symmetric craniofacial skeleton (deformational plagiocephaly [DP]).

In craniosynostotic plagiocephaly involving any of the paired coronal or lambdoid sutures, the restriction of skull vault growth occurs perpendicular to the fused suture (Virchow's law) [2,3]. Isolated craniosynostosis involving premature fusion of a single coronal suture results in an anterior plagiocephaly with brow retrusion on the affected side; similarly, craniosynostosis of a single lambdoid suture will restrict posterior cranial growth on the same side. The asymmetry is often accentuated as the remaining unfused sutures expand to enable accommodation of the rapidly growing infant brain. The majority of patients with craniosynostosis do not have an identifiable genetic cause, but this proportion is increased in patients with >1 suture involved [2,3].

Alternatively—and far more commonly—plagiocephaly is caused by deformational forces acting on one side of the back of the head, which distorts the normal symmetry of the skull in the absence of skull growth restriction due to craniosynostosis [4]. This deformity is characterized by a parallelogram-type deformity. This appears clinically as mild to severe occipital flattening, with or without ipsilateral anterior shift of the ear and orbital involvement [5]. The flattening of the posterior neurocranium, resulting from the external forces applied to the head, has led to the condition also being referred to as "flat head syndrome" [6]. The importance of external forces can be seen in the close relationship between DP and sleeping position [7], among other factors that may influence external head forces [8-12].

Objectives

Since the 1980s, "back to sleep" campaigns have successfully publicized the benefits of supine sleeping for reducing the risk of sleep-related death, including sudden infant death syndrome [13]. Although these campaigns reduced the incidence of sudden infant death syndrome by 40%, an undesirable consequence has been an increase in the referrals of cases of DP, leading to more referrals to specialist centers [14,15]. The majority of cases of DP will resolve without intervention, and surgical treatment is not required [16]. However, in a subset of children, DP persists, even into teenage years [17]. Although physiotherapy and helmet therapy may play a role in improving head shape and limiting other long-term effects [18,19], understanding the factors that increase the risk of DP may help to prevent DP from developing. The aims of this systematic review and meta-analysis were to critically assess the evidence for risk factors for DP and to make evidence-based recommendations for reducing the prevalence of DP. This study was previously presented as a meeting abstract at the Royal College of Paediatrics and Child Health Conference on June 15, 2021.

Methods

The study protocol, analysis, and reporting were conducted in line with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines [20-22]. The protocol was registered with PROSPERO (CRD42020204979).

Search Strategy

A search of PubMed and Web of Science was performed covering the period from August 21, 2010, to August 21, 2022 (this included an initial search from August 21, 2010, to August 20, 2020, and an update search from August 21, 2010, to August 20, 2022, to ensure that the list of included studies was as up to date as possible). The combination of PubMed and Web of Science provides >97.5% coverage of published literature [23,24]. To balance comprehensive coverage with a pragmatic approach to ensure that the study was completed with limited available resources, additional databases were not searched, and hand searching and gray literature searches were also not performed. The search terms included "plagiocephaly" AND "risk factor."

Study Eligibility

Study titles and abstracts were screened and assessed for relevance by a single reviewer (CRTH, NB, or AN). Specifically, original studies were included if they assessed risk factors for DP. Studies in a non-English language, those involving nonhuman subjects, and low-quality or nonoriginal studies (meeting abstracts, reviews, case series, case reports, and editorials) were excluded. Duplicates were identified by assessing study titles and removed manually by CRTH. Full-text review was performed after screening by a single reviewer (CRTH, NB, or AN). Studies not reporting nonobstetric risk factors for DP were excluded. Studies reporting preventive measures such as tummy time were included. However, studies involving treatments such as physical therapy and helmet therapy were not included. As screening was performed by a single reviewer, there were no discrepancies to be resolved.

Data Extraction and Reporting

Data extraction and reporting followed the PRISMA guidelines. However, due to resource limitations, data from eligible full-text articles were extracted by a single reviewer (CRTH, NB, or AN). The main outcomes of interest were odds ratios (ORs) and risk ratios (RRs) with 95% CIs, or significant associations, for risk factors for DP (or biomarkers for DP; eg, oblique diameter difference index). These outcomes were split into factors that were associated with DP and those that were not. Other items extracted from the eligible studies included authors, country of study, funding source, study design, study aims, total participants, percentage female, population assessed, age at baseline, and selection criteria.

Meta-Analysis

A meta-analysis of ORs and RRs for factors associated with DP was performed. The inconsistency index (I^2) and a Q statistic for chi-square significance for specific *df* were calculated to assess interstudy heterogeneity. Both fixed effects and random effects were reported. *P* values for 95% CIs were calculated.

Excel (Microsoft Corp) and Prism (GraphPad Software) were used for statistical analysis.

Funnel Plots

Publication bias was assessed using funnel plots of ORs and RRs for DP risk factors against study precision (1/SE). The Egger test for asymmetry was conducted using linear regression, with *P*<.05 indicating publication bias [25].

Results

Overview

The searches of PubMed and Web of Science yielded 159 articles; after removing 35 (22%) duplicates, 124 (78%) articles were screened based on abstract content. Of these 124 articles, 77 (62.1%) were not relevant. Full-text screening of the remaining 47 articles resulted in the exclusion of 20 (43%) irrelevant articles (these did not report nonobstetric risk factors for DP), 3 (6%) non-English articles, and 5 (11%) articles that were not accessible. Thus, of the initial 159 articles, 19 (11.9%) were eligible for inclusion in this study (Figure 1). The characteristics of the included studies are presented in Table 1.

Pogliani et al [36]; Italy	NR	Retrospective cohort study	To assess risk factors for DP at birth	413 (50)	Healthy newborns	<72 h from birth	Neonates at gestational age >33 wk born between May 2011 and January 2012; newborns with extreme low birth weight or presenting with major congenital malformations needing NICU transfer were excluded; children of mothers with a documented TORCH[g] infection were also excluded	ORs and RRs for risk factors for DP	Association between DP and male sex	NR
Roberts et al [37]; United Kingdom	NR	Retrospective cohort study	To test the hypothesis that ventriculoperitoneal shunt insertion significantly increases contralateral DP	339 (42)	Children aged 0-16 y with ventriculoperitoneal shunts	NR	Children aged 0-16 y with at least 1 follow-up scan from the surgical database at the pediatric neurosurgery department of Birmingham Children's Hospital between 2006 and 2013; children without imaging were excluded	ORs and RRs for risk factors for DP	DP was associated with occipital shunt placement; a statistically significant difference in the probability of becoming plagiocephalic between neonates and children aged 12-16 y was observed; boys were more likely to develop shunt-associated plagiocephaly than girls	No difference in DP between neonates and infants, neonates and children aged 3-5 y, neonates and children aged 1-3 y, and neonates and children aged 5-12 y
Sheu et al [38]; United States	Cooperative agreement from the Centers for Disease Control and Prevention (U01DD000494) and Title V Maternal and Child Health Block Grant funds from the Health Resources and Services Administration	Retrospective cohort study	To assess factors that may explain a 9-fold increase in plagiocephaly in Texas from 1999 to 2007	6295 (38)	Infants with DP	NR	Cases identified using the Texas Birth Defects Registry with a definite diagnosis of DP (British Paediatric Association code 754.050), born between January 1, 1999, and December 31, 2007; cases of plagiocephaly with craniosynostosis were excluded	Mean difference or percentage difference for risk factors for DP	Lower maternal education level was associated with DP	No association of DP with maternal age or race and ethnicity, infant sex; mean age at DP diagnosis did not significantly change over time

Study; country	Funding source	Study design	Study aims	Participants, n (% female)	Population assessed	Age at baseline	Selection criteria	Outcomes	Factors associated with DP[a]	Factors not associated with DP
Solani et al [39]; Iran	Grant funding from the Vice-Chancellor for Research, Kashan University of Medical Sciences, Kashan, Iran	Case-control study	To determine the risk factors of positional plagiocephaly in healthy infants	300 (NR)	Healthy Iranian infants	8-12 wk	Healthy full-term (gestational age >37 wk) infants aged 8-12 wk who were referred to the pediatric neurology clinic at Shahid Beheshti Hospital in Kashan, affiliated with Kashan University of Medical Sciences, were included	ORs for risk factors for DP	Factors associated with DP included male sex, head circumference, and supine sleeping position	Firmness of headrest was not associated with DP
Tang et al [40]; United States	NR	Prospective cohort study	To assess the prevalence of DP in infants with NBPP[h] and spontaneous recovery from DP	28 (50)	Full-term infants aged >3 mo and <1 y with NBPP	Mean 3 (SD 3) mo	Full-term infants aged >3 mo and <1 y with NBPP; infants with neurological or congenital comorbidities in addition to NBPP, helmet therapy for plagiocephaly, and surgical procedures related to NBPP were excluded; infants with craniosynostosis were also excluded	Mean difference or percentage difference for risk factors for DP	NR	Maternal age and race (Black or White) were not associated with DP
Valkama et al [41]; Finland	NR	Case-control study	To assess the prevalence of DP in children with DDH[i]	120 (56)	Children with DDH with or without DP	Children with DDH: mean 8.0 (SD 1.4) y; matched controls: mean 7.9 (SD 1.3) y	Children with DDH from among newborn infants born at the Oulu University Hospital in Oulu, Finland, were included; preterm children and children with disabilities were excluded	ORs and RRs for risk factors for DP	10.3% of the children with DDH and only 1.5% of the control children had DP	OCLR was equal between children with DDH and controls; no association between side of DDH and DP

Study; country	Funding source	Study design	Study aims	Participants, n (% female)	Population assessed	Age at baseline	Selection criteria	Outcomes	Factors associated with DP[a]	Factors not associated with DP
Van Vlimmeren et al [42]; Netherlands	Grant from the Scientific Committee of The Royal Dutch Association for Physiotherapy (BU002/10)	Prospective cohort study	To assess skull shape in healthy newborns until age 5.5 y in children with position preference at 7 wk and those without and in children with position preference who received pediatric physical therapy intervention and those who did not	380 (53)	Healthy newborns	<48 h from birth	Healthy newborns (gestational age ≥36 wk) born between December 2004 and September 2005 at Hospital Bernhoven; children with congenital muscular torticollis (Kaplan type 2 and 3), dysmorphism, or syndromes were excluded	Mean difference or percentage difference for risk factors for DP	Association between DP and position preference	No association between potential risk factors (nursing, feeding, sleeping, and playing positioning habits) at age 7 wk and skull deformity at age 24 mo and 5.5 y; a trend toward significance between time spent playing prone (tummy time) at age 7 wk and the ODDI[j] percentage at age 24 mo
Weernink et al [43]; Netherlands	ZonMw, the Netherlands Organization for Health Research and Development (170.992.501)	Case-control study	To assess the influence of adherence to recommendations for vitamin D supplement intake of 10 µg/d (400 IU) in the first months of life (child) on the occurrence of DP of the child at age 2-4 mo	823 (46)	Infants with DP and those without	2-4 mo	Children born between November 22, 2009, and June 9, 2010, with mild to severe DP from the Helmet Therapy Assessment in Deformed Skulls study; controls were included from a 2010 survey on infant milk feeding	ORs and RRs for risk factors for DP	Insufficient vitamin D supplement intake during early infancy was associated with DP; maternal sociodemographic factors associated with DP included mother's age and mother's education level; infant factors associated with DP included male sex, formula feeding, and milk formula consumption after birth	Maternal sociodemographic factors not significantly associated with DP included mother's country of birth (other than the Netherlands); infant factors not associated with DP included time child spent outdoors

Study; country	Funding source	Study design	Study aims	Partici-pants, n (% female)	Popula-tion as-sessed	Age at baseline	Selection crite-ria	Out-comes	Factors associat-ed with DP[a]	Factors not as-sociated with DP
Van Cruchten et al [9]; Nether-lands	NR	Cohort study	To assess the im-pact of risk fac-tors on the type and sever-ity of DP	184 (30.4)	Infants seen at outpatient clinic with a parental concern for DP	3-14 mo	Exclusion cri-teria consisted of children aged >14 mo or <3 mo and other forms of cranial defor-mation, such as cranial syn-ostosis	Differ-ences in ODDI for risk fac-tors for DP	Negative corre-lation between age and ODDI; positive correla-tion between ODDI and posi-tion preference right and posi-tion preference left	No association between OD-DI and devel-opmental de-lay, family history of DP, sex, and torti-collis

[a]DP: deformational plagiocephaly.

[b]OR: odds ratio.

[c]RR: risk ratio.

[d]NR: not reported.

[e]NICU: neonatal intensive care unit.

[f]OCLR: oblique cranial length ratio.

[g]TORCH: toxoplasmosis, other (including infections such as syphilis, varicella-zoster, and parvovirus B19), rubella, cytomegalovirus, and herpes simplex virus.

[h]NBPP: neonatal brachial plexus palsy.

[i]DDH: developmental dysplasia of the hip.

[j]ODDI: oblique diameter difference index.

Demographic Factors

Age

The study by van Cruchten et al [9] reported a negative correlation between age and oblique diameter difference index (a biomarker for DP). However, the study by Sheu et al [38] (which assessed factors associated with a 9-fold increase in plagiocephaly between 1999 and 2007 in Texas, United States) reported no association between age and DP. Finally, the study by Roberts et al [37], which assessed DP in children with ventriculoperitoneal shunts, reported that being aged 12 to 16 years at the time of shunt insertion was associated with DP.

Sex

Of the 19 studies, 4 (21%) demonstrated an association between male sex and DP [33,36,39,44], 1 (5%) reported borderline association [37], and 7 (37%) reported no association between male sex and DP [9,28-30,32,35,38]. Of these 12 studies, 6 (50%) [29,30,33,36,39,43] reported ORs, and a meta-analysis of these ORs revealed interstudy heterogeneity (I^2=68.5%; Q statistic=15.89; df=6). The pooled fixed and random effects ORs for DP related to male sex were 1.71 (95% CI 1.43-2.04; P<.001) and 1.51 (95% CI 1.07-2.12; P=.02), respectively (Figure 2A [29,30,33,36,39,43]). Asymmetry analysis of the funnel plot excluded publication bias (P=.12; Figure 2B).

Figure 2. Meta-analysis and funnel plot for male sex. (A) Forest plot of odds ratios for deformational plagiocephaly related to male sex with fixed and random effects. (B) Funnel plot with linear regression test of asymmetry. The blue line indicates random effects. *Mild to moderate deformational plagiocephaly (DP; univariate analysis); **severe DP (univariate analysis).
Race

Race was investigated by Tang et al [40], who included a cohort of children with brachial plexus palsy. In this group, race was not associated with DP that developed after brachial plexus injury.

Developmental Factors

Developmental Delay

Developmental delay was investigated as a risk factor for DP by van Cruchten et al [9], who concluded that developmental delay was not associated with DP.

Developmental Dysplasia of the Hip

Developmental dysplasia of the hip (DDH) was investigated as a risk factor for DP by Valkama et al [41], who assessed the prevalence of DP in children with DDH. DDH was associated with DP compared to controls without DDH.

Head Circumference

Head circumference was investigated by Solani et al [39], who concluded that it was associated with DP (OR 1.22, 95% CI 1.06-1.40).

Motor Milestones

Reaching fewer motor milestones by age 6 months was investigated as a risk factor by 2 (11%) of the 19 included studies [27,30]. The first study reported that reaching fewer motor milestones by age 6 months was associated with DP (adjusted OR [aOR] 2.35, 95% CI 1.25-4.42) [27]. The second study found an association between delay in motor development and DP [30]. A meta-analysis of the ORs from these studies identified no interstudy heterogeneity (I^2=0%; Q statistic=1.67; df=3; Figure 3A [27,30]). The pooled fixed and random effects ORs for DP related to delayed motor milestones were both 2.56 (95% CI 1.66-3.96; P<.001). Asymmetry analysis of the funnel plot excluded publication bias (P=.18; Figure 3B).

Figure 3. Meta-analysis and funnel plot for reaching fewer motor milestones by age 6 months. (A) Forest plot of odds ratios for deformational plagiocephaly related to reaching fewer motor milestones by age 6 months with fixed and random effects. (B) Funnel plot with linear regression test of asymmetry. The blue line indicates fixed effects. *Adjusted OR (aOR) for deformational plagiocephaly (DP; multivariate analysis); **odds ratio (OR) for mild to moderate DP (only univariate analysis available); ***aOR for severe DP (multivariate analysis).
Overweight and Underweight

Being overweight at diagnosis of DP was investigated as a risk factor for DP by Kim et al [30], who reported that being overweight at diagnosis was not associated with DP. The same study reported that being underweight at diagnosis was also not associated with DP.

Dietary Factors

Bottle-Only Feeding

Bottle-only feeding was investigated by Kim et al [30], who demonstrated that bottle-only feeding was associated with DP (aOR 4.65, 95% CI 2.70-8.00).

Breast Feeding

The duration of exclusive breast feeding was investigated by Aarnivala et al [27], who demonstrated that the duration of exclusive breast feeding was not associated with DP.

Formula Feeding

Formula feeding was investigated by Weernink et al [43], who reported that children who developed DP by age 2 to 4 months were more likely to be formula fed (aOR 1.51, 95% CI 1.00-2.27).

Vitamin D Intake

Vitamin D intake in infants was investigated by Weernink et al [43], who reported that children who developed DP by age 2 to 4 months were more likely to have insufficient vitamin D intake (aOR 7.15, 95% CI 3.77-13.54).

Maternal Factors

Maternal Age

Of the 19 included studies, 3 (16%) demonstrated an association between maternal age and DP [28,32,43]. However, 3 (16%) of the 19 studies reported no association [30,38,40]. Only 1 (17%) of these 6 studies reported an OR indicating that increased maternal age was a protective factor for the development of DP (OR 0.94, 95% CI 0.91-0.97) [43].

Maternal Education Level

Of the 19 included studies, 3 (16%) demonstrated an association between maternal education level and DP [33,38,43], and 1 (5%) reported no significant association [28]. Only 2 (67%) of

the 3 studies reported ORs [33,43]. Of these 2 studies, 1 (50%) indicated that low maternal education level was an adverse factor in the development of DP (aOR 1.97, 95% CI 1.19-3.26) [43], while 1 (50%) suggested that postsecondary education was not a protective factor (OR 0.71, 95% CI 0.43-1.16) [33].

The OR from the former was used in a meta-analysis with the inverse OR from the latter, which demonstrated no interstudy heterogeneity (I^2=0%; Q statistic=0.86; df=1; Figure 4 [33,43]). The pooled fixed effects OR for DP related to low education level was 1.66 (95% CI 1.17-2.37; P<.005).

Figure 4. Meta-analysis for maternal education level. *Reciprocal odds ratio (OR) for postsecondary education.
Maternal Language Barriers

The study by Ballardini et al [28] investigated whether infants with mothers who experience a language barrier when receiving medical advice had a higher rate of DP. The study suggested that maternal language barrier was not associated with DP in the infant.

Maternal Race and Country of Origin

Of the 19 included studies, 3 (16%) investigated whether DP was associated with maternal race and country of origin [28,38,43]. All 3 studies suggested that maternal race and country of origin was not associated with DP in the infant.

Length of Time in the Country of Study

The study by Mawji et al [33] investigated whether the length of time spent by mothers in the country in which the study was conducted was associated with DP. The study reported that length of time in the country of study was not associated with DP.

Pacifier Use

Pacifier use by mothers in healthy infants was investigated as a risk factor for DP by Aarnivala et al [27], who reported that pacifier use was not associated with DP.

Tummy Time Instructions

The study by Ballardini et al [28] investigated whether DP was associated with mothers receiving instructions about tummy time. The study reported that receiving instructions about tummy time was not associated with DP.

Medical and Surgical Factors

Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia was investigated as a risk factor for DP by Ifflaender et al [29], who included a cohort of infants born prematurely. The study reported that bronchopulmonary dysplasia was not associated with DP.

Chronic Lung Disease

Chronic lung disease grade II was investigated by Launonen et al [34], who also assessed DP risk factors in infants born prematurely. The study reported that chronic lung disease grade II was associated with DP.

Family History of DP

Family history of DP was investigated by van Cruchten et al [9]. The study suggested that family history of DP was not associated with DP.

History of Illness

History of illness was investigated by Aarnivala et al [27]. The study suggested that history of illness was not associated with DP.

Intracranial Hemorrhage

Intracranial hemorrhage was investigated by Ifflaender et al [29], who assessed DP risk factors in infants born prematurely. The study reported that intracranial hemorrhage was not associated with DP.

Macrocephaly

Macrocephaly at birth was investigated by Kim et al [30]. The study suggested that macrocephaly at birth was not associated with DP. Macrocephaly at diagnosis of DP was also investigated, and it was found that this factor too was not associated with DP (OR 1.38, 95% CI 0.63-3.04) [30]. A lack of association was reported for subgroups with mild to moderate DP (OR 1.48, 95% CI 0.62-3.53) and severe DP (OR 1.19, 95% CI 0.04-3.58) [30].

Mechanical Ventilation

Of the 19 included studies, 2 (11%) demonstrated an association between mechanical ventilation and the development of DP in preterm infants [29,34]. Of these 2 studies, 1 (50%) reported an OR of 1.10 (95% CI 1.00-1.14) for mechanical ventilation [34]. The other study also suggested that the duration of total

respiratory support (continuous positive airway pressure and intermittent mandatory ventilation) and the duration of continuous positive airway pressure alone were associated with DP, while intermittent mandatory ventilation alone was not associated with DP [29].

Necrotizing Enterocolitis

Necrotizing enterocolitis was investigated by Ifflaender et al [29], who included a cohort of infants born prematurely. The study reported that necrotizing enterocolitis was not associated with DP.

Obesity

Obesity at diagnosis of DP was investigated by Kim et al [30]. Obesity at diagnosis of DP was defined as BMI >97th percentile. The study concluded that obesity at diagnosis of DP was associated with DP (aOR 2.45, 95% CI 1.02-5.90). The study also suggested that obesity at diagnosis of DP was associated with severe DP (aOR 4.10, 95% CI 1.42-11.90) but was not associated with mild to moderate DP (aOR 2.29, 95% CI 0.86-6.05).

Occipital Shunt Placement

Occipital shunt placement was investigated by Roberts et al [37], who concluded that occipital shunt placement was associated with DP compared to frontal shunt placement.

Torticollis

Torticollis was investigated by 3 (16%) of the 19 included studies, all of which reported no association between torticollis and DP [9,26,38].

Positional and Environmental Factors

Carriers, Bouncers, Car Seats, and Headrests

Time spent in carriers, bouncers, and car seats was investigated by Aarnivala et al [27], who reported that time spent in carriers, bouncers, and car seats was not associated with DP. Firmness of headrest was investigated by Solani et al [39], who reported that firmness of headrest was not associated with DP (OR 1.31, 95% CI 0.72-2.37).

Change of Crib End

Change of crib end (ie, alternating the infant's sleeping position by placing their head at different ends of the crib) was investigated as a risk factor for DP by 2 (11%) of the 19 included studies [33,42]. Both studies suggested that change of crib end was not associated with DP.

Feeding Position

Feeding position was investigated as a risk factor for DP by 2 (11%) of the 19 included studies [33,42]; both demonstrated that feeding position was not associated with DP.

Latency in Head Turning

Latency in head turning was investigated by Leung et al [31], who concluded that latency in head turning was not associated with DP.

Playing Position

Playing position was investigated by van Vlimmeren et al [42], who demonstrated that playing position was not associated with DP.

Head Position Preference

Head position preference was investigated by 6 (32%) of the 19 included studies, all of which demonstrated an association between head position preference and DP [9,27,28,31,33,42]. Of these 6 studies, 2 (33%) [33,34] reported ORs, and a meta-analysis of these ORs revealed negligible interstudy heterogeneity (I^2=27.6%; Q statistic=2.76; df=3) (Figure 5A [33,34]). The pooled fixed and random effects ORs for DP related to head position preference were 4.75 (95% CI 3.36-6.73; P<.001) and 4.96 (95% CI 3.10-7.93; P<.001), respectively. Asymmetry analysis of the funnel plot excluded publication bias (P=.28; Figure 5B).

Figure 5. Meta-analysis and funnel plot for head position preference. (A) Forest plot of odds ratios for deformational plagiocephaly related to head position preference with fixed and random effects. (B) Funnel plot with linear regression test of asymmetry. The blue line indicates fixed effects.
Sleeping Position

Sleeping position (supine vs prone) was investigated by 3 (16%) of the 19 included studies [28,33,39]. Of these 3 studies, 2 (67%) demonstrated an association between supine sleeping and DP [33,39], while 1 (33%) reported a protective effect from prone sleeping (OR 0.13, 95% CI 0.03-0.40) or side sleeping (OR 0.22, 95% CI 0.05-0.71) [28]. The ORs from 2 (67%) [33,39] of the 3 studies were used with the inverse OR from the third study [28] in a meta-analysis, which demonstrated negligible

interstudy heterogeneity (I^2=19.1%; Q statistic=2.47; *df*=3; Figure 6A [28,33,39]). The pooled fixed and random effects ORs for DP related to sleeping position were 3.12 (95% CI 2.21-4.39; *P*<.001) and 3.22 (95% CI 2.14-4.84; *P*<.001), respectively. Asymmetry analysis of the funnel plot excluded publication bias (*P*=.20; Figure 6B).

Figure 6. Meta-analysis and funnel plot for supine sleeping position. (A) Forest plot of odds ratios for deformational plagiocephaly related to supine sleeping position with fixed and random effects. (B) Funnel plot with linear regression test of asymmetry. The blue line indicates fixed effects. *Supine versus prone; **reciprocal prone versus supine; ***reciprocal side versus supine.
Time Spent Prone on the Floor

The study by Aarnivala et al [27] investigated time spent prone on the floor and reported no association with DP.

Tummy Time

Tummy time was investigated by 4 (21%) of the 19 included studies [28,30,33,42]. Of these 4 studies, 1 (25%) reported an association between reduced tummy time when awake and DP (aOR 3.51, 95% CI 1.71-7.21) [30]. The remaining studies (3/4, 75%) reported that tummy time was not associated with DP but provided no ORs [28,33,42].

Time Spent Outdoors

Time spent outdoors was investigated by Weernink et al [43], who reported no association with DP.

Time Spent Supine on the Floor

Time spent supine on the floor was investigated as a risk factor for DP by Aarnivala et al [27], who reported that children with DP at age 12 months spent more time supine on the floor at age 6 months.

Summary of Nonobstetric Factors Associated With DP

A summary of 16 nonobstetric factors associated with DP is presented in Table 2. ORs are provided for 12 (75%) of these 16 nonobstetric factors.

Table 2. Odds ratios (ORs) for factors associated with deformational plagiocephaly. ORs are reported from single studies unless marked with a superscript ("a" or "b") indicating pooled ORs from fixed or random effects meta-analyses.

Factors	OR (95% CI)	References
Insufficient vitamin D intake	7.15 (3.77-13.54)	[42]
Head position preference	4.75[a] (3.36-6.73)	[33,34]

Discussion

Principal Findings

This study assessed evidence of association with DP for 43 nonobstetric factors (demographic factors: n=3, 7%; developmental factors: n=6, 14%; dietary factors: n=4, 9%; maternal factors: n=8, 19%; medical and surgical factors: n=11, 26%; and positional and environmental factors: n=11, 26%). Of these 43 factors, 16 (37%) were associated with DP (demographic factors [male sex]: n=1, 6%; developmental factors [DDH, head circumference, and delay in motor milestones]: n=3, 19%; dietary factors [bottle-only feeding, formula feeding, and vitamin D intake]: n=3, 19%; maternal factors [maternal age and maternal education level]: n=2, 12%; medical and surgical factors [chronic lung disease grade II, mechanical ventilation, and obesity at diagnosis of DP]: n=3, 19%; and positional and environmental factors [head position preference, sleeping position, reduced tummy time, and time spent supine on the floor]: n=4, 25%). With the notable exceptions of maternal age, mechanical ventilation, and tummy time, these associations were either supported by nonconflicting evidence or a meta-analysis that resolved conflicting evidence into an association. Of the 16 factors, 12 (75%) had ORs that ranged from 1.10 (mechanical ventilation) to 7.15 (insufficient vitamin D intake). Of the 5 factors assessed by meta-analysis (male sex, reaching fewer motor milestones by age 6 months, maternal education level, head position preference, and sleeping position), only 1 (20%; male sex) was associated with interstudy heterogeneity (≥50%). No evidence of publication bias was detected.

Evidence-Based Recommendations

Strategies to reduce the prevalence of DP have included guidance about the infant's environment, positioning, and handling, with the goal of creating a nonrestrictive environment that promotes spontaneous and unhindered physical movement and symmetrical motor development [27,45].

On the basis of the evidence presented in this study, the following 11 recommendations, presented in order of importance, are offered with the aim of reducing the prevalence of DP.

First, to ensure bone health in infants, it is critical that vitamin D intake is adequate [46]. Vitamin D level should be assessed regularly during development, and dietary supplementation should be considered if vitamin D level is low.

Second, during the first months of life, babies develop a head position preference [47], and this preference is more often to the right [44,48]. The increased compressive forces on one side of the head for prolonged periods causes flattening on the side being compressed. It has been proposed that the position of the fetus in the later stages of pregnancy may, in part, be responsible for position preference [28,49]. However, there is also evidence that position preference can be modified by varying head

position during sleep to encourage equal distribution of pressure [50]. Other strategies to mitigate head position preference should be used, such as gently moving the infant's head to the unfavored side when asleep or physical therapy with or without kinesiological tape to reduce tightness in the neck muscles to facilitate easier neck turning [51,52].

Third, sufficient tummy time should be provided to strengthen the infant's head, neck, and arms and reduce time spent supine when awake.

Fourth, as infants tend to turn away from windows and toward the center of a room, it is recommended to alternate the infant's sleeping position by placing their head at different ends of the crib. This concept is supported by 2 studies suggesting no association between crib end change and DP [33,42]. However, it is important to state that the lack of association between crib end change and DP does not necessarily mean that changing the crib end will provide an effective treatment for established DP; it may merely help to reduce the risk of DP developing.

Fifth, although bottle-only feeding should not be discouraged, it is recommended to alternate feeding positions, using both the dominant and nondominant sides when holding the infant. Bottle feeding, as opposed to exclusively breast feeding, may be positively associated with obesity (which has also been identified as a risk factor for DP) [53]. This coassociation may, in part, explain the association of bottle-only feeding with DP.

Sixth, although formula feeding should also not be discouraged, it is recommended to alternate feeding positions. It has been suggested by Weernink et al [43] that this particular risk factor is associated with lower maternal education level. Similar to bottle feeding, formula feeding, as opposed to exclusively breast feeding, may be positively associated with obesity (itself a risk factor for DP) [53].

Seventh, if motor milestones are delayed, infants should be referred for specialist assessment by a pediatrician. Similarly, obesity (BMI >97th percentile) should be identified and managed by a specialist pediatrician.

Eighth, to mitigate the impact of low maternal education level, educational resources and face-to-face education outlining factors associated with DP, as well as recommendations to reduce their impact, should be provided to all families at the 6-week postnatal infant check-up, with particular emphasis on those with low educational levels. A lower maternal education level results in worse health outcomes in infancy and later life [54]; although improving the education level of future mothers should be a national priority, there are other factors associated with low education level that may be immediately modifiable. These include access to information and access to resources [55].

Ninth, Information should be provided to families that male infants are at higher risk of DP. Losee et al [49] suggested that male infants tend to have larger, less flexible heads at birth, which are more likely to become deformed by compressive forces in utero and in the birth canal. Families should be particularly encouraged to engage with strategies to mitigate DP in male infants.

Tenth, information should be provided to families that infants with greater head circumference are at higher risk of DP. Families should be particularly encouraged to engage with strategies to mitigate DP in these infants.

Eleventh, information should also be provided to families that infants who have had mechanical ventilation are at higher risk of DP. Families and care teams of infants requiring mechanical ventilation should be encouraged to engage with strategies to mitigate DP in these infants.

Alternative strategies for mitigating the impact of DP, such as helmet therapy, although costly for individuals and health care systems, may help avoid more invasive strategies [56]. It has been demonstrated that education provided by health care professionals, such as health visitors, midwives, and nurses, can successfully reduce the prevalence of DP [57]. Adopting these recommendations may lead to a reduction in the prevalence of DP.

Strengths of This Study

The strengths of this study include a robust methodology. The protocol was registered with PROSPERO, and the reporting was in line with the PRISMA 2020 guidelines [22]. The databases searched provided >97.5% coverage [23]. Standardized data extraction was performed to minimize errors. Meta-analysis was performed where data allowed. Funnel plots suggested that publication bias did not impact the results; thus, a trim-and-fill analysis was not necessary to correct for asymmetry [58].

This study represents the most comprehensive analysis of nonobstetric factors associated with DP published to date. A systematic review by Bialocerkowski et al [59] only identified 5 factors associated with DP, of which 3 (60%) were nonobstetric factors (male sex, supine position, and neck problems) [59]. Another systematic review by De Bock et al [60] identified male sex, supine sleeping position, limited neck rotation, head position preference, lower level of activity, and reduced tummy time as the most important risk factors [60]. By contrast, our study provides evidence of association for 16 factors and confirms the association of male sex, supine sleeping position, head position preference, and reduced tummy time with DP.

A more recent systematic review by Inchingolo et al [61] provided only 2 recommendations to mitigate the impact of nonobstetric risk factors for DP: at least 30 minutes of tummy time and the use of a passive sleep curve mattress to improve harmonious skull growth. In addition, it did not include meta-analyses to support these recommendations. By contrast, our study makes 11 recommendations for nonobstetric factors to reduce the prevalence of DP. The systematic review by Inchingolo et al [61] also did not assess publication bias. Our review suggested that none of the recommendations were influenced by publication bias.

Limitations of This Study

To ensure the completion of the study, additional databases were not searched, and hand searching and gray literature searches were also not performed. This inevitably limited the

comprehensiveness of this study, although no systematic review can claim to be truly comprehensive because this would necessitate continual inclusion of newly published studies. The search terms were designed to be specific yet pragmatic to ensure the completion of the work with limited resources; thus, some studies may have been overlooked. Due to resource limitations, it was not possible to record more detailed reasons for the exclusion of screened articles other than not reporting risk factors for DP. Resource constraints also prevented the screening process from being conducted by 2 independent reviewers. Instead, abstract and full-text screening was performed by a single reviewer. This impacts the reproducibility of the study due to the increased potential for errors in study selection when screening is undertaken by a single reviewer. That said, because the selection criteria were clearly set out, errors due to the application of these criteria during the screening process are likely to have had minimal impact on the study outcomes. In addition, it was not feasible, due to resource limitations, to contact study authors to attempt to collect raw data if a study did not report ORs for a risk factor. This may have limited the data that could have been used in meta-analysis. If contacting authors had been feasible, more factors could potentially have been analyzed quantitively to resolve discrepancies between the included studies. This represents a significant limitation of our study.

These factors may, in part, account for the apparent disparities reported in our results compared to other literature. These disparities include the apparent lack of association between developmental delay and DP [9], while demonstrating a significant association between reaching fewer motor milestones and DP [27,30]. A recent systematic review by Martinuik et al [62] included 19 studies that assessed the association between developmental delay and DP. Notwithstanding the fact that the authors included multiple studies that used the same study population more than once, a positive association between developmental delay and DP was reported in a majority of the studies [62]. The fact that our study did not demonstrate a similar association may, in part, be due to the inclusion of studies that assessed different populations, as well as methodological limitations in our search strategy that limited the identification of studies that may have met our eligibility criteria. Another study of a large primary care cohort of 77,108 patients has provided further evidence in support of an association between developmental delay and DP [63]. That said, the literature remains conflicting, with other studies unable to demonstrate an association between presence or degree of developmental delay and DP [64]. Commentators have highlighted the fact that most studies are retrospective and observational by design, and this limits conclusions about the correlative versus causative relationship between developmental delay and DP [65].

Another disparity reported in our study is that torticollis was not associated with DP [9,26,38]. A number of literature reviews have previously reported an association between congenital muscular torticollis and DP [8,59]. Although these studies were published a decade or so ago, it logically follows that if other positional factors, such as head position preference and sleeping position, have been found in more contemporaneous studies to

be significantly associated with DP [28,33,34,39], then torticollis would also be expected to be found to be associated with DP. These conflicts reported in the literature may be due to the limitations of individual study design or differences between different study populations. Therefore, we recommend interpreting with caution the lack of association between torticollis and DP reported in our study, given the lack of a mechanistic explanation that reconciles this result with other positional factors that were found to be associated with DP.

In this review, we have included a study involving patients who developed plagiocephaly after ventriculoperitoneal shunt insertion [37]. Although the authors characterized the plagiocephaly as "positional," implying that external forces had caused the skull deformity, an alternative hypothesis is that shunt-associated plagiocephaly is a different disease entity from DP [37]. This study has been included for comprehensiveness [37], but the results should be interpreted with caution alongside those of other studies.

Finally, another limitation includes the lack of a Grading of Recommendations Assessment, Development, and Evaluation (GRADE) assessment of evidence quality, which impacts the certainty of the conclusions and recommendations set out in this study.

Conclusions

In summary, this study provides the most comprehensive meta-analytic assessment of nonobstetric factors associated with DP published to date. It offers 11 evidence-based recommendations that can be adopted by health care systems globally to reduce the prevalence of DP. Future research should focus on investigating factors for which the literature is conflicting but quantitative data are lacking to enable meta-analyses to be performed; for example, maternal age was the only factor reported to be protective against DP, but conflicting studies reported that there was no association without providing quantitative data. Thus, maternal age as a protective factor for DP should be investigated further to provide quantitative data for meta-analytic approaches to determine its protective effect. Further research should also address the nature of specific relationships between risk factors and DP; for example, both bottle-only feeding and formula feeding have been associated with DP. Studies should focus on understanding the nature of this relationship, that is, whether this relationship is due to mechanical forces associated with bottle-feeding or whether a reduction in, or lack of, breast milk intake or a lack of complimentary foods alongside breast milk results in nutritional differences that impact skull development [66]. As our study also highlighted an association between obesity and DP, research on other early-life or environmental exposures should be conducted to elucidate their effects on growth and development, particularly skull growth and head shape [67,68]. Finally, randomized controlled trials, although considered the gold standard study design for obtaining reliable evidence of an intervention's effectiveness, should not be conducted for the interventions herein that relate to risk factors for DP development that have already been assessed through meta-analysis. However, randomized controlled trials could provide further evidence for an intervention—if ethically

appropriate—where the evidence for a particular risk factor is relatively weak, such as when only a single cohort study has provided the evidence for a risk factor's influence on the development of DP.

Data Availability

All data generated or analyzed during this study are included in this paper.

Authors' Contributions

CRTH developed the methodology, performed screening and data extraction, performed data analysis, interpreted the results, and wrote and edited the manuscript. NB performed screening and data extraction, interpreted the results, and wrote and edited the manuscript. AN performed screening and data extraction, interpreted the results, and edited the manuscript. FJBD interpreted the results and edited the manuscript. JO conceived of the study, interpreted the results, and edited the manuscript.

Conflicts of Interest

CRTH and AN received consultancy fees from Advanced Orthomolecular Research in Calgary, Alberta, and their family members work for the aforementioned company, which, although not directly connected to this research, produces nutraceutical compounds, including vitamin D, which is part of the subject matter of this research. All other authors declare no other conflicts of interest.

Abstract

Background: Health locus of control (HLOC) is a theory that describes how individuals perceive different forces that influence their lives. The concept of a locus of control can affect an individual's likelihood to commit to behaviors related to their health. This study explores the literature on the relationships between HLOC and medical behavioral interventions.

Objective: This study aims to better understand how HLOC constructs can potentially affect patient responses to health behavioral interventions and to propose a series of guidelines for individuals interested in designing medical behavioral interventions related to HLOC.

Methods: We used the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) methodology and performed an analysis of 50 papers related to the topic of HLOC and medical behavioral interventions. Inclusion criteria were studies that had a behavioral intervention involving patients and contained a metric of at least 1 of the constructs related to HLOC. The initial screening and search were conducted by 2 researchers (AY and SM) separately. The results were then combined and compared.

Results: Our findings explore the influence of different levels of HLOC along with the importance of both patient- and health-related context when assessing the relationships between HLOC constructs and the likelihood of health behavior change. The findings show that different constructs related to HLOC can act as reliable predictors for patient responses to medical behavioral interventions. Patients who score higher on internal HLOC measures are more likely to exhibit behaviors that are consistent with positive health outcomes. Patients who score higher on chance HLOC are more likely to exhibit behaviors that may lead to adverse health outcomes. These conclusions are supported by most of the 50 studies surveyed.

Conclusions: We propose guidelines for individuals designing medical behavioral interventions so that they can make use of these relationships linked to HLOC. The three guidelines suggested are as follows: (1) in most situations, improving internal HLOC will improve health outcomes for patients; (2) patients with high external HLOC should be further studied to determine the source of the external HLOC; and (3) patients with a high chance HLOC are less likely to follow preventative behaviors or be responsive to interventions. Limitations of the study are that the primary search and analysis were conducted by 2 principal researchers (AY and SM). Interpretation and development of the guidelines are subject to individual interpretation of results and may not be applicable to all contexts.

Introduction

Overview

Health locus of control (HLOC) refers to an individual's beliefs about the extent to which they have control over their health outcomes. Loci of control (LOCs) are typically split into 2 categories: internal and external forces. Individuals who have a higher internal LOC tend to believe that their actions can influence their health outcomes directly. Individuals with a higher external LOC are more likely to believe that their health outcomes are determined by external factors such as luck, fate, or the actions of other people. HLOC has been used as a theoretical model to predict the likelihood of individuals performing health-related behaviors across multiple settings. Medical behavioral interventions describe a broad range of activities; examples include the following: increasing the likelihood of individual vaccination rates through health messaging, increasing an individual's willingness to follow a meal plan and diet by communicating the benefits of weight loss, and increasing medication adherence through targeted messaging provided by a physician to a patient.

Medical behavioral interventions are meant to affect the health behaviors of individuals with the intention of improving health outcomes. HLOC is often used as a lens to interpret how an individual interprets and internalizes health-related stimuli. Health messaging, medication efficacy, and behavioral changes are all factors that have relationships with HLOC constructs [1,2]. Understanding an individual's HLOC can therefore be an important factor in determining the most effective approach to medical behavioral interventions.

Research Question

The research question we are seeking to address is how do HLOC constructs affect the efficacy of health behavioral interventions? To explore this question, we conducted a systematic review of academic studies and randomized controlled trials related to health behavioral interventions and HLOC constructs. In addition to this research question, we also seek to develop a series of guidelines for individuals interested in designing medical behavioral interventions related to HLOC. The next section will provide background on the research space, specifically the HLOC and behavioral interventions in the health care context.

Background

HLOC Theory

The theory of LOC was developed in the 1950s by Julian Rotter [3]. Rotter separated the LOCs into 2 constructs: internal control and external control. The distinction between the 2 constructs is the extent to which an individual believes that the outcome of an event is "contingent on their own behavior" or "a function of chance, luck, or fate" [4,5]. HLOC is an extension of the LOC theory and relates to how much control people believe they have over their health. HLOC can also be either internal or external. HLOC extends the idea of external control by creating additional constructs to better define the source of external control. Studies on external HLOC (E HLOC) typically split the construct into 3 distinct sources: powerful others HLOC (PO HLOC), chance HLOC (C HLOC), and god HLOC (G HLOC) [2,6]. Internal HLOC (I HLOC) represents the belief of individuals in their ability to impact their health status, while E HLOC represents individual belief that external sources affect personal health [7].

Table 1 [4] describes the constructs of the LOC theory we focus on in this study. Internal and external LOCs are used to distinguish the individual constructs described in the table.

Table 1. Locus of control.

Locus of control	Description
Internal	Individuals believe in their impact on their behavioral outcomes
External: powerful others	The belief of external sources and factors influencing one's life and decisions
External: chance	The belief of chance and fate influence one's life and decisions
External: god	The belief through religion of a higher power influencing one's life and decisions

The HLOC constructs are independent of each other and can be applied to different contexts. People with higher I HLOC tend to believe in their influence on their behavioral outcomes, while individuals who have higher E HLOC believe that factors beyond their control affect those outcomes more strongly [8]. The impact of I HLOC can be effective toward physical self-care [9] and may also be an influential motivation relating to participation and the use of technologies or other tools designed for health care [5,10,11]. E HLOC and PO HLOC can be significant especially when it comes to the use of provider-recommended digital tools [1]. Individuals with I HLOC and PO HLOC beliefs may be more willing to use mobile health apps and platforms and are more likely to participate in monitoring health behaviors and developing web-based trackers [1]. HLOC has been used as a framework for analyzing individual health-related behaviors, particularly those related to platform use and trust.

HLOC remains a relevant theory for analyzing individual behavior within a health context. During the COVID-19 pandemic, many individuals experienced increases in factors related to I HLOC such as anxiety, fear, and depression. This increase led to many individuals experiencing posttraumatic stress disorder [8]. I HLOC is a commonly used framework for assessing individual factors influencing stress and developing solutions to manage anxiety [8]. E HLOC describes the extent to which an individual believes outside forces affect their life. The construct of powerful others in a health care context is

usually a measurement of individual trust in a health-related platform, app, or doctor [12].

Medical Behavioral Interventions

Medical behavioral interventions refer to a wide range of strategies for the promotion of healthy behaviors in individual patients with the goal of improving health care outcomes [13-15]. Interventions can take on different forms including communicating health information to patients, providing incentives for desired behavior, or directly administering medication. Behavioral interventions tend to combine communication of information along with incentivization of healthy behaviors such as dieting, exercise, medication adherence, or cessation of substance abuse [16-19].

The efficacy of behavioral interventions depends on many factors. The desired health outcome and the demographics of the patient have large effects on the efficacy of different forms of interventions. For example, social support has been demonstrated to improve patient adherence to behavioral interventions related to lifestyle change such as dieting or exercise [20,21]. Interventions that are focused on acute diseases can change the efficacy of social incentives. Studies on behavioral interventions and cancer show that the severity of the disease affects adherence to guidelines delivered through an information-based health intervention [22-24]. Patients who are in the early stages of cancer tend to react strongly to new sources of information and seek out more when prompted, whereas patients in the latter stages are more receptive to the information provided by a trusted source such as a physician [25]. The consistency with which patients follow behavioral interventions is also not guaranteed. Most interventions tend to be administered over a period between 6 and 12 months. Past the intervention period, there is no certainty that patients who were receptive to the intervention messaging continued with the recommended behaviors [26-28].

In response to these issues, research has suggested that interventions tailored to specific individuals and their needs are more suitable than generalized approaches for behavioral change [29-32]. HLOC is a theory that is specific to individuals. An individual's perception of the world and what affects their health is an indicator of how they will respond to different forms of intervention [33-35]. Exploring this avenue of research can help uncover relationships between individual perceptions and the predictive efficacy of health interventions that would otherwise be unclear.

Methods

Overview

To accomplish our research objectives, we approached a systematic review of the literature using the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) methodology (Multimedia Appendix 1). PRISMA is a common methodology used to synthesize literature and filter sample pools in preparation for analysis [36-38]. Specifics regarding the search are reported below.

PRISMA Search

We used the following terms when searching for papers related to our review: "Health Locus of Control"; "Behavior Change"; "Behavioral Change"; "Behavioral Change Interventions"; "Medication Adherence"; "HLOC"; "Patients"; "Healthcare; "Culture"; "Empirical"; and "Locus of Control." The terms were searched individually, then altogether using the keyword of "OR" connecting all of the different terms. Finally, the terms were searched together using the keyword "AND." These individual searches also included linked terms with "AND": "Health Locus of Control" AND "Behavior Change"; "Health Locus of Control" AND "Behavioral Change"; "Health Locus of Control" AND "Behavioral Change Interventions." The spelling of "Behaviour" was also used in the search for completeness. These keywords were used in a title plus abstract search through the databases of Web of Science, IEEE Xplore, the ACM Digital Library, the AIS e-Library, and PubMed. The search was conducted between November and December 2022. Additional details regarding the search and search strategy are available in Multimedia Appendix 2.

Inclusion criteria were studies that had a behavioral intervention involving patients and contained a metric of at least 1 of the constructs related to HLOC. Only studies that had actual data were considered; proposals and simulations were excluded. Additionally, only studies that were published in peer-reviewed journals were considered for inclusion. The initial screening and search were conducted by 2 researchers (AY and SM) separately. The results were then combined and compared. The initial search identified 357 papers potentially relevant to the study. Only references were used as a check for this stage, no abstracts or full texts of papers were read. After additional filtering, 245 redundant papers were removed from this pool. Reasons for paper removal during this stage included duplication due to cross-referencing and singular papers that appeared in multiple databases. Papers were then further checked for relevancy to the research scope. Filtering at this stage occurred from a reading of paper abstracts for relevance. If a study was not relevant based on a read of the abstract because it did not deal with medical behavioral intervention or HLOC or contain actual data, it was excluded. Papers that proposed studies but did not conduct behavioral interventions were also excluded at this stage. This resulted in the removal of an additional 72 papers, with 50 remaining for analysis. During this stage, citation software Zotero (Corporation for Digital Scholarship) was used to collect and compare citations and documentation.

Data Extraction and Data Synthesis

Data extraction occurred after the identification of the items to be included in the analysis. Data extracted included the type of study, sample size, and interaction effects related to HLOC and the medical behavioral intervention. The full text of papers filtered through the first steps was read. Extraction was conducted by 2 independent researchers (AY and SM). Discrepancies were solved through a discussion of the 2 researchers and consensus was required to include information in the final document. Multimedia Appendix 3 [1,5,8,12,22,23,25,27,39-80] contains the results of this data extraction process. Data synthesis took on a similar form to

extraction, 2 independent researchers (AY and SM) evaluated the information collected and discrepancies were handled through consensus decision after discussion. After collating the results from the review, we analyzed the frequencies of studies that had relationships between the primary HLOC constructs and related health care behaviors. From this analysis, we developed a series of guidelines for researchers interested in the field of patient behavioral change in health care settings.

Results

Overview

The following sections will cover the results of the data synthesis. Topics of discussion include relationships between constructs, behavioral health interventions, and the influence of contextual factors such as disease and patient characteristics observed within the studies. Figure 1 contains the PRISMA flow diagram summarizing the search process.

The main health behaviors discussed in all the papers reviewed in this study are labeled into 5 main categories. These categories are preventative health behaviors, mental health, personal health perception, vaccination hesitancy, and physician trust. The number of papers that have focused on each health behavior is shown in Table 2.

The number of HLOC constructs that have been focused on in the 50 papers reviewed for this study can be seen in Table 3. Some studies have focused on several constructs, and some have focused on only one. The following table shows the counts of HLOC constructs that are mainly highlighted in this study's review papers.

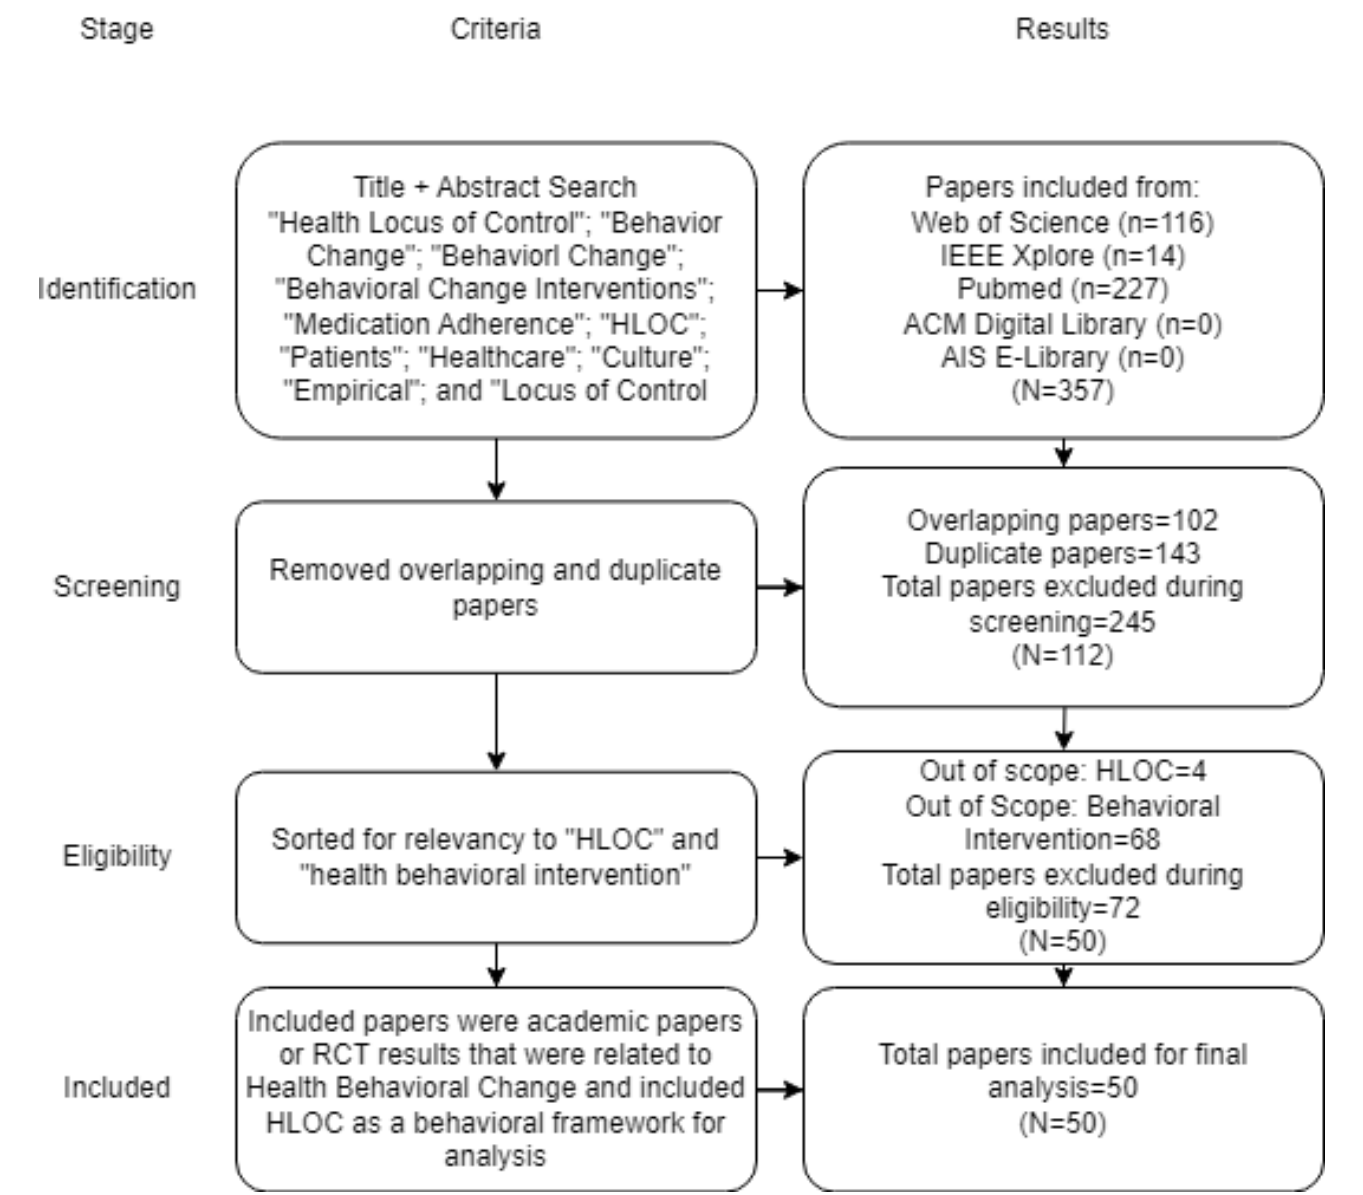
Figure 1. PRISMA Search Strategy and Results.


Table 2. Health behaviors.

Health behavior	Papers (n=50), n (%)
Preventative health behaviors	22 (44)
Mental health	20 (40)
Personal health perception	5 (10)
Vaccination hesitancy	2 (4)
Physician trust	1 (2)

Table 3. Number of HLOC[a] constructs.

HLOC constructs	Uses (n=50), n (%)
Internal HLOC	45 (90)
Powerful others HLOC	37 (74)
Chance HLOC	34 (68)
God HLOC	9 (18)

[a]HLOC: health locus of control.

HLOC and General Health

The relationship between HLOC and general patient health depends on many different factors. However, common relationships between HLOC constructs and patient health can be observed that are generalizable across contexts. The discussion in this section will focus on the I HLOC, E HLOC, PO HLOC, and C HLOC.

Higher I HLOC generally leads to better health outcomes overall due to higher rates of patient self-efficacy. Higher patient self-efficacy leads to an increase in behaviors that are beneficial to overall patient health. These behaviors can include improved medication adherence, preventative health behaviors, and an increase in healthy activities. These behaviors and outcomes are observable across income levels and other demographic characteristics [39,40].

Higher E HLOC within individuals can have different outcomes depending on the prevailing construct: C HLOC or PO HLOC. Higher C HLOC generally leads to more negative health behaviors and health outcomes in individuals. Individuals with high C HLOC tend to believe that health is an uncontrollable outcome that is determined by chance. As a result, those individuals tend to perform fewer preventative behaviors that could improve health outcomes. PO HLOC has a less clear relationship with general health. The source of the powerful other has a large impact on the decision an individual makes. For instance, individuals with a high PO HLOC who see physicians as the primary source of powerful others are likely to adhere to medical recommendations and have better health outcomes as a result. Individuals who have similarly high PO HLOC but view friends and family as the powerful other may have mixed results, as the friends and family may not recommend behaviors that are consistent with medical recommendations.

HLOC and Health Interventions

Research has shown that higher I HLOC can lead to more preventative behavior from patients [41]. Patients with higher PO HLOC have more potential influences [21]. In fact, those with a higher PO HLOC are more likely to engage in preventative behaviors, particularly if the influence comes from physicians or other health care professionals [42]. However, if the PO HLOC comes from religion or a belief in a higher power, health care behaviors are likely more context dependent and less predictable [43]. For example, a high PO HLOC sourced to a patient's family may cause contradictory health outcomes such as lower vaccination rates, higher social contact, and higher physical activity. On the other hand, those with a higher C HLOC, or the belief that health outcomes are beyond their control, are less likely to engage in preventative health behaviors, often believing that their efforts won't matter.

Studies have found that individuals with higher I HLOC are more likely to engage in healthy dietary behaviors. This includes less consumption of unhealthy foods and more intake of healthy foods. On the other hand, those with higher C HLOC are less likely to adopt beneficial dietary patterns [44]. Interestingly, individuals with higher PO HLOC tend to have more beneficial dietary patterns. For example, parents can be seen as power others, and if an individual has a higher PO HLOC, they may be more likely to adopt a healthy diet based on their parents' influence [44]. Overall, an individual's HLOC plays a significant role in their dietary behaviors and can be a useful factor to consider when developing effective interventions for improving nutrition.

When it comes to substance abuse, research suggests that HLOC can play a significant role in this context. Individuals with higher I HLOC tend to make self-centered decisions that can lead to reduced substance abuse. This includes decisions such as smoking reduction, birth control use, and weight loss [9]. Additionally, those with lower I HLOC are less likely to make these self-centered decisions and tend to act more carelessly toward their health [45]. Examples would be more alcohol

consumption and daily smoking. Similarly, individuals with a higher C HLOC have been found to be more likely to smoke. Conversely, those with a higher PO HLOC are less likely to smoke due to the influence of their family or physicians [45]. Understanding an individual's HLOC can be an important factor in developing effective interventions to reduce substance abuse and improve overall health outcomes.

Additional Factors

Besides the individual contexts of the relationships between constructs, individual patient characteristics can also affect how HLOC constructs impact health behaviors. Patients who have chronic conditions tend to have higher C HLOC, particularly over longer periods. The severity of illnesses also affects the usual relationships between HLOC constructs and patient health. In the context of chronic conditions, such as asthma, patients with higher self-efficacy and higher I HLOC are in more control of their condition, whereas patients with higher E HLOC beliefs can potentially lead to poorer control [46].

Patient Characteristics

Several factors have been found to influence HLOC, including social contact, health information–seeking behavior, and trust in health care providers. For example, social contact has been found to lead to better health care behaviors across all income levels [39]; higher I HLOC has been found to lead to more social behaviors, which in turn leads to positive health influence [47]; and health information–seeking behavior has been linked to higher I HLOC, indicating individuals with higher I HLOC are more likely to seek out information to be well aware of their health decisions outcome [39]. Higher E HLOC, and mostly higher PO HLOC, can increase patients' level of trust, and patients who are more trusting have been found to be more likely to follow their physician recommendations [12]. C HLOC has also been found to have a moderating effect on patient self-efficacy and self-management behavior [48]. High self-efficacy leads to more self-management, and depending on the level of patients' C HLOC, this relationship can be either strengthened or weakened.

E HLOC has been found to affect death-related anxiety. Higher PO HLOC can lead to less stress regarding the uncontrollable nature of death based on the trust in others' (physicians') influence on one's health outcomes [49]. However, higher C HLOC has been found to increase the level of anxiety and depression at the end of life, as it indicates patients' lack of control over their health and the inevitability of death [22]. These patterns are also applicable to healthy patients as they age (Aviad and Cohen-Louck [72]). E HLOC can also impact patients both positively and negatively. An elevated E HLOC can result in an increased level of depression and anxiety for a patient. For example, patients with high E HLOC have been found to have poor coping skills, which could result in higher levels of depression. Within the same context, patients with high E HLOC linked to caregivers are more likely to rely on their physician, worry less, and adapt to their conditions [22,81].

Caregiver Characteristics

The impact of an individual's health decisions on other individuals and their relationship with them can also affect their perceived HLOC. For example, if a patient is concerned about their child's health outcome, the parent's I HLOC and E HLOC may be influenced by their perception of their ability and connected anxiety related to their child's health outcomes. For example, parental caregiving quality increases when a child faces challenges such as a chronic condition [27]. Some studies have found mothers to be the main caregivers in special chronic conditions such as type 1 diabetes [82,83]. Parents of children dealing with diabetes were found to have higher I HLOC, whereas patients who had failed to reach that control level tended to have lower levels of I HLOC and higher levels of G HLOC and C HLOC [82]. Mothers and other caregivers have also been found to influence patients' behavior and coping styles. The level of I HLOC or E HLOC of the caregiver can significantly impact the patients' active or passive coping style and how they behave toward their condition and perceived anxiety level [84].

Disease Characteristics

Terminal illnesses can lead to unique cases where higher I HLOC causes greater stress and anxiety for patients as they experience a greater loss of control [22,50]. The relationship between these 2 constructs is stronger as the illness becomes more serious. A reversal of this relationship is possible. Patients who are provided with an option for treatment or hopeful messaging can decrease stress and anxiety among patients with higher I HLOC. The likely reason for this phenomenon is that patients with higher I HLOC perceive a return of control, which leads to lower stress and more proactive behaviors when positive messaging is provided.

Patients with cancer across all stages tend to have higher PO HLOC and decreased I HLOC. Higher PO HLOC tends to manifest in a lowering of anxiety if the source of the powerful other is rooted in religion or part of the G HLOC [25]. The reverse of this relationship has also been observed. Patients with cancer with higher I HLOC tend to have lower E HLOC. The higher I HLOC is usually indicative of a higher quality of life for the duration of the disease [51]. This might be due to the impact of I HLOC in the hope of recovery, which leads the patient to a better mental state and lowers the anxiety and depression rates.

Uncertainty is a major consideration across multiple studies focused on patient behaviors. Uncertainty is defined as any situation where a decision maker is unable to accurately predict outcomes because they lack information or sufficient environmental cues [85]. In the concept of HLOC, individuals with higher I HLOC are more likely to react to uncertainty as a controllable decision and opportunity, whereas individuals with higher E HLOC may consider their uncertainty as untrustworthy evidence of a situation [86]. Patients with a higher level of I HLOC tend to be more involved in their health-related situations and have less uncertainty about them [51,87,88]. Higher I HLOC and more level of uncertainty in patients can result in less stress and anxiety rates.

Research shows that uncertainty mediates between HLOC with quality of life, anxiety, and depression [51]. It has been illustrated that the level of a patient's education and the complexity of a treatment can directly affect patients'

uncertainty which can be reduced by improving the level of education and patients' knowledge about the related phenomenon [89-91]. Physicians and health professionals can be external resources for providing such information to patients with higher PO HLOC and help them overcome their uncertainty and improve their mental health [91,92]. Patients with higher I HLOC have been found to have better coping with their condition and adapt well to the change, along with information-seeking behavior, which would result in improved level of knowledge about their condition and reduced level of stress [51,87]. Additionally, patients who have dealt with chronic conditions for longer periods feel less uncertainty and less stress about their condition because of their perceived knowledge about their situation over time which would result in their improved quality of life and mental health. With chronic conditions, such as asthma, patients with higher self-efficacy and higher I HLOC are in more control of their condition, whereas patients with higher E HLOC beliefs can potentially lead to poorer control [46]. In the case of patients with dementia, higher E HLOC has been observed with lower patient depression, which could be because E HLOC may be linked to acceptance of chronic conditions (Halse et al [50]).

Discussion

Principal Findings

Through analysis of the data, we observed intersections between HLOC characteristics of patients and health outcomes. The most commonly recurrent themes are related to I HLOC, E HLOC, and C HLOC. The effects of these constructs varied across studies. Based on common patterns observed across the data, we offer the following suggestions for individuals designing medical behavioral interventions. First, in most situations, improving I HLOC will improve health outcomes for patients. I HLOC has been observed to improve patient health outcomes across many different contexts. Patients with higher I HLOC feel a greater sense of ownership over their health, which leads them to take more proactive measures and makes them more receptive to health behavioral interventions. The one exception to this guideline is situations where a patient's health condition is terminal and an individual has limited control over the outcome. In such situations, high I HLOC can be problematic and lead to higher stress in contexts where patients feel a loss of control [88]. In these situations, cultivating E HLOC or G HLOC or minimizing I HLOC through a discussion around acceptance of outcomes and a release of personal control may be beneficial [51]. Second, patients with high E HLOC should be further studied to determine the source of the E HLOC. A common misconception of patients with high E HLOC is that they are not as receptive to health messaging because they are not intrinsically motivated like individuals with high I HLOC. Individuals with high E HLOC can be just as receptive and proactive as individuals with high I HLOC, but the source of the external influence is an important factor to consider. Patients who perceive their physicians or similar caregivers as the source of the E HLOC will be more receptive to following suggestions provided by the perceived authority [3]. However, patients who identify their main E HLOC source as friends, family, or media may hold beliefs that are contradictory to positive health

messaging [52]. Determining the source of E HLOC is crucial to a better understanding of how those patients are likely to respond to health interventions. Third, patients with high C HLOC are less likely to follow prepreventative behaviors or be responsive to interventions. Across all studies, contexts, and situations surveyed for this review, patients with higher C HLOC were less prone to be proactive about their health. This likely stems from the idea common to individuals with demonstrable high C HLOC that actions are ultimately meaningless because everything happens through chance including health outcomes. To address these issues, health interventionalists should identify patients who exhibit high C HLOC and seek to educate them on the benefits of behavioral change. Demonstrations on the effectiveness of interventions can also help to decrease C HLOC and improve healthy patient behaviors.

Comparison to Prior Work

We explored the relationship between HLOC and health behavioral interventions in this paper. Previous studies have explored similar relationships related to individual-level constructs and responses to health behavioral interventions and health messaging. In this section, we explore some of the prior work in the literature and how it relates to individual-level beliefs regarding personal health.

HLOC and more generally LOC as a whole pertain to a high degree of conceptual similarities with the attributional notion of locus of cause, which refers to individuals' perception of their causation [93]. The concepts, however, differ in the way a specific behavior is observed: either from an outside observer's perspective or one observing his or her behavior [94]. The locus of cause is considered internal when someone can perform a task and tries to do so. In this case, failing the task is attributed to a lack of trying and effort of the person. In contrast, when someone does not have the required abilities for a specific task, the locus of cause appears to be external, and the related failure is assumed to be due to external circumstances [93,94]. Similarly, the theory of self-attribution bias highlights a situation in which individuals excessively attribute credit to their abilities for past successes, while assigning blame to others for failures [95-97]. Based on this concept, individuals attribute themselves to positive outcomes, linking them to their actions and efforts, while ascribing negative results to external factors such as bad luck [98]. In the context of LOC, individuals either perceive themselves to have the ability to control an outcome and try to do so or perceive themselves as not having the ability to control an outcome and therefore do not put any effort into achieving that. It can be concluded that the LOC can be simplified as a way of attributing the cause and outcomes of one's actions to oneself [94].

Studies have posited that older people and those with lower levels of education have higher levels of E HLOC beliefs over internal ones [40]. In addition to education, various studies have reported higher E HLOC in individuals with low sociodemographic status or negative health-related behavior such as smoking and drinking [1,99-104]. This association has been specifically investigated by Wallston and Wallston [105], which highlighted higher PO HLOC and higher C HLOC in individuals with less than 12 years of education. Conversely,

higher I HLOC can be seen in individuals with high socioeconomic status or positive health behavior such as regular exercising or staying on a healthy diet [53]. On the same stream of thoughts, the HLOC theory has been considered as a possible mediator between socioeconomic status and health outcomes [53,106].

Limitations and Strengths of the Systematic Review

The systematic review has inherent limitations. Observation of a field of research is dependent upon the scope and perception of the researchers cataloging the information. Analysis and interpretation of results are affected by subjective factors. In this paper, we have attempted to minimize individual biases and subjectivity by establishing inclusion and exclusion criteria and having sourcing and analysis of data conducted by 2 researchers (AY and SM) independently. The strengths of the systematic review are the ability to provide a comprehensive view of the state of research and the ability to generate guidelines that are related to current trends and recent phenomena in the field.

Future Work

This study focused on the literature surrounding HLOC constructs and health behavioral interventions. New health behavioral interventions related to the COVID-19 pandemic and the subsequent policies offer new avenues for the exploration of HLOC and individual health behaviors. Future studies could explore how social distancing, vaccinations, or quarantining is related to the idea of HLOC and the propensity of individuals to adhere to guidelines. In general, it is probable for individuals with higher PO HLOC to be influenced by other individuals' suggestions. However, individuals with higher I HLOC are also likely to get this influence from others depending on the situation. A relative example of this context is the nonforcing manipulation through nudges. Nudging entails organizing and modifying a decision-making scenario without restricting choice options or imposing force, in a way to alter someone's behavior in a predictive way [107]. For instance, a smoker with high I HLOC may decide to quit smoking due to a close friend telling him or her about the infertility risks caused by smoking. In this example, the individual's decision about willingly stopping an internal choice with the intention of maintaining his or her health is taking place because of someone else's nudge. In other words, this person believes in having self-control over this decision and is aware of having the choice of not quitting as well but is still influenced to do so. Many

examples can be applicable in this context, depending on the specific scenario and individuals' circumstances. We recommend future research to expand on the impact of "compelling versus noncompelling manipulation," as well as "effective nudges from friends or family versus strangers" on HLOC.

An exploration of the individual sources of E HLOC can also be beneficial. E HLOC is often interpreted in a similar manner to I HLOC. However, the sources of E HLOC are myriad and can vary from individual to individual. More studies that explore how changes to different HLOC constructs affect patient behaviors over time would support the relationships observed in many of the papers. One additional avenue of research is the implementation of health interventions with artificial intelligence. Research on this topic has already explored the possibility of integrating language models or similar generative agents with adaptive responses to improve patient health outcomes [108,109]. The guidelines suggested in this paper could also be tested in a longitudinal study where changes in HLOC construct strength could be measured against patient behaviors in response to behavioral interventions.

This study's methodology is a comprehensive literature review. Studies were filtered and analyzed based on relevance but there was no metric applied to rate the quality of the studies or to determine the suitability of the findings beyond the existence of data collection and analysis. Future studies could apply more stringent metrics toward inclusion of studies, such as by omitting studies that do not exceed a certain sample size or only including studies that meet a particular duration.

Conclusions

The study of HLOC and medical behavioral interventions is the study of how each individual responds to messaging and motivations regarding their health-related behaviors. An increased understanding of the constructs and relationships across these 2 ideas can lead to better-designed studies and interventions across different populations. Further exploration of this topic can focus on the importance of individual characteristics and the influence of context on each HLOC construct. The patterns and relationships frequently observed can help both academics and practitioners better design studies to explore questions related to improving health outcomes. Better-designed interventions can lead to individuals taking a more active role in managing their health, ultimately leading to improved health outcomes for everyone.

Abstract

Background: Blended therapy (BT) combines digital with face-to-face psychological interventions. BT may improve access to treatment, therapy uptake, and adherence. However, research is scarce on the structure of BT models.

Objective: We synthesized the literature to describe BT models used for the treatment of psychological disorders in adults. We investigated whether BT structure, content, and ratio affected treatment efficacy, uptake, and adherence. We also conducted meta-analyses to examine treatment efficacy in intervention-control dyads and associations between treatment outcomes versus BT model structure.

Methods: PsycINFO, CINAHL, Embase, ProQuest, and MEDLINE databases were searched. Eligibility criteria included articles published in English till March 2023 that described digital and face-to-face elements as part of an intervention plan for treating psychological disorders in adult patients. We developed a coding framework to characterize the BT interventions. A meta-analysis was conducted to calculate effect size (ES; Cohen *d* and 95% CIs) regarding pre- and posttreatment outcomes in depression and anxiety versus BT structure. The review was registered with PROSPERO and followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines.

Results: Searches identified 8436 articles, and data were extracted from 29 studies. BT interventions were analyzed and classified according to mode of interaction between digital and face-to-face components (*integrated* vs *sequential*), role of the components (*core* vs *supplementary*), component delivery (*alternate* vs *case-by-case*), and digital materials assignment mode (*standardized* vs *personalized*). Most BT interventions (n=24) used a cognitive behavioral therapy approach for anxiety or depression treatment. Mean rates of uptake (91%) and adherence (81%) were reported across individual studies. BT interventions were more effective or noninferior to treatment as usual, with large spread in the data and a moderate to large ES in the treatment of depression (n=9; Cohen *d*=–1.1, 95% CI –0.6 to –1.6, *P*<.001, and *z* score=–4.3). A small, nonsignificant ES was found for anxiety outcomes (n=5; Cohen *d*=–0.1, 95% CI –0.3 to 0.05, *P*=.17, and *z* score=–1.4). Higher ESs were found in blended interventions with supplementary design (depression: n=11, Cohen *d*=–0.75, 95% CI –0.56 to –0.95; anxiety: n=8, Cohen *d*=–0.9, 95% CI –0.6 to –1.2); fewer (≤6) face-to-face sessions (depression: n=9, Cohen *d*=–0.7, 95% CI –0.5 to –0.9; anxiety: n=7, Cohen *d*=–0.8, 95% CI –0.3 to –1.3); and a lower ratio (≤50%) of face-to-face versus digital sessions (depression: n=5, Cohen *d*=–0.8, 95% CI –0.6 to –1.1; anxiety: n=4, Cohen *d*=–0.8, 95% CI 0.006 to –1.6).

Conclusions: This study confirmed integrated BT models as feasible to deliver. We found BT to be effective in depression treatment, but anxiety treatment results were nonsignificant. Future studies assessing outcomes across different psychological disorders and therapeutic approaches are required.

Trial Registration: PROSPERO CRD42021258977; https://www.crd.york.ac.uk/prospero/display_record.php?RecordID=258977

Introduction

The Impact of Psychological Disorders

Psychological disorders affect approximately 1 billion people globally and were responsible for 10% of the prepandemic global burden of disease in 2019, with estimates of the mental health burden increasing [1]. Depression and anxiety disorders cost US $1 trillion per year globally [2]. Evidence-based, effective mental health care is available, but its provision does not reach everyone who needs it [2,3].

Digital (or Online) Therapy

Digital psychological therapy provides an opportunity to enhance patient access to psychological treatment [4,5] and is recommended by the World Health Organization as a cornerstone of "comprehensive, integrated and responsive mental health and social care services" [1]. Research regarding digital therapy has largely focused on internet-delivered cognitive behavioral therapy (CBT), demonstrating its efficacy and cost-effectiveness [6,7], particularly in the treatment of depression and anxiety [8-12]. Although uptake and adherence to digital therapy in the research setting have shown improvement [13], engagement is still low, particularly in routine mental health care [14-17]. In addition, research suggests stakeholder preference for face-to-face interventions [18,19]. A systematic review [20] reported on concerns raised by health professionals about the use of digital therapy alone, including perceived nonsuitability for patients due to symptom severity, lack of digital access and literacy, and perception of digital treatment as being less engaging than face-to-face treatments. This review indicated that blended psychological therapy (also called "blended therapy" or "blended care") was perceived as a midway option between digital and face-to-face therapy.

Blended Therapy

Blended therapy (BT) is a model of care that combines digital and face-to-face delivery of psychological therapy, integrating benefits from both modalities. Specifically, the face-to-face component is delivered by a mental health professional, such as a psychologist, while the digital component is patient driven [21-23]. Integrating digital therapy with face-to-face interventions in a blended model has the potential to save professionals' and patients' time (eg, transport to and from the clinic); increase the frequency of sessions; improve treatment uptake, adherence, and maintenance; and boost therapy effects [24-26].

A systematic review by Erbe et al [24] (N=44) found that BT may improve dropout rates and save health professionals' time compared with exclusively face-to-face interventions. Despite increasing evidence of the benefits of blended psychological therapy for patients [22,24], there is a lack of research specifically focused on "what, how, where, and when" BT is effective to inform future BT interventions [21,22,27]. The rationale for our systematic review emerges from the scarcity of data specifically focusing on BT processes including BT content and structure, which hinders scientific reproducibility of BT and impacts its implementation success.

Objectives of This Review

Seeking to address these gaps in BT literature, our systematic review and meta-analysis expands on the work of Erbe et al [24] and aims to (1) identify and describe the structure, content, and ratio of the face-to-face and digital components in BT interventions applied for the treatment of psychological disorders and (2) investigate whether there is an association among the structure, content, and ratio of blended components and the treatment efficacy of, uptake of, and adherence to BT.

Methods

Design

This review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) [28] guidelines and was registered with PROSPERO (CRD42021258977). The PRISMA checklist is provided in Multimedia Appendix 1.

Search Strategy

The PsycINFO, CINAHL, Embase, ProQuest, and MEDLINE databases were searched using keywords and Medical Subject Headings terms—"blended"; "online"; "face-to-face"; "treatment"; "therapy"; "care"; "mental disorders"; "psychological distress"; and "psychological disease"—for articles published in English (Multimedia Appendix 2). The search included articles published till May 2022, and an updated search was conducted in March 2023. Reference lists of the included studies were also manually searched.

Study Selection

Inclusion and Exclusion Criteria

Studies that described or applied an intervention where both digital and face-to-face elements were integrated or delivered sequentially were included. We included studies in which the participants were aged ≥18 years and diagnosed with a psychological disorder. Studies solely investigating populations

other than this target group (health care professionals, student cohorts, employees, etc) were excluded.

Comparators

The comparator or control groups included treatment as usual (pharmacological or psychological intervention and standard medical care), waitlist, or other interventions.

Data Abstracted

The primary focus was the intervention design, including descriptions of the structure, content, and ratio of the sessions used in each model. Secondary outcomes were (1) a psychological therapy approach used in the BT models, (2) patient groups for which BT was applied, (3) treatment efficacy, (4) uptake and adherence, (5) health service outcomes (eg, cost-effectiveness), (6) patients' acceptability of BT, (7) therapeutic alliance rates, and (8) barriers and facilitators reported.

Article Screening and Selection

All search results were uploaded into Covidence software [29]. Two reviewers (KFN-Z and JMS) screened the titles and abstracts independently. Full-text reviews based on the eligibility criteria were conducted by KFN-Z and PB or JMS.

Data Extraction

Data extraction was conducted by KFN-Z using a purpose-designed data extraction template. Extraction results were partially reviewed (6/29, 20%) by a second coder (JMS) to assess accuracy. To capture any missing data, the corresponding authors were e-mailed twice. Data extracted

included the following: (1) study characteristics—authors, year of publication, country, study setting, study aims, study type, sample size, control group (where applicable), therapy approach applied, primary or secondary psychological outcomes, and symptom assessment measures and participant characteristics such as age, sex, diagnosed psychological disorders, severity of symptoms, and individual study outcomes; (2) intervention characteristics—BT intervention design based on the structure, content, and ratio of BT sessions; number, periodicity, and duration (in minutes) of face-to-face and digital sessions; treatment length (in weeks); and (3) BT intervention outcomes—treatment efficacy, uptake, adherence, cost-effectiveness, acceptability, therapeutic alliance, and barriers and facilitators to BT reported.

Data Analysis

To address the objectives of this review, quantitative variables regarding the BT intervention structure were summarized and described. We used descriptive statistics (mean, percentages, and range) to describe quantitative data regarding study and participant characteristics; BT intervention uptake, adherence, and completion rates; treatment length (in weeks); number, time (in minutes), ratio, and periodicity of face-to-face and digital sessions; treatment acceptability; efficacy; and therapeutic alliance. Barriers to and facilitators of BT were qualitatively analyzed using a thematic analysis [30] approach. Qualitative data on BT structure and content were analyzed using a content analysis approach [31]. Categories and subcategories were summarized in a framework that builds on the concepts described by Erbe et al [24] (Textbox 1).

Textbox 1. Classification—blended model designs.

Interaction between face-to-face and digital components: *integrated* vs *sequential*

- *Integrated* models present both the digital and face-to-face components as collaborating parts within a therapy regimen, with both components delivered within the course of the intervention [24].

- *Sequential* models present the digital component delivered in entirety before or after face-to-face component delivery [24]. Sequential interventions start by delivering a "batch" of either face-to-face or digital sessions. Once the first "batch" is finished, the other component gets delivered.

    - *Stepped care* is considered a special type of *sequential* design in which the digital component is a step in the intervention sequence [24]. *Stepped care* interventions deliver the least intensive or costly treatment first and then progress to more intensive or aftercare treatment, if required. Hence, the "blend" in stepped care only effectuates after the first stage (digital) of treatment is complete and if patients require additional (face-to-face) care.

Role of the components in the intervention: *core* vs *supplementary*

- *Core* components are an indispensable part of the blended intervention, as they deliver new therapeutic elements (ie, modules complement each other).

- *Supplementary* components present content that has already been discussed during the intervention, that is, content of one component is supplementary to the content delivered in the main component. For example, face-to-face content may be supplemented by reinforcing exercises and homework on the web.

Delivery pattern of face-to-face or digital components: *alternate* vs *case by case*

- *Alternate* delivery is a configuration in which each session is delivered by alternating face-to-face or digital components in a fixed ratio. The distribution of components is preset for the entire intervention; this may feature as a 1:1 ratio, but other ratios (eg, 2 digital to1 face-to-face) of distribution are possible.

    - *Linear* delivery is specific to *sequential* designs in which all digital sessions are delivered in a row followed by all face-to-face sessions in a row, or vice versa.

- *Case-by-case* delivery is a configuration in which therapists assess and formulate a strategy for distributing the face-to-face or digital sessions adapted to the clients' or patients' needs on a case-by-case basis.

Digital content assignment: *personalized* vs *standardized*

- *Personalized* content assignment is not preset; therapists and patients decide which materials to complete, tailoring them to patients' needs.

- *Standardized* content assignment is largely preset; materials are delivered to all patients undergoing treatment with little or no changes to content.

Meta-Analyses

Although a meta-analysis was not originally included in the registered protocol, data collection and analysis processes indicated the relevance of meta-analyzing treatment outcomes for enhancing systematic review results. The meta-analysis was conducted using the Comprehensive Meta-Analysis program [32] to investigate treatment efficacy between the treatment and control dyads. A meta-analysis of *BT interventions only* was also conducted to investigate associations between BT structure and content and treatment outcomes. Pre-post outcome means and SD, alongside data on sample size at post–time points were included in the analysis. Standardized difference in means (Cohen d) and 95% CIs were used as effect size (ES) measures, and z values were used to test the null hypothesis (ES=0). We used a random effects meta-analysis due to expected heterogeneity. ES was set to negative numbers to show the change in symptoms (the lower the number, the higher the reduction in symptoms). Heterogeneity was assessed using Q test (Q), I-squared (I^2), Tau-squared (T^2), and Tau (T) scores.

Publication bias was assessed using funnel plots and the trim and fill method by Duval and Tweedie [33].

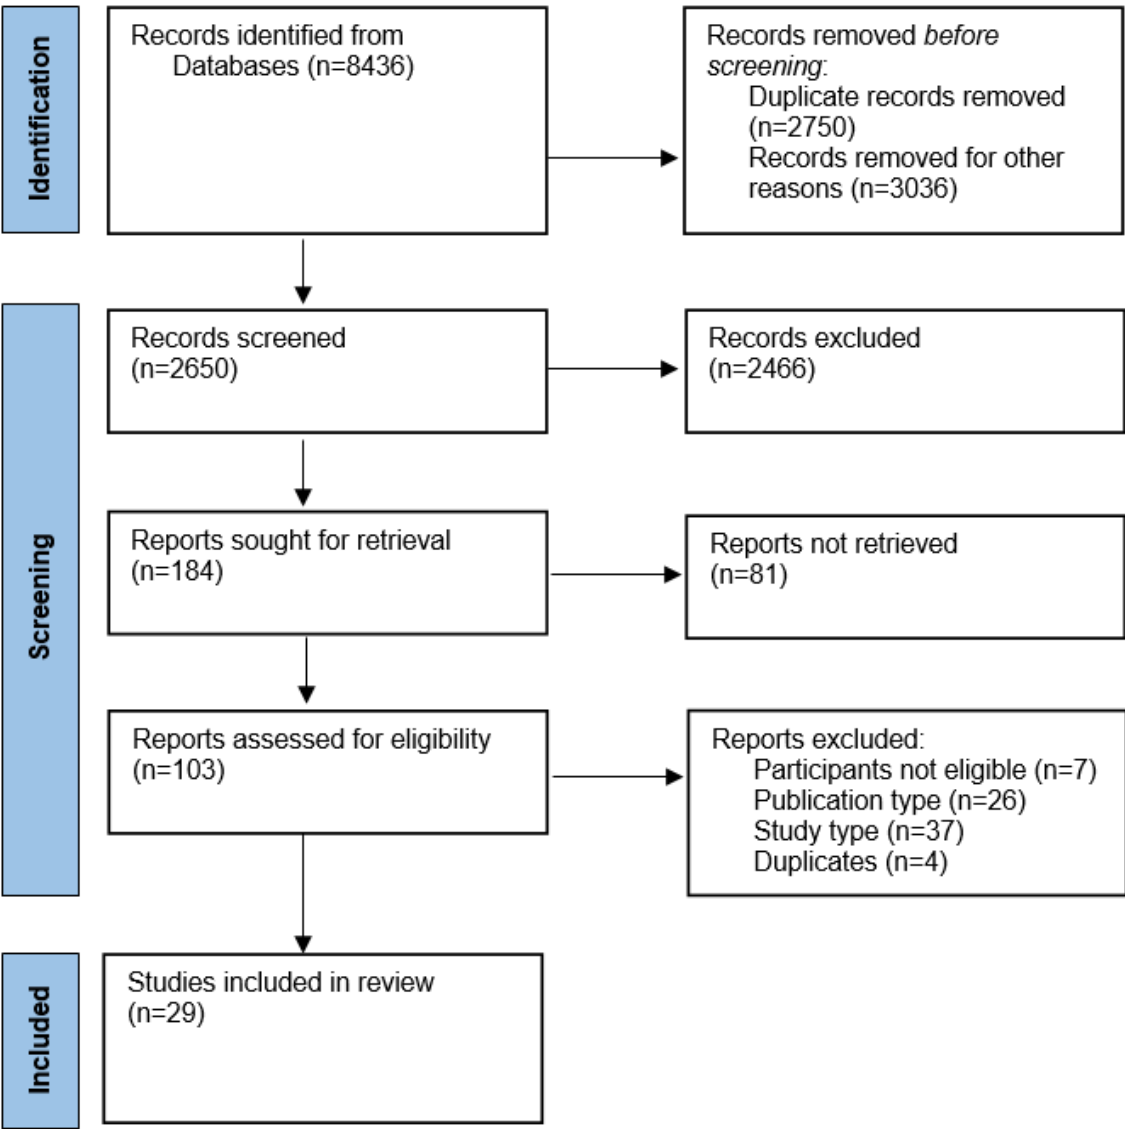
Risk of Bias and Quality Assessment

Two independent reviewers (KFN-Z and JMS) assessed the risk of bias using the National Institutes of Health Study Quality Assessment Tool (quantitative) [34], the Critical Appraisal Skills Programme qualitative checklist [35], or the Mixed Methods Appraisal Tool [36].

Results

Database Search Results

Database searches identified 2650 papers after removal of duplicates. Title and abstract screening resulted in 103 articles for full-text review. A total of 30 eligible articles were identified but only 29 were included in the review—one eligible paper was excluded as it reported the same data. The PRISMA diagram in Figure 1 [28] provides the details of the process.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram.


Quality Assessment

Quality assessment deemed most studies (n=22) to be of "good quality" as they addressed most of the quality assessment criteria applied. Seven articles [23,37-42] were classified to be of "fair" quality (Multimedia Appendix 3).

Study Characteristics

Of the 29 articles, 25 (86%) were prospective studies (randomized controlled trials [RCTs], n=14; feasibility or pilot, n=4; cohort or single arm, n=7); 3 (10%) were retrospective analyses of cohort studies; and 1 (3%) study used qualitative methods only. Most BT interventions (22/29, 76%) primarily treated depression, either exclusively (13/29, 45%) or in combination with anxiety treatment (9/29, 31%). Most studies (28/29, 96%) used a CBT approach, with 3 (10%) combining CBT and other approaches such as dialectical behavioral therapy and acceptance and commitment therapy (n=2) and motivational interviewing (n=1). Outcomes assessed were primarily symptom reduction (25/29, 86%), although 4 (14%) studies reported on the intervention process or working alliance outcomes as the primary focus (Table 1).

Collectively, the studies included a total of 12,322 (range 3-4448) patient participants, with 57.71% (n=7111) receiving BT interventions. Of the studies reporting on symptom reduction (28/29, 96%), all prescreened for clinical levels of psychological morbidity (Table 2).

Table 1. Characteristics of reviewed studies.

Study; country	Study setting	Study aims	Study design	Participants, N; BT[a] group, n; comparator, n	Therapy type; clinical outcomes
Askjer and Mathiasen [43], 2021 and Mathiasen et al [44],[b] 2022; Denmark	Specialized mental health care	Explore if WA[c] predicted treatment outcomes	Exploratory; secondary analysis from an RCT[d]	76; 38; 38; comparator: F2F[e] CBT[f]	CBT; WA, depressive symptoms
Berger et al [45], 2018; Germany	Routine outpatient psychotherapy practices	Investigate web-based treatment as adjunctive to depression treatment vs regular psychotherapy	Two-armed, pragmatic RCT	98; 51; 47; comparator: TAU[g]: psychotherapy	CBT; depressive symptoms
Bisson et al [46], 2022; United Kingdom	Primary and secondary mental health settings	Determine if CBT-TF[h] was noninferior to F2F CBT-TF for PTSD[i]	Pragmatic, multicenter, noninferiority RCT	196; 97; 99; comparator: F2F CBT-TF	CBT; severity of symptoms of PTSD
Cloitre et al [47], 2022; United States	Routine care in mental health outpatient clinics	Assess 2 ratios of F2F sessions to self-guided work on trauma-exposed veterans	Quasi-experiment with a noninferiority design	202; 202; NC[j]	Transdiagnostic, trauma-informed CBT; PTSD and depression
Duffy et al [48], 2020; England	Specialized mental health care service	Investigate iCBT[k] as a prequel for high-intensity depression and anxiety treatment	Uncontrolled feasibility design (open study)	123; 123; NC	CBT; anxiety and depression and work and social functioning
Etzelmueller et al [49], 2018; Germany	Routine care practice (clinics)	Evaluate patient experience of a blended iCBT service	Qualitative, semistructured interviews	15; 15; NC	CBT; ND[l] depression
Høifødt et al [37], 2013; Norway	University outpatient clinic	Evaluate effectiveness and acceptability of a guided web-based program for depression	RCT	106; 52; 54; comparator: delayed treatment, waitlist, or TAU	CBT; depression symptoms
Jacmon et al [42], 2009; Australia	Psychology private practice	Assess cost-effectiveness and convenience of partially digital depression treatment	Single-arm, pretest-posttest study	9; 9; NC	CBT; depression levels
Kemmeren et al [50], 2019; France, Germany, Poland, and Netherlands	Multisetting (specialized mental health and routine primary care)	Examine use of and engagement to blended CBT for depression	Exploratory, secondary study from RCT	231; 231; NC	CBT; ND depression
Kenter et al [51], 2013; Netherlands	Mental health care center; routine care	Report on the uptake of digital treatment, on the profile of patients who prefer digital therapy, and on symptom reduction vs waitlist	Observational study (electronic patient database)	104; 55; 49; comparator: waitlist	PST[m]; ND depression, anxiety, and burnout
Kenter et al [52], 2015; Netherlands	Mental health service	Compare the effects and costs between blended and F2F treatments	Naturalistic study: examined records of patients	4448; 168; 4280; comparator: TAU: F2F	CBT; ND depression and anxiety
Kok et al [38], 2014; Netherlands	Outpatient clinics	Assess clinical effectiveness of internet-based guided self-help vs waitlist	RCT	212; 105; 107; comparator: waitlist	Psychotherapy; phobia and avoidance behavior
Kooistra et al [23], 2016; Netherlands	Outpatient specialized mental health care center	Develop and evaluate a structured, blended CBT protocol for patients with depression	Focus-groups and single-arm, pre-post	30; 9; NC (12 patients)	CBT; ND depression

Study; country	Study setting	Study aims	Study design	Participants, N; BT[a] group, n; comparator, n	Therapy type; clinical outcomes
Kooistra et al [26], 2019; Netherlands	Specialized mental health care (outpatient services)	Compare costs and effectiveness of blended vs standard CBT for depression	Pilot RCT with 2 parallel groups	102; 53; 49; comparator: CBT-F2F	CBT; self-reported depression severity
Kooistra et al [53], 2020; Netherlands	Outpatient specialized mental health clinics	Investigate WA in bCBT[n] for depression	Exploratory, secondary study from pilot RCT	92; 47; 45; comparator: regular CBT	CBT; ND depression levels
Lungu et al [54], 2020; United States	Employer program	Evaluate the effectiveness of a video-based CBT and internet intervention	Retrospective cohort study	385; 385; NC	CBT+UTP[o], ACT[p], and DBT[q]; ND depression and anxiety
Ly et al [55], 2015; Sweden	Clinical setting	Evaluate a blended treatment for depression	Noninferiority RCT	93; 46; 47; comparator: F2F BA[r]	BA; depression
Månsson et al [39], 2013; Sweden	Clinical setting	Explore clinical outcomes and user experiences of internet-delivered therapy. To develop or test a bCBT model	Mixed methods, case series, pilot study (prepost re BT testing)	23; 15; NC (patients, n=15; therapists, n=8)	CBT; ND anxiety and depression
Månsson et al [40], 2017; Sweden	Outpatient psychiatric clinic	Evaluate an internet-based support as adjunct to F2F CBT	Feasibility study	54; 45; NC (patients, n=45; therapists, n=9)	CBT; ND anxiety and depression symptoms
Mol et al [56], 2018; Netherlands	Outpatient clinic	Explore therapist behaviors; adherence; and patient outcome in digital therapy	Observational study	64; 45; NC (patients, n=45; therapists, n=19)	CBT; ND depression levels
Nakao et al [57], 2018; Japan	Outpatient medical institutions	Evaluate effectiveness of web-based bCBT in reducing therapist time in patients with depression	Single-blinded RCT	40; 20; 20; comparator: waitlist + pharmacological treatment	CBT; depression symptoms
Romijn et al [41], 2021 and Romijn et al [58];[b] Netherlands	Outpatient specialized mental health care centers	Explore therapist fidelity to bCBT protocols for anxiety disorders	Mixed methods (derived from a larger RCT)	114; 52; 62; comparator: CBT F2F	CBT; anxiety symptoms
Tarp et al [59], 2022; Denmark	Public municipal outpatient alcohol clinics	Describe development and testing of a digital program; participant experiences; and usability of BT	Feasibility and pilot study	32; 22; NC (development: 7 therapists+3 patients)	CBT + motivational interviewing; —[s] (intervention system usability)
Thase et al [60], 2018; United States	Department of psychiatry of medical schools	Evaluate the efficacy of computer and therapist-assisted CBT vs standard CBT	Noninferiority RCT	154; 77; 77; comparator: CBT F2F	CBT; depression symptom severity
van de Wal et al [61], 2017; Netherlands	Cancer hospitals: academic, regional, and outpatient	Investigate the efficacy of BT for FCR[t] in cancer survivors	RCT: 2-arm, parallel group, longitudinal	88; 45; 43; comparator: TAU (any)	CBT; FCR severity
Vernmark et al [62], 2019; Sweden	Mental health care centers	Explore patient- and therapist-rated WA in bCBT and WA as a predictor for change	Exploratory secondary study from RCTs	151; 75; NC	CBT; depression levels
Witlox et al [63], 2021; Netherlands	Mental health service at general practices	Examine the effectiveness of blended ACT for older adults with anxiety	RCT (single-blinded)	314; 150; 164; comparator: TAU (FTF CBT)	ACT; anxiety severity

Study; country	Study setting	Study aims	Study design	Participants, N; BT[a] group, n; comparator, n	Therapy type; clinical outcomes
Wu et al [64], 2021; United States	Employer mental health program clinical services	Evaluate the outcomes of a blended care coaching program for anxiety and depression	Retrospective cohort analysis	1496; 1496; NC	CBT-based + CBT, DBT, and ACT; anxiety and depression symptoms
Wu et al [65], 2021; United States	Employer mental health program clinical services	Examine the effectiveness and the impact of bCBT on anxiety and depression	Retrospective cohort analysis	3401; 3401; NC	CBT+DBT and ACT; anxiety and depression symptoms

[a]BT: blended therapy.

[b]Linked study.

[c]WA: working alliance.

[d]RCT: randomized controlled trial.

[e]F2F: face to face.

[f]CBT: cognitive behavioral therapy.

[g]TAU: treatment as usual.

[h]iCBT-TF: internet-guided cognitive behavioral therapy with trauma focus.

[i]PTSD: posttraumatic stress disorder.

[j]NC: no comparator.

[k]iCBT: internet-delivered cognitive behavioral therapy.

[l]ND: not disclosed.

[m]PST: problem-solving therapy.

[n]bCBT: blended cognitive behavioral therapy.

[o]UTP: unified transdiagnostic protocol.

[p]ACT: acceptance and commitment therapy.

[q]DBT: dialectical behavioral therapy.

[r]BA: behavioral activation.

[s]Not applicable.

[t]FCR: fear of cancer recurrence.

Primary outcomes of individual studies included efficacy or effectiveness (14/29, 48%) [37-39,45,46,48,54,55,57, 60,61,63-65]; working alliance (3/29, 10%) [43,53,62]; usability and uptake (3/29, 10%) [50,51,59]; feasibility (2/29, 7%) [23,42]; and patient or therapist (4/29, 14%) [40,41,49,56] experience. One (4%) study [47] explored multiple primary outcomes of therapeutic alliance, compliance, and symptom reduction, and 2 (7%) studies [26,52] reported dual outcomes of efficacy and cost.

Classification of BT Models

On the basis of the models defined by Erbe et al [24], the majority (26/29, 90%) of the studies reported an *integrated* intervention design, where new therapeutic content was delivered either (1) across both the face-to-face and digital modalities (*core*; n=14) or (2) primarily using one modality (usually the face-to-face component) with additional content delivered as *supplementary material* (n=12). Integrated interventions were the most common designs for addressing depression (n=14) and depression and or anxiety (n=8). Three studies were classified as *sequential* designs and described a *core* role for both face-to-face and digital components. One sequential model was delivered as *stepped care* in which most patients received digital therapy only.

BT delivery was further differentiated based on whether both components were delivered in a preset, *alternate* format or a tailored, *case-by-case* arrangement. Most integrated interventions (17/26, 65%) used an *alternate* delivery format. Therapeutic content within integrated and alternate designs had either *core* (9/17, 53%) or *supplementary* (8/17, 47%) roles.

In 19 (65%) studies, patients engaged with digital content following a *standardized* program with minimal tailoring of the materials presented. In contrast, 10 (35%) studies described a more *personalized* manner of assigning or interacting with digital content where the therapist and patient have more autonomy to choose, change, or create digital content according to individual need. An overview of model classifications is presented in Table 3.

Table 3. Blended therapy model classification per study.

[a]F2F: face to face.

[b]Sequential models present a *linear* pattern of delivery.

Structure, Content, and Ratio of Sessions in BT Models

Overview

Within the *integrated* model, 81% (21/26) of studies reported commencing BT with the face-to-face component. Five *integrated* interventions began treatment with the digital component; of those, 4 [38,42,47,51] used the digital component as the intervention "anchor"—that is, the digital component led the therapeutic process. One [48] *sequential* intervention (stepped care) used the digital modality as a prequel for high-intensity face-to-face treatment based on patient symptom severity. Digital sessions were mostly delivered via website platforms with individualized access. Overall, digital session components presented CBT-based content and followed the frameworks used in face-to-face settings. Digital content was typically asynchronous. Intervention structure and content is summarized in Multimedia Appendix 4.

Face-to-Face Versus Digital Sessions Distribution in BT Models

In total, 26 (87%) studies reported the number of face-to-face sessions, which ranged from 3 to 21 sessions (mean 7, SD 4.2). Of those reporting the number of face-to-face sessions, 24 (92%) used an *integrated* intervention design. Mean face-to-face session duration across studies was 49 minutes (SD 11.7, range 27-65 min/session). Periodicity of sessions were reported by 24 studies, with most of those studies describing face-to-face sessions as delivered weekly (12/24, 50%) [23,26,37,39,41,42,45,49,53,57,59,64].

A total of 20 (69%) studies reported on the number of digital sessions (mean 8, SD 3, range 4-14 sessions)—of those studies, 18 (90%) presented an *integrated* design. Although the mean time for digital sessions was largely undefined and unreported, 12 (41%) studies [37,40,45,47,50,52,57,60-63,65] reported that digital modules were typically developed to range between 15 and 60 minutes. Eight (28%) studies [42,45,46,48,57,59,60,64] allowed patients to complete modules at their own pace; 13 (45%) studies [39,40,42,45,48,49,54-56,60,61,64,65] reported digital sessions' periodicity to be flexible; weekly (14/29, 48%) [23,26,37,38,41,46,47,51-53,57,59,62,63] or fortnightly (2/29, 7%) [43,50] completion was also reported.

Face-to-Face and Digital Ratio

In total, 16 (55%) studies [23,26,37,41,42,45-50,53,56,60,62,65] reported the ratio of face-to-face and digital sessions. Most of those studies had an *integrated* design (14/16, 88%) and typically delivered sessions at a 1:1 ratio (1 face-to-face to 1 digital).

Treatment Length

The BT mean length of treatment was 12 (SD 5.1, range 6-26) weeks; however, this was unreported for 5 studies [38,49,51,52,63] (Table 4).

[i]any: anytime (ie, no pattern from the outset).

Outcomes of BT Interventions

Treatment Uptake

In total, 25 (86%) studies reported on BT uptake mean rates (mean 91%, SD 10.2%, range 60%-100%). Of those, 24 (96%) studies [23,26,37-43,45-48,50,51,53,55-57,59-63] reported a mean uptake of 92% (SD 8.2%, range 73%-100%) and 1 (4%) study [49] reported a lower uptake (60%). A total of 14 (48%) studies reported on treatment completion rates, with an average of 61% (SD 29.4%, range 11.5%-100%) of patients completing treatment.

Treatment Adherence

Our review considered adherence as completing a minimum number of sessions determined by each study. However, adherence criteria differed across studies and there was a lack of data to confirm whether session structure or ratio influenced adherence to intervention. A total of 23 (279%) studies reported on BT adherence rates, with a mean of 81% (SD 11.8%). In total, 20 (69%) *integrated* studies reported on BT adherence (mean 83%, SD 11%, range 62%-100%). In contrast, all *sequential* studies (3/29, 10%) had a comparatively lower mean adherence (64%, SD 1.8). Dropout rates were reported in 25 (86%) studies, with 24 of those reporting <40% dropout rates (mean 18.5%, SD 17.2%, range 0%-38%). The intervention with the lowest adherence rate (16%) and highest dropout rate (84%) [38] had a *sequential* design.

Regarding the role of components within BT, interventions with *supplementary* designs presented higher adherence (mean 88%, SD 9%, range 72.5%-100%) than *core* designs (mean 76%, SD 11.7%, range 16%-100%). Details on the uptake and adherence reported per study are available in Multimedia Appendix 5.

XSL•FO
RenderX

Health Service Outcomes

Four (14%) studies reported on the impact of BT on therapist time: 2 studies [42,55] found a decrease, one study reported an increase [52], and one found no change [26] in the time needed to deliver therapy. Findings related to efficacy and costs were mixed, with one study [52] suggesting that BT was not cost-effective compared with face-to-face therapy, while another study [55] highlighted reduced costs due to the potential of BT for treating twice as many patients as compared with face-to-face treatment.

Patient Satisfaction and Working Alliance

Eight (28%) studies [23,37,38,43,45,46,49,63] reported on patient satisfaction with BT treatment—criteria for determining patient satisfaction were heterogeneous, but all studies reported it as "high." Four (14%) studies [43,47,53,62] reported on working alliance and reported it as "high." Two (7%) studies [43,62] suggested that the therapist-rated working alliance predicted treatment outcomes and that this may be specific to BT.

Barriers to and Facilitators of Intervention Uptake and Engagement

Potential barriers to intervention uptake reported [23,46,49,51,59] included *a lack of understanding about the intervention* and *digital challenges*. Reported [42,51,59] facilitators to intervention uptake included *convenience and flexibility of the digital component, anonymity,* and *autonomy enabled by the BT design.* Barriers to intervention engagement identified [37,38,42,45,46,48-50,56,61] included *the good enough effect* (ie, when patients drop out during the initial stages of the intervention arguing they "feel better" and "no longer need therapy" [66]), *being left unchecked, reduced therapy support* (ie, lack of therapist follow-up regarding digital activities), and *digital challenges*. Facilitators of intervention engagement included *experience in the use of technology, a program tailored to patient-specific needs, patient-therapist digital communication between sessions,* and *a patient-therapist working alliance fostered throughout the intervention* [37-39,43,45-50,52,57,64,65].

Treatment Efficacy

We conducted a meta-analysis to examine differences in treatment outcomes. There were only a sufficient number of studies to meta-analyze depression and anxiety outcomes.

Data pooled from 9 RCT studies demonstrated a moderate to large, significant improvement in depression symptoms (Cohen $d=-1.1$, 95% CI –0.6 to –1.6, $P<.001$). However, comparing treatment outcomes for anxiety interventions with controls (n=5), there was no significant improvement across studies (Cohen $d=-0.1$, 95% CI –0.3 to 0.05, $P=.17$). Between-study heterogeneity was high and did not change after conducting publication bias assessment using the funnel plot trim and fill method, both in the depression ($Q=90.3$; $P<.001$; $I^2=91.1$; $T^2=0.1$; $T=0.7$) and anxiety groups ($Q=1.1$; $P=.17$; $I^2=0$; $T^2=0$; $T=0$). We noted that estimates of heterogeneity are impacted by the very small number of studies analyzed (<10 studies).

Meta-analysis was also conducted to examine associations between depression and anxiety scores on various scales and BT structure. For depression, mixed-effect analysis suggested higher effects sizes for interventions where the therapeutic content was delivered primarily face to face with digital content *supplementing* the face-to-face content (n=11; Cohen $d=-0.75$, 95% CI –0.56 to –0.95) compared with digital therapeutic content delivered as *core* (n=10; Cohen $d=-0.5$, 95% CI –0.4 to –0.7)—however, differences were not statistically significant ($P<.08$). Similar associations were found for anxiety, with higher ESs for *supplementary* (n=8; Cohen $d=-0.9$, 95% CI –0.6 to –1.2) compared with *core* structure (n=5; Cohen $d=-0.6$, 95% CI –0.22 to –0.98). Mixed-effect analysis also indicated statistically significantly ($P<.001$) higher ESs for interventions with ≤6 face-to-face sessions both for depression (n=9; Cohen $d=-0.7$, 95% CI –0.5 to –0.9) and anxiety (n=7; Cohen $d=-0.8$, 95% CI –0.3 to –1.3) compared with interventions with >6 face-to-face sessions for depression (n=11; Cohen $d=-0.6$, 95% CI –0.4 to –0.8) and anxiety (n=5; Cohen $d=-0.7$, 95% CI –0.4 to –1). Similarly, interventions with >50% of sessions delivered digitally had higher ESs ($P<.001$) both for depression (n=5; Cohen $d=-0.8$, 95% CI –0.6 to –1.1) and anxiety (n=4; Cohen $d=-0.8$, 95% CI 0.006 to –1.6) compared with interventions where >50% sessions were delivered face to face, both for depression (n=9; Cohen $d=-0.5$, 95% CI –0.3 to –0.7) and anxiety (n=3; Cohen $d=-0.58$, 95% CI –0.3 to –0.9). Data regarding meta-analyses are available in Multimedia Appendix 6.

Discussion

Overview

We reviewed blended psychological therapy models and classified them according to their structure, content, and ratio of face-to-face and digital sessions. Most BT interventions were CBT-based and addressed depression—for which models with *integrated* and s*upplementary* designs resulted in improved treatment efficacy. Interventions typically used an *integrated* design with the face-to-face component "anchoring" the intervention. Essential, therapeutic content across treatment designs was typically delivered as both face to face and digital (ie, a *core* design) and in an *alternate* pattern. However, several studies used digital components to *supplement* therapeutic content delivered face to face. Most interventions also relied on *standardized* digital content rather than content tailored to individual patients.

Our study confirms that BT leads to improved overall patient uptake (mean 91%) and adherence (mean 81%), contrasting with the lower uptake and adherence rates previously reported for digital therapy alone. For example, an observational cohort study analyzed clinical data from 15,882 patients assessed for digital-only treatment of various psychological disorders, reporting 22% uptake and 68% adherence rates [14]. In addition, review studies on digital therapy for depression and anxiety symptoms [16] and for depression alone [17] indicated mean uptake rates of 56% (range 21%-88%) and 88% (range 42%-100%), respectively, as well as mean adherence rates of 18% (range 7%-42%) and 60% (range 14%-93%), respectively.

These contrasting findings suggest a potential connection between improved engagement with digital components when these are integrated into an intervention with a more prominent role of the therapist, that is, in a blended format.

Meta-Analysis Results: Treatment Versus Control Dyads

Across CBT-based RCTs, symptom reduction was observed for both depression and anxiety—although the reduction in anxiety symptoms was not substantial. Our result contrasts with overall findings on effectiveness of digital-only interventions exclusively addressing anxiety [67], which indicate effective outcomes. However, a subgroup analysis in that study confirmed similar ESs of both digital and face-to-face anxiety treatments. The lack of significance of our results might reflect the fact that only 1 included study addressed anxiety as a primary intervention outcome, while the other 4 interventions primarily targeted posttraumatic stress disorder, Fear of Cancer Recurrence, or depression. This suggests that transdiagnostic interventions may not be sufficient for treating anxiety—even with therapist guidance.

Meta-Analysis Results: BT Treatment Outcomes Versus the BT Model

Our analysis indicated that interventions that delivered face-to-face sessions for depression and anxiety in a lower ratio (≤50%) and in a lower number (≤6) had higher, statistically significant overall ESs. As the ratio of face-to-face sessions was similar in *core* or *supplementary* models, it is unclear what role digital sessions played in the delivery of therapeutic content compared with simply supplementing face-to-face sessions. Moreover, ESs for depression and anxiety in *supplementary* designs (Cohen d=–0.75 and Cohen d=–0.87, respectively) were higher than those in *core* designs (Cohen d=–0.53 and Cohen d=–0.6, respectively). Those findings suggest that therapeutic content may achieve better results when introduced by therapists and reinforced digitally—a characteristic of *supplementary* models, in which the digital component extends or reinforces face-to-face content. In addition, supplementary models might provide a more seamless transition between face-to-face and digital content as therapists can identify and discuss challenging topics with patients before they go on the web, what could result in enhanced patient engagement, adherence and treatment results. This argument is supported by studies on participants' preference for BT models that enable greater therapist-patient interaction [21,50,68,69]. In addition, participants' views reported across our study also suggest that improved digital access and support from therapist facilitated BT engagement.

The higher ESs of *supplementary* versus *core* designs may also reflect the therapists' preference for face-to-face contact. This argument finds support in studies on health professionals' preferences regarding face-to-face versus digital delivery, both in blended [68,70] and digital-only [20,71] interventions. Those studies suggest that, despite recognizing the advantages of digital interventions, professionals perceive face-to-face delivery as more attractive than digital delivery, which could influence the endorsement of digital therapy delivery as a supplement. This suggests that therapists might feel more comfortable *engaging with* and *promoting* the digital arm in a *supplementary* way.

In addition, it is possible that both therapists and patients expect the "bulk" of the therapeutic content to be delivered face to face in blended interventions, explaining why we found BT *core* models to be less efficacious than *supplementary*. Therapy expectations would also help explain the contrast of our results with research [67,72] on using digital therapy alone for depression and anxiety, which found digital interventions to be as good as or better than face-to-face interventions. Perhaps because patients engaging in digital-only treatment would *expect* therapeutic content to be delivered digitally, as there is no face-to-face option, they fare better on the digital component than they would in a BT model.

Optimizing Effectiveness, Time, and Resources in BT Treatment

One aim of BT interventions [24] is to enable better balance between treatment effects; patient engagement; treatment time; and the use of resources for both patients and therapists. BT models with *integrated, core, alternate,* and *standardized* designs allow for optimized treatment delivery. However, the results of our meta-analysis suggest that *supplementary* BT models are more effective. Considering these arguments, perhaps a midway alternative would be to promote a more digitally focused role of the therapist in a blended design. Following this idea, therapists would support and encourage patients to complete digital content as an enhancing adjunct to face-to-face contact—and not only as an "add-on" feature. A more digitally focused role of the therapist might promote increased patient engagement, enabling improved outcomes with lower doses of face-to-face treatment.

Study Limitations

We optimized database search terms with the assistance of a librarian; however, it is possible that eligible studies were not included in this review. In addition, the analysis did not assess the potential impact of heterogeneities found among selected studies on the variables analyzed, for example, whether different populations, settings, or therapeutic approach applied in the interventions might affect uptake or adherence or even the way blended sessions are delivered. Furthermore, the small number of studies included in our meta-analysis impacted the breadth of our results. In addition, there were limited studies describing intervention structure and content of both face-to-face and digital components in detail. Despite having contacted authors regarding missing data, several gaps remained on key variables investigated (eg, number and time of face-to-face and digital sessions, adherence parameters, and acceptability of intervention), which impacted the depth of analysis. Hence, the outcomes reported in this study should be interpreted with caution.

Recommendations

Despite growing evidence regarding BT efficacy, the lack of clearer, detailed data reporting on its structure and content poses challenges to scientific reproducibility of BT, possibly affecting its implementation success. Details related to the number, time, and distribution of sessions; specific content of both digital and face-to-face sessions, as well as the role, relevance, and influence of the digital component within the therapy plan;

feedback on face-to-face and digital session content; and the use of assigned digital materials as well as the perception of its usefulness from the perspective of both therapists and patients are examples of useful data that are not adequately reported. We recommend that future studies include a more detailed reporting of methodology, particularly regarding the structure and content of sessions.

Conclusions

This systematic review examined blended models for the treatment of psychological disorders to identify what aspects of BT underpin effective treatment and improved engagement. Evidence suggests that implementing an integrated model is feasible in the treatment of psychological disorders. BT was reported as being either more effective or noninferior to face-to-face treatment, particularly when applied to the treatment

of anxiety and depression. BT interventions studied reported high mean uptake and adherence rates, showing promise in improving engagement to treatment. Higher ESs were found for depression and anxiety outcomes in interventions with *integrated*, *supplementary* models; with a lower number of face-to-face sessions; and with a lower ratio of face-to-face versus digital sessions, suggesting that combining a more digitally focused therapist role with fewer face-to-face sessions can be effective and increase access to treatment.

To support improved reporting, we have developed a taxonomy for BT models based on the key themes identified in this review regarding model structure and components. Future studies detailing the structure and content of BT models may help identify suitable models for the treatment of different psychological disorders.

Authors' Contributions

KFN-Z, HLS, PB, LB, and JMS were responsible for conceptualization and protocol development. The literature search was conducted by KFN-Z and JMS, and study selection was carried out by KFN-Z, JMS, and PB. Data analysis was performed by KFN-Z and JMS. The initial draft was prepared by KFN-Z and JMS, and all authors (KFN-Z, HS, PB, LB, and JMS) participated in reviewing and editing the draft.

Abstract

Background: Depression is a prevalent global mental health disorder with substantial individual and societal impact. Natural language processing (NLP), a branch of artificial intelligence, offers the potential for improving depression screening by extracting meaningful information from textual data, but there are challenges and ethical considerations.

Objective: This literature review aims to explore existing NLP methods for detecting depression, discuss successes and limitations, address ethical concerns, and highlight potential biases.

Methods: A literature search was conducted using Semantic Scholar, PubMed, and Google Scholar to identify studies on depression screening using NLP. Keywords included "depression screening," "depression detection," and "natural language processing." Studies were included if they discussed the application of NLP techniques for depression screening or detection. Studies were screened and selected for relevance, with data extracted and synthesized to identify common themes and gaps in the literature.

Results: NLP techniques, including sentiment analysis, linguistic markers, and deep learning models, offer practical tools for depression screening. Supervised and unsupervised machine learning models and large language models like transformers have demonstrated high accuracy in a variety of application domains. However, ethical concerns related to privacy, bias, interpretability, and lack of regulations to protect individuals arise. Furthermore, cultural and multilingual perspectives highlight the need for culturally sensitive models.

Conclusions: NLP presents opportunities to enhance depression detection, but considerable challenges persist. Ethical concerns must be addressed, governance guidance is needed to mitigate risks, and cross-cultural perspectives must be integrated. Future directions include improving interpretability, personalization, and increased collaboration with domain experts, such as data scientists and machine learning engineers. NLP's potential to enhance mental health care remains promising, depending on overcoming obstacles and continuing innovation.

Introduction

Background

Depression is a prevalent mental health disorder affecting 280 million people worldwide and accounts for more than 47 million disability-adjusted life-years [1,2]. Characterized by symptoms such as persistent feelings of sadness, diminished interest, and impaired daily functioning, depression can severely impact an individual's quality of life [3] and is associated with suicide and premature mortality from comorbidities [4]. However, traditional methods of diagnosing and screening for depression primarily rely on subjective clinical assessments, which can be time-consuming and susceptible to the inherent biases of health care professionals [5].

In recent years, researchers have explored advanced technologies like natural language processing (NLP) to address the limitations of traditional methods in detecting and understanding depression [6,7]. NLP, a field of artificial intelligence (AI), enables machines to automatically analyze and extract valuable insights from textual data [8]. This technology shows immense potential in transforming how we identify and manage mental health disorders. By leveraging the vast amount of digital information generated daily, including social media posts, electronic health records, and web-based forums, NLP can assist in detecting subtle linguistic cues and patterns that may indicate depressive symptoms [9].

The integration of NLP in detecting depression offers multiple advantages. Not only does it promise improved accuracy and efficiency, but it also brings the advantage of scalability. By analyzing large amounts of textual data on a population level, NLP enables a comprehensive understanding of depression, potentially leading to early detection and intervention. In addition, NLP-based approaches might contribute to the reduction of the stigma surrounding mental health [10] by providing a more objective and nonjudgmental assessment of individuals' emotional well-being. This shows that NLP can help create a more supportive environment for those dealing with depression.

However, while NLP shows significant potential for mental health care, we must also recognize the challenges and ethical considerations that come with its implementation. Issues like privacy concerns, data security, and potential biases demand critical analysis. In this literature review, we aim to explore the current state of research on using NLP techniques for detecting depression. We will discuss the successes and limitations of this rapidly evolving technology, along with its future scenarios in improving mental health diagnosis and care. By shedding light on this rapidly evolving field, our goal is to foster informed discussions and encourage further advancements that will ultimately benefit individuals living with depression while promoting more effective mental health screening systems.

This Review

This literature review aimed to provide a broad overview of the potential and challenges of using NLP for depression screening by extracting valuable information from textual data. While we discuss various NLP techniques and their applications, the focus is on presenting a comprehensive view of the field rather than delving into technical details. Our goal is to offer readers a high-level understanding of the opportunities and limitations presented by NLP in detecting depression while also highlighting ethical considerations and future directions. By providing this broad perspective, we hope to foster further exploration and innovation in applying NLP to enhance mental health support systems.

Methods

Literature Search Strategy

A comprehensive literature search was conducted using 3 web-based databases—Semantic Scholar, PubMed, and Google Scholar. These databases were chosen for their extensive coverage of research in the fields of computer science, health care, and AI. The search aimed to identify studies focusing on depression screening using NLP techniques.

The search strategy involved using a combination of relevant keywords and Boolean operators. The following search terms were used: "depression screening" OR "depression detection" AND "natural language processing" OR "NLP." This search query was tailored to each database to ensure compatibility with their specific search functions.

The inclusion criteria for selecting studies were broad, encompassing a range of study designs, including original research articles, review papers, and technical reports. Studies were included if they discussed the application of NLP techniques for depression screening or detection, addressed the successes and limitations of such approaches, or explored ethical considerations and potential biases. No restrictions were placed on the publication date to ensure a comprehensive overview of the historical development and current state of the field.

Study Selection and Data Extraction

The initial search yielded many results. To manage the screening process efficiently, the titles and abstracts of the retrieved studies were imported into reference management software (Zotero). Duplicates were removed, and the remaining studies were screened.

During the initial screening, studies were assessed based on their relevance to the research topic. Studies that did not specifically address depression screening or detection using NLP were excluded. Studies focusing solely on other mental health disorders without a clear connection to depression were also excluded.

In the study selection process, 2 independent reviewers initially screened titles and abstracts against the predefined inclusion and exclusion criteria. Discrepancies between the reviewers were identified and resolved through a consensus meeting, where both reviewers discussed their decisions and clarified any misunderstandings related to the criteria. If consensus could not be reached, a third independent reviewer was consulted to provide an additional perspective and make the final decision. The full texts of the remaining studies were then reviewed in detail by the 2 independent reviewers, following the same process described for the title and abstract screening. Studies

were included in the final selection if they provided substantial contributions to the understanding and application of NLP in depression screening. This included discussions on NLP techniques, depression detection methods, classification models, datasets, ethical considerations, cross-cultural perspectives, or future directions in the field.

Data extraction was performed concurrently with the full-text review. Relevant information from each study was extracted and organized into a structured format. This included details, such as the study's main objectives, methodologies used, key findings, limitations, and potential future directions suggested by the authors. The extracted data were then synthesized and analyzed to identify common themes and gaps in the literature, forming the basis for the discussion section of this literature review.

This review aimed to provide an up-to-date overview of the field by following the literature search strategy. It highlights the potential and challenges of using NLP for depression screening, along with ethical considerations and future research directions.

Task Definition and Scope

Overview

The primary task addressed in this literature review is the detection or screening of depression using NLP techniques. This task involves the automatic analysis of textual data, such as social media posts, electronic health records, or clinical interview transcripts, to identify indicators of depressive symptoms and provide a classification or assessment of an individual's mental health status.

The scope of this review encompasses various subtasks and aspects related to depression detection, including the following: (1) classification, (2) severity classification, (3) depressive symptoms identification, (4) risk assessment, and (5) personalized depression analysis.

Classification

This involves categorizing textual data into depressive or nondepressive states, often using supervised machine-learning algorithms. The goal is to accurately distinguish between individuals experiencing depression and those who are not.

Severity Classification

Beyond binary classification, some studies focus on assessing the severity of depressive symptoms. This involves categorizing depression into different levels or stages, such as mild, moderate, or severe, based on the linguistic cues present in the text.

Depressive Symptoms Identification

NLP techniques are used to identify specific depressive symptoms, such as negative emotion, persistent feelings of sadness, changes in cognitive processes, or expressions of hopelessness. This task helps in understanding the nuanced emotional and cognitive states associated with depression.

Risk Assessment

Some studies aim to go beyond detection and focus on assessing the risk of depression-related outcomes, such as suicide risk or the likelihood of developing major depressive disorder. This task involves analyzing linguistic cues that may indicate a higher risk for adverse events.

Personalized Depression Analysis

There is a growing interest in personalized depression analysis, where NLP techniques are used to tailor interventions and treatments to individuals. This involves identifying unique linguistic patterns and behaviors associated with specific subgroups of depressed individuals.

By outlining these tasks and scope, we provide a clear framework for the literature review and ensure that the discussion remains focused on the application of NLP in depression detection and related areas.

Results

Overview

The literature search strategy described in the Methods section returned a diverse range of studies focusing on various aspects of depression detection using NLP techniques. These studies spanned different methodologies, including original research, review articles, and technical reports. The key findings from these studies focusing on the NLP techniques are summarized in Table 1 below and presented in a structured format for clarity. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram is presented in Figure 1 and the PRISMA checklist is presented in Multimedia Appendix 1.

Table 1. Summary of natural language processing (NLP) techniques for depression detection.

NLP techniques	Methodology	Relevance to depression detection	Limitations	Study	Sample size, n	Dataset	Method	Results
Sentiment analysis	Analyzes the emotional tone of the text	Identifies negative language	Limited understanding of depression	Rathner et al [11], 2017	220 participants	Recruited participants were asked to reflect on their past year	LIWC[a] based features	R^2 value of 0.104
Sentiment analysis	Analyzes the emotional tone of the text	Identifies negative language	Limited understanding of depression	Prabhu et al [12], 2022	189 sessions	DAIC-WOZ[b]	Word2vec feeds them as input to long short-term memory	82.3% accuracy
Linguistic markers	Identifies linguistic features related to depression	Captures cognitive distortions and identifies the use of certain types of words	May overlook contextual complexities	Islam et al [13], 2018	7145 comments	Facebook user comments	Decision tree classifier from feature obtained through LIWC	F-measure of 0.71
Linguistic markers	Identifies linguistic features related to depression	Captures cognitive distortions and identifies the use of certain types of words	May overlook contextual complexities	De Choudhury et al [14], 2021	554 users	Twitter	LIWC for determining 22 specific linguistic styles	72.4% accuracy
Word embedding	Creates vectorized word representations	Preserves semantic relationships	May miss nuanced semantics	Stankevich et al [15], 2018	887 users	CLEF[c] and eRisk 2017	Word embeddings and support vector machine model	F_1-score of 63.4%
Word embedding	Creates vectorized word representations	Preserves semantic relationships	May miss nuanced semantics	Lopez-Otero et al [16], 2017	189 sessions	DAIC-WOZ	GLoVe[d] vector inputs	F_1-score of 73%
Word embedding	Creates vectorized word representations	Preserves semantic relationships	May miss nuanced semantics	Mallol-Ragolta et al [17], 2019	189 sessions	DAIC-WOZ	GloVe embeddings	Unweighted average recall of 0.66
Word embedding	Creates vectorized word representations	Preserves semantic relationships	May miss nuanced semantics	Dinkel et al [18], 2020	189 sessions	DAIC-WOZ	Pretrained word embeddings (ELMo[e])	F_1-score of 84%
Word embedding	Creates vectorized word representations	Preserves semantic relationships	May miss nuanced semantics	Rutowski et al [19], 2020	16,000 sessions	American English spontaneous speech	GloVe word embedding	AUC[f] of 0.8
Convolutional neural networks and recurrent neural networks	Captures local and sequential information in language data	Models language patterns of depressed individuals	Complex architectures, data-hungry	Korti and Kanakaraddi [7], 2022	__g	Twitter	Recurrent neural network with long short-term memory	91% accuracy
Convolutional neural networks and recurrent neural networks	Captures local and sequential information in language data	Models language patterns of depressed individuals	Complex architectures, data-hungry	Tejaswini et al [20], 2022	13,000 posts	Reddit and Twitter	Fasttext with long short-term memory	87% accuracy

NLP techniques	Methodology	Relevance to depression detection	Limitations	Study	Sample size, n	Dataset	Method	Results
Large language models	Captures complex linguistic nuances and context	Achieves high-level understanding	Computationally expensive and requires specific fine-tuning	Senn et al [21], 2022	189 sessions	DAIC-WOZ	Fine-tuning BERT[h] and its variants	F_1-score of 0.62
Large language models	Captures complex linguistic nuances and context	Achieves high-level understanding	Computationally expensive and requires specific fine-tuning	Hayati et al [22], 2022	53 participants	Interview questions	Few-shot learning on GPT[i]-3	F_1-score of 0.64
Large language models	Captures complex linguistic nuances and context	Achieves high-level understanding	Computationally expensive and requires specific fine-tuning	Németh et al [23], 2022	Approximately 80,000 posts	Data acquired through SentiOne	Fine-tuning DistilBERT	73% precision

[a]LIWC: Linguistic Inquiry and Word Count.

[b]DAIC-WOZ: Distress Analysis Interview Corpus–Wizard-of-Oz set.

[c]CLEF: Conference and Labs of the Evaluation Forum.

[d]GLoVe: global vectors for word representation.

[e]ELMo: embeddings from language models.

[f]AUC: area under the curve.

[g]Not available.

[h]BERT: bidirectional encoder representations from transformers.

[i]GPT: generative pretrained transformer.

Historical Timeline of NLP Development and Relevance of Depression

NLP has gone through substantial development over the years, with technological advances and research contributing to its growth. Throughout its history, the field of NLP has continually expanded its capabilities, and the relevance of depression screening within this timeline has become increasingly noticeable.

Early Years and Rule-Based Systems (1950s-1970s)

The origins of NLP can be traced back to the 1950s with the development of early computer programs like the Georgetown-IBM Experiment (developed jointly by Georgetown University and IBM) [24], which attempted to translate Russian sentences into English using basic rules and structures. In the 1970s, rule-based systems gained prominence. Systems like SHRDLU [25] demonstrated limited language understanding by manipulating blocks in a virtual world based on user commands. However, these systems had difficulty handling the complexity of natural language, including expressions of emotions and sentiment.

Knowledge-Based Approaches and Syntax Analysis (1980s-1990s)

In the 1980s, there was a shift toward knowledge-based approaches, including expert systems [26]. Researchers attempted to encode linguistic rules and world knowledge to improve language understanding. In the 1990s, statistical methods, such as the hidden Markov model (HMM) [27] and part-of-speech tagging [28], gained popularity. These methods improved parsing and syntactic analysis, but the understanding of context, semantics, and emotions in language remained challenging.

Machine Learning and Statistical Methods (2000s-2020s)

Machine learning algorithms, such as support vector machine and multi-layer perceptron improved performance on several NLP tasks, including sentiment analysis. Deep learning models, such as recurrent neural networks (RNNs) and convolutional neural networks (CNNs), later enhanced NLP. Word embeddings

like Word2Vec and global vectors for word representation (GloVe) captured semantic relationships between words. Attention mechanisms and transformers, used in models like bidirectional encoder representations from transformers (BERT) and generative pretrained transformer (GPT), achieved remarkable results in language understanding and generation. These methods in relation to depression will be explained in detail in the Classification Models for Depression Detection: Machine Learning and Current State of the Art Models in Depression Detection sections.

Relevance of Depression in the NLP Timeline

With the growth of web-based platforms and social media, textual data became abundant, and there was increased interest in the application of NLP for sentiment analysis and mood detection. Early efforts to identify emotional states and linguistic markers of depression emerged. The deep learning revolution then enabled more nuanced sentiment analysis and emotion recognition. Researchers started to explore the detection of mental health conditions, including depression, using NLP techniques. Studies focused on extracting linguistic cues related to depressive symptoms and emotional states from text data. Specific methods of depression detection using NLP will be further discussed in the following sections.

NLP Techniques for Depression Detection

NLP techniques have been shown to be important in obtaining valuable insights from textual data acquired through social media, web-based forums, or textual health records for depression detection [13,20]. Given certain textual data, NLP can convert—through multiple steps—the textual data into a format that can point toward the presence or absence of depression. Among the initial steps in depression detection through NLP, *text preprocessing* and *feature extraction* play an essential role. Text preprocessing involves converting text data into a structured format suitable for analysis. Researchers have used techniques like tokenization, stemming, and lemmatization to achieve this [12]. Tokenization breaks down a certain transcript into individual words or tokens (which are parts of words). Stemming and lemmatization are both processes that involve reducing words to their base or root forms. Stemming often uses chopping (eg, jumps → jump, caring → car), while lemmatization applies language and context analysis for accurate reductions (eg, better → good, caring → care).

Another NLP technique that has been used to convert text into a more usable representation that has led to an increase in the accuracy of depression detection is feature extraction from text. Some examples of these methods include bag of words and term frequency-inverse document frequency [6]. The bag of words method creates a count-based representation of words present in a certain text by treating each word as a separate unit and, therefore, ignoring the order of the words. Term frequency-inverse document frequency assigns weights to words based on their count in a document and across the entire dataset, giving more importance to rare but distinctive words. These

methods enable researchers to transform raw textual data into a quantitative representation, which can be used for further processing down the road.

One of the most widely used NLP techniques, and one that has been used as a proxy for identifying depression in language is *sentiment analysis* [29]. This approach examines the emotional tone of a text. Prior studies have shown a higher correlation between individuals with depression and the use of more negative words and the frequent expression of emotions related to sadness and hopelessness in their written language [30]. The linguistic inquiry and word count tool [31] is one example of such a sentiment analysis technique. This tool enables the automatic analysis of texts into preset word categories associated with depression—including negative emotions and cognitive processing [11]. By quantifying the emotional expressions in text data, researchers can gain valuable insights into the emotional state of individuals, which can in turn point toward the identification of potential depressive symptoms.

Researchers have also made substantial efforts to identify *linguistic markers and cues* that capture patterns related to depression. For example, prior studies have revealed that certain linguistic features, such as an increased use of first-person pronouns and a decreased use of third-person pronouns, can indicate the presence of depression [14,32]. In addition, the presence of cognitive distortions, characterized by negative thinking, has been found in the language of individuals with depression [33]. This suggests that by examining language patterns, NLP techniques offer a window into the cognitive and emotional processes underlying depression.

Recent advancements in NLP have enhanced the field of mental health disorder detection in general, especially using vectorized representations of language. *Word embeddings* and *contextual analysis using deep learning models* have substantially improved the accuracy and performance of depression detection models [34-37]. Word embeddings are created by transforming words into continuous vector representations, capturing semantic relationships and contextual meaning between words. To grasp the concept of word embeddings, envision a vector space where words are positioned based on their semantic meanings, allowing for intriguing relationships like "king" – "man" + "woman" = "queen" (see Figure 2 for the visualization of this analogy). Static word embeddings, such as GloVe [37], transform words into fixed vector representations that capture global semantic relationships, while dynamic embeddings, like embeddings from language model (ELMo) [38], provide context-dependent word representations. In the context of depression-related text data, previous studies have leveraged both GloVe [15-17] and ELMo [18] embeddings to capture word semantics and have achieved better accuracy in depression detection tasks. By preserving semantic relationships, word embeddings enable NLP models to better understand the meaning of words in context, which enhances the capacity to identify linguistic indicators of depression.

Figure 2. Visualization of how word embeddings capture analogy information from the words.
In summary, the use of NLP techniques, such as sentiment analysis, linguistic markers, and recent advancements like word embeddings contribute to a powerful toolkit for detecting depression from the text. These techniques have enabled researchers and clinicians to gain valuable insights into an individual's mental health state through their written and spoken languages, potentially giving rise to more accurate detection and intervention strategies for depression and other mental health disorders. As research in this domain continues to evolve, combining the strengths of classic NLP with cutting-edge developments—which will be described in the coming section—promises to enhance the understanding of depression further, leading to improved mental health outcomes for individuals worldwide.

Classification Models for Depression Detection: Machine Learning

Machine learning models have emerged as a powerful tool in depression and mental health disorder detection in general, offering good capabilities to classify depressive and nondepressive states accurately. Leveraging the large amount of digital text data generated daily, these models have the potential to enhance mental health care by enabling more efficient and objective approaches to identifying and managing depression.

One approach is supervised machine learning where various algorithms have been applied to depression detection tasks, particularly binary classification (depressed or nondepressed) based on linguistic features extracted from text. Logistic regression, support vector machines, random forests, naive Bayes, and multi-layer perceptron classifiers are among the commonly used models, and they have shown promising results in accurately identifying and classifying depressive states [11,23,39]. These models use labeled datasets to learn patterns and relationships between textual features and depression status, contributing to more accurate and robust predictions.

Another set of approaches are the unsupervised machine learning techniques which have been used to uncover hidden structures within the depressed population. Techniques, such as K-means and hierarchical clustering, aim to identify distinct subgroups based on their linguistic patterns [40]. By grouping individuals

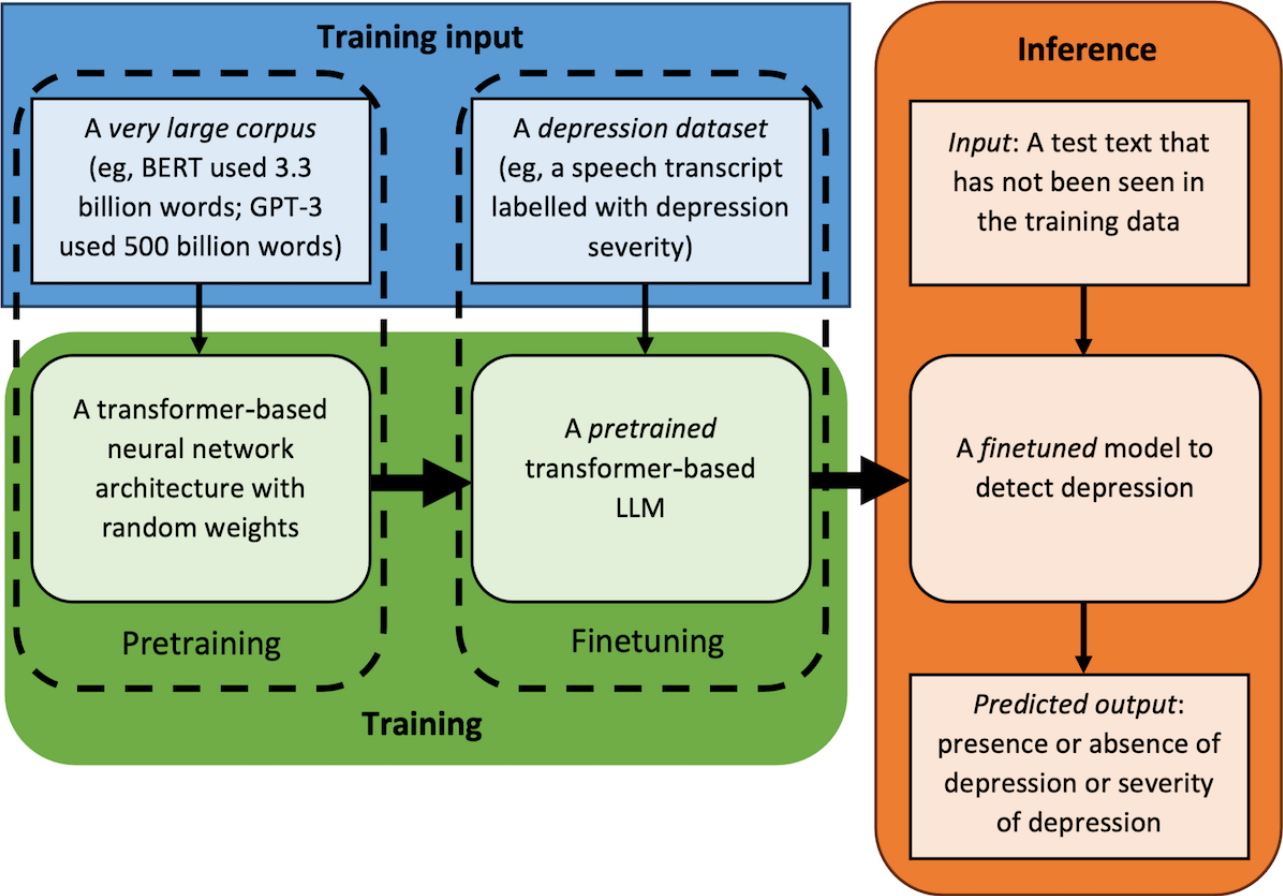
with similar language use together, these clustering approaches have the potential to uncover different characteristics of depression. Such insights could lead to the development of personalized treatment strategies, catering to the unique needs of subgroups within the larger depressed population.

The introduction of deep learning has further advanced depression detection in the scope of NLP. For example, in the context of depression detection, CNNs and RNNs have gained popularity for their ability to capture sequential information and model temporal dependencies in language data [7,20]. CNNs effectively analyze local patterns within a text, while RNNs are well-suited for understanding the contextual dependencies that arise from sequential data. By capturing the linguistic cues related to depression, these deep learning architectures have substantially increased the performance of depression detection models from prior machine learning models. For example, Tejaswini et al [20] developed a novel approach called Fasttext convolution neural network with long short-term memory to detect depression in social media text data obtained from Reddit and Twitter. Their method achieved an 87% accuracy in distinguishing depression from nondepression in a dataset comprising of 13,000 samples, highlighting its potential for early detection of depressive states.

Current State of the Art Models in Depression Detection

Transformer-based large language models (LLMs), another class of deep learning models, have also shown exceptional results in mental health detection tasks [41]. These models, characterized by their substantial number of parameters, often in the hundreds of millions to trillions, are artificial neural networks designed for natural language understanding and generation, using a self-attention mechanism to process input data in parallel and capture contextual information across long sequences. The transformer architecture [42] has been widely used in language modeling tasks and has proved to be highly effective in sentiment analysis [29,43-45]. In the context of depression detection, these models excel at understanding the complex and nuanced emotional language used by individuals experiencing depression [21,22,39].

One of the essential attributes of LLMs in the context of depression detection lies in their ability to do transfer learning—a technique that involves pretraining a model on a large and comprehensive dataset before fine-tuning it for a specific task. This paradigm has exhibited immense potential in the domain of depression detection [19]. Notable pretrained language models, such as BERT [46], MentalBERT [47], and GPT [48] have been fine-tuned on datasets curated from depression-related text sources. This strategic adaptation enables these models to grasp the details of the lexicon and linguistic context unique to depression [21,22]. The outcome is a refined model capable of discerning and contextualizing the language manifestations that accompany depression, thereby enhancing both accuracy and generalizability in depression detection models. Figure 3 shows the typical steps taken to generate a fine-tuned model from a pretrained model to make an inference and predict depression.

Figure 3. Steps to generate a typical large language model (LLM)–based depression detection model. BERT: bidirectional encoder representations from transformers; GPT: generative pretrained transformer.


By pretraining on vast and diverse linguistic datasets, these LLMs develop an innate comprehension of the structures and nuances of human language. This foundational knowledge enables them to decode the unique linguistic markers and emotional cues exhibited by individuals struggling with depression. The understanding of context enables these models to not only identify obvious expressions of depressive thoughts and emotions but also to identify the subtle and sometimes ambiguous linguistic signals that often evade traditional diagnostic approaches.

In summary, incorporating machine learning and deep learning models into depression detection has not only enhanced accuracy but also opened new avenues for understanding and managing mental health disorders. The ability of these models to identify patterns, relationships, and distinct subgroups within the depressed population offers valuable insights for early detection, personalized treatment, and more effective mental health interventions. As research in machine learning and deep learning continues to advance, the potential for further improving depression detection and mental health care becomes increasingly promising. Using the power of these technologies responsibly will be critical in realizing their full potential in enhancing mental health care and supporting individuals affected by depression. Table 1 summarizes the different NLP techniques discussed above.

Datasets Used for Depression Detection

The availability of appropriate datasets plays a vital role in training and building NLP models, including for tasks, such as depression detection. In recent times, several publicly accessible datasets, which include a depression label, have emerged [49-55]. Some of the datasets used for depression detection are presented in Table 1.

One of the most popular datasets is the "distress analysis interview corpus/wizard-of-Oz set" [51]. This dataset consists of audio (which includes transcript) and video recordings that

simulate clinical interviews designed to assess distress levels related to depression, anxiety, and posttraumatic stress disorder. During these interviews, some participants act out distress, showcasing symptoms and experiences associated with depression, while others take on the role of interviewers, referred to as the "Wizard-of-Oz." Researchers use this dataset to develop and evaluate computational methods and algorithms for automatic distress detection and analysis, specifically focusing on cues related to depression-related distress. In another dataset, as presented in the study by Matcham et al [56], they presented data collected from 623 participants with a history of recurrent major depressive disorder. The study used smartphone sensors, wearable devices, and app-based questionnaires over 11 to 24 months. In addition, speech data were collected every 2 weeks through a speech task involving predetermined text and open-ended responses, with 82.2% of participants providing speech data.

However, despite these advancements, certain characteristics of the datasets present challenges when it comes to the trained models' ability to generalize. For example, small and imbalanced datasets (as observed in Jamil et al [55], where only 5% of the tweets contained a reference to depression) can cause underfitting or overfitting, such that the model becomes too tailored to the training data, making it less effective in handling new and unseen data [57]. In addition, the lack of diversity in the data, with most of the samples originating from specific demographics, may limit the applicability of the models across different populations. These limitations highlight the need for continuous improvement in dataset curation and selection to enhance the performance and applicability of depression detection models.

Validation and Evaluation Metrics

Evaluating NLP models for depression detection involves carefully selecting appropriate metrics to assess their performance. In this context, some commonly used quantitative evaluation metrics include accuracy, precision, recall, F_1-score [58], and the area under the receiver operating characteristic curve [59]. The results of different studies using these metrics can be seen in Table 1. Researchers often use cross-validation and external validation strategies to ensure the models' generalizability and effectiveness.

However, being mindful of the potential limitations and biases associated with these quantitative metrics and validation techniques is essential. For instance, while accuracy is a commonly used metric, more informative evaluations metrics are needed for imbalanced datasets—where one class significantly outweighs the others. The model may achieve high accuracy in such cases by classifying most samples into the majority class [60], but might not reflect the actual performance of the prediction model.

Cross-validation techniques [61], which are widely used for model evaluation, also have limitations that need to be considered. One common approach involves splitting the dataset into 2 parts, using one for training the model and the other for testing its performance. However, this method may introduce higher bias, as crucial information from the unutilized data is left out during the training phase.

Another cross-validation technique, leave-one-out cross-validation, attempts to mitigate bias by training on the entire dataset while sequentially leaving out one data point for testing. Although this approach uses all data points, it can lead to higher variation in the testing phase, mainly if the omitted data point is an outlier. In addition, the leave-one-out cross-validation method demands substantial execution time as it iterates over the number of data points, making it computationally expensive for large datasets.

Alternatively, researchers can opt for k-fold cross-validation, where the dataset is divided into k subsets, and the model is trained on all except one subset reserved for evaluation. This approach helps reduce bias compared with simple two-part cross-validation, but it can still introduce variation in the testing phase due to the different subsets used for evaluation.

As researchers use cross-validation to assess NLP models for depression detection, they must be mindful of these limitations and biases. Ensuring accurate and reliable model assessment requires understanding the trade-offs of each method and carefully selecting the most appropriate validation technique based on the dataset's characteristics and research objectives. By being aware of these considerations, we can ensure more robust and trustworthy evaluations of NLP models in the crucial domain of depression detection.

Aside from quantitative metrics, qualitative evaluation metrics also play a substantial role in assessing the performance of NLP models for depression detection, as they offer insights beyond numerical measurements. While quantitative metrics provide valuable information about the models' accuracy and efficiency, qualitative evaluation metrics explore the models' interpretability, user experience, and overall impact.

One important qualitative evaluation metric is interpretability [62]. NLP models, especially those using complex deep learning techniques, are often considered "black boxes" because it is challenging to understand how they arrive at their predictions. However, interpretability is essential in applications related to mental health. Clinicians, researchers, and users must comprehend how the model reaches its conclusions to trust its decisions. Therefore, techniques that explain the model's predictions, such as attention mechanisms or feature visualization [63], are essential for ensuring the model's transparency and interpretability.

User experience and acceptability are also crucial qualitative metrics to consider. When deploying NLP-based depression detection systems in real-world settings, it is vital to measure end users' experiences—such as patients and therapists. Feedback from users can shed light on the system's usability, ease of integration into existing workflows, and its ability to provide valuable insights during the prediction. Exploring user perspectives can help improve the model's design, its practicality, and effectiveness in real-world mental health settings.

Ultimately, qualitative evaluation metrics complement quantitative assessments by offering a more comprehensive understanding of the NLP model's impact on mental health care. By considering interpretability and user experience, we

can develop more well-rounded and effective NLP-based depression detection systems that align with the needs and expectations of both patients and mental health professionals.

Cultural and Multilingual Perspectives

The cultural and linguistic diversity surrounding mental health expressions presents distinctive challenges when it comes to detecting depression across different languages and cultures [64,65]. Researchers have recognized these challenges and sought to address them through cross-cultural research, highlighting the necessity for culturally sensitive depression detection models [66].

An illustrative example of such efforts is the study conducted by Lyu et al [67]. In this research, the focus was on depression detection using text-only social media data from the Chinese platform Weibo. The researchers considered a broader range of linguistic features that are relevant to depression, considering cultural factors and suicide risk specific to the Chinese language. To achieve this, they analyzed depression scores and past posts from 789 Weibo users. The outcome was a predictive model that showed promising results in detecting depression among the Chinese-speaking population.

This study served as an important reminder of the need for cultural expressions when it comes to improving the recognition of depression within specific linguistic and cultural groups. By considering the unique ways in which individuals from different languages and cultural backgrounds communicate their mental health experiences, we can improve the accuracy of depression detection models and make them more inclusive. As we continue to explore and expand our understanding of cross-cultural and multilingual perspectives on depression detection, we can move toward providing better mental health support and care for diverse populations around the world.

Discussion

Principal Findings

This literature review explored the potential of NLP in enhancing depression screening by analyzing textual data. The review revealed a range of NLP techniques, including sentiment analysis; linguistic markers; word embeddings; and deep learning models, such as CNNs, RNNs, and LLMs, that have been successfully applied to depression detection. The studies demonstrated the efficacy of these techniques, with machine learning models achieving high accuracy in classifying depressive states. However, ethical concerns, including privacy, bias, and interpretability, were also identified as critical challenges. In addition, the importance of cross-cultural and multilingual perspectives was emphasized, highlighting the need for culturally sensitive models. The review further discussed the integration of depression detection using NLP within the research domain criteria (RDoC) framework, mapping linguistic cues to psychological and biological constructs. Overall, the findings showcase the potential of NLP in enhancing mental health support systems while also presenting ethical and technical challenges that require continued innovation and collaboration.

Comparison to Prior Work

The main findings of this review align with prior work in the field, which has also identified the potential of NLP techniques in mental health detection [9,10,29]. However, this review extends the understanding by incorporating the latest advancements in LLMs and their application to depression detection. Previous studies have largely focused on traditional machine learning techniques, while this review highlights the significant potential impact of deep learning and LLMs, as well as the comparison of current state-of-the-art models with prior classification models for depression detection.

Integration of Depression Detection Using NLP Within the RDoC Framework

The RDoC framework provides a comprehensive approach to investigating mental health and psychopathology by focusing on fundamental psychological and biological systems rather than relying solely on traditional diagnostic categories. The RDoC framework acknowledges the complexity of mental health conditions and aims to foster new research approaches that lead to improved diagnosis, prevention, intervention, and treatment [68]. Here, we will explore how the detection of depression using NLP aligns with the principles and objectives of the RDoC framework.

The RDoC framework is organized into several major functional domains, each containing psychological and biological dimensions or constructs that span the range from normal to abnormal functioning [68]. Depression, a multifaceted mental health condition, touches upon multiple domains within the RDoC framework. These domains include negative valence systems, positive valence systems, cognitive systems, and social processes. NLP techniques for depression detection often analyze textual data to extract linguistic cues, sentiment, and cognitive patterns related to depression [14,29,30,32]. These patterns can be mapped onto constructs within the RDoC domains to gain insights into the underlying psychological and biological mechanisms associated with depressive symptoms.

For example, persistent negative emotions, such as sadness, hopelessness, and irritability, often characterize depression. This can be mapped to the negative valence systems domain in the RDoC framework. Some NLP methods that practice sentiment analysis for depression detection use linguistic markers associated with negative emotions and cognitive distortions [29,30]. Similarly, the cognitive systems domain in the RDoC framework focuses on cognitive processes and depression often involves cognitive distortions. NLP techniques can identify linguistic markers indicative of cognitive distortions within a text, connecting cognitive processes and linguistic expressions in depression [33].

Depression can also be mapped to the social processes domain within the RDoC framework which encompasses constructs related to social behavior, social cognition, and social communication. NLP methods offer insights into individuals' social expressions and interactions through their textual data, including social media posts and web-based forum discussions [20].

Ethical Considerations and Limitations in NLP for Depression Detection

As NLP holds great potential in enhancing depression detection, it also gives rise to a range of ethical concerns that require careful consideration. Mental health data are highly sensitive. The information shared by individuals could include personal experiences, emotions, and medical history. Therefore, one of the main concerns includes safeguarding privacy and security of mental health data. To ensure the protection of individuals seeking support through NLP-based mental health services, it becomes crucial to use robust privacy and security measures. For privacy, even if data are anonymized, there may be a risk of reidentification. Clinical notes provide significant contextual information (eg, favorite movies and sports) that could be used by adversaries to be linked back to some other background information (eg, age group, general location information, etc) and identify the individual. Privacy regiments for NLP-based models, in addition to anonymization, should include guaranteed statistical privacy through differential privacy [69]. For security, in addition to cryptographic protection of data storage with support for provable worst-case security, an authentication and authorization regimen should be put in place to ensure the prevention of accidental or intentional unauthorized access.

Further ethical challenges arise from the potential biases that NLP models may inherit from the training data, giving rise to concerns regarding the robustness of depression detection [70-72]. Lack of robustness can have several adverse impacts when NLP is deployed in analyzing mental health text. A poor NLP model generalization (the distribution shift from the data the model is trained with to the data used in deployment) may lead to the model's failure to generalize well across various linguistic styles, terminologies, or expressions used by individuals. Lack of contextual understanding is another challenge as it might lead to the model losing essential contextual information, making it challenging to understand the full spectrum of an individual's mental state. Finally, bias and fairness issues are important aspects of model robustness. For instance, if certain demographic groups are underrepresented in the training data, it can lead to reduced accuracy for those specific populations, causing inequalities in health care.

In addition to these concerns, another substantial challenge arises from the integration of third-party application program interfaces and cloud-based services in NLP-based depression detection. While using third-party application program interfaces can enhance the capabilities of NLP models by, for example, incorporating pretrained language embeddings, it introduces a layer of dependency and potential security risks. These risks come from the need to share sensitive mental health data with external services, raising questions about data ownership, use, transparency, and compliance with privacy regulations.

A recent study by Straw et al [70] shed light on the integration of AI in health care. It underscored the critical need for collaboration between computer scientists and medical professionals to address biases in NLP models used in psychiatry. The research involved a comprehensive literature review of NLP applications in mental health, specifically evaluating biases in GloVe [37] and Word2Vec [36] word embeddings. The findings revealed significant biases related to religion, race, gender, nationality, sexuality, and age. Moreover, the review highlighted the need for more attention to these biases in existing research, signaling a limited cross-disciplinary collaboration in this domain.

Straw et al [70] emphasized the importance of addressing biases to prevent health gaps caused by AI and data-driven algorithms. They offered valuable recommendations for future research to minimize potential harm. By proactively working to identify and mitigate biases in NLP models, we can strive to create more equitable and just mental health support systems, ensuring that the benefits of NLP technology are accessible and effective for all individuals, regardless of their background or demographic characteristics. Textbox 1 summarizes some of the challenges and opportunities in using NLP for detecting depression.

Textbox 1. Challenges and opportunities in natural language processing for depression detection.

Challenges and opportunities

- Privacy concerns: robust anonymization techniques

- Biases: transparency and fairness

- Interpretability: explainable artificial intelligence

- User feedback: user-centric design

- Cross-cultural variations: culturally sensitive models

- Small, imbalanced datasets: data diversity

Limitations of the Study

While this review provides valuable insights into the application of NLP for depression screening, some limitations should be acknowledged. First, the scope of the literature search was confined to 3 databases: Semantic Scholar, PubMed, and Google Scholar. Although these sources cover a wide range of academic publications, the exclusion of other major databases like IEEE Xplore and Scopus may have resulted in the omission of relevant studies, particularly those focusing on technical advancements in NLP. This may limit the breadth of the findings and leave certain innovations in NLP techniques underrepresented.

In addition, this review relies on qualitative synthesis without performing a meta-analysis of the selected studies. A quantitative meta-analysis could have provided a more robust statistical evaluation of the effectiveness of different NLP techniques in depression screening. Furthermore, while ethical

and cross-cultural issues were discussed, the review does not deeply analyze how these concerns are addressed across different studies. This omission could overlook critical gaps in ensuring the fairness and applicability of NLP models across diverse populations, limiting the generalizability of the findings.

Future Directions

Despite the substantial potential that NLP has shown in depression detection, several challenges still lie ahead. The ambiguous characteristics of natural language and the ever-changing nature of language use in diverse contexts make it difficult to achieve consistently accurate detection. In addition, the risk of overfitting on small datasets and the necessity for large-scale, diverse datasets to ensure robust model training remain pressing concerns [41].

Future studies should focus on tackling these challenges to advance the field of NLP in depression detection. One important avenue for exploration is improving the interpretability of NLP models. As complex deep learning techniques become prevalent, it becomes increasingly crucial to understand and explain how these models arrive at their predictions. For example, the use of LLMs for interpretable mental health analysis has been explored in studies like that of Yang et al [73]. These models aim to provide not just predictions but also explainable insights into the mental health status of individuals. This direction holds the potential for improving the trustworthiness and clinical applicability of LLMs in depression screening. Future research should continue to address the challenges of accuracy, ethical considerations, and collaboration between NLP experts and mental health professionals to fully realize the benefits of LLMs in this context.

Personalization is another crucial aspect that future research should address. Depression is a complex and highly individualized condition, and so a one-size-fits-all approach may not be sufficient to meet the variable needs of individuals. Developing personalized depression detection tools that consider an individual's unique linguistic pattern, behavior, and context can enhance the accuracy of the detection process. These tools can cater to specific user requirements and provide tailored support and interventions.

Integrating user feedback and domain expertise in developing NLP models to achieve these advancements is crucial. Engaging with end users, including patients and mental health professionals, can provide valuable insights into the strengths and limitations of the models and help refine them to suit real-world applications better. Collaborating with domain experts, such as psychologists and psychiatrists, can ensure that the models align with clinical practices and address the most relevant aspects of depression detection and treatment.

Overall, the future of NLP in depression detection holds significant potential, but it also demands continued innovation and collaboration. By addressing challenges, improving interpretability, and personalizing depression detection tools, we can pave the way for more effective, user-centric, and clinically relevant solutions that contribute substantially to mental health care.

Conclusions

In conclusion, adopting NLP techniques for depression detection holds significant potential in enhancing mental health support systems. This literature review has explored various NLP methodologies, applications, and challenges in detecting depression using textual data. While obstacles remain, ongoing advancements in NLP, ethical considerations, and cross-cultural insights pave the way for more accurate, accessible, and equitable mental health solutions.

The evolving field of NLP offers the potential for more effective detection of depression, but challenges persist. Overcoming the complexity of natural language and obtaining diverse datasets are key focus areas. Ethical considerations underscore the need for data privacy and model transparency. Integrating cross-cultural insights ensures culturally sensitive solutions that cater to diverse populations. With continued progress and collaboration, NLP can improve mental health care and well-being worldwide.

Authors' Contributions

BGT created the outline, researched papers, and led the drafting of the initial manuscript, incorporating feedback from coauthors. AR provided detailed feedback on the draft. HP, RV, RS, SK, and VB critically reviewed the paper and offered valuable insights. VB supervised the study and provided guidance throughout the research process. The collaborative efforts of all authors have resulted in the final manuscript. All authors read and approved the final manuscript.

Abstract

Background: Co-creation is increasingly recognized for its potential to generate innovative solutions, particularly in addressing complex and wicked problems in public health. Despite this growing recognition, there are no standards or recommendations for method use in co-creation, leading to confusion and inconsistency. While some studies have examined specific methods, a comprehensive overview is lacking, limiting the collective understanding and ability to make informed decisions about the most appropriate methods for different contexts and research objectives.

Objective: This study aimed to systematically compile and analyze methods used in co-creation to enhance transparency and deepen understanding of how co-creation is practiced.

Methods: To enhance transparency and deepen understanding of how co-creation is practiced, this study systematically inventoried and analyzed methods used in co-creation. We conducted a systematic methods overview, applying 2 parallel processes: one within the peer-reviewed Health CASCADE Co-Creation Database and another within gray literature. An artificial intelligence–assisted recursive search strategy, coupled with a 2-step screening process, ensured that we captured relevant methods. We then extracted method names and conducted textual, comparative, and bibliometric analyses to assess the content, relationship between methods, fields of research, and the methodological underpinnings of the included sources.

Results: We examined a total of 2627 academic papers and gray literature sources, with the literature primarily drawn from health sciences, medical research, and health services research. The dominant methodologies identified were co-creation, co-design, coproduction, participatory research methodologies, and public and patient involvement. From these sources, we extracted and analyzed 956 co-creation methods, noting that only 10% (n=97) of the methods overlap between academic and gray literature. Notably, 91.3% (230/252) of the methods in academic literature co-occurred, often involving combinations of multiple qualitative methods. The most frequently used methods in academic literature included surveys, focus groups, photo voice, and group discussion, whereas gray literature highlighted methods such as world café, focus groups, role-playing, and persona.

Conclusions: This study presents the first systematic overview of co-creation methods, providing a clear understanding of the diverse methods currently in use. Our findings reveal a significant methodological gap between researchers and practitioners, offering insights into the relative prevalence and combinations of methods. By shedding light on these methods, this study helps bridge the gap and supports researchers in making informed decisions about which methods to apply in their work. Additionally, it offers a foundation for further investigation into method use in co-creation. This systematic investigation is a valuable resource for anyone engaging in co-creation or similar participatory methodologies, helping to navigate the diverse landscape of methods.

Introduction

Overview

Co-creation has emerged as a powerful approach for fostering collaboration and innovation across various disciplines [1]. Co-creation has the potential to produce new or improved tailored practices and solutions, which address complex challenges and generate meaningful outcomes for a defined need [2,3]. In health care, co-creation is thought of as a potential way to bridge the bench-to-bedside divide [4,5] by developing interventions that are more acceptable and contextually appropriate, thereby potentially enhancing their effectiveness and impact on health outcomes [6]. It can be used to address complex problems in public health (eg, the obesity epidemic, persisting poverty, or food insecurity), which are particularly resistant to resolution [1,4]. Additionally, co-creation has been widely used in health care at a rapidly expanding rate [7].

At the core of co-creation is the active engagement of multiple stakeholders in a collective intelligence process to collaboratively design and implement projects, processes, services, and solutions [7-9]. Rooted in the potential for tapping into diverse perspectives, skills, expertise, and experiences, co-creation stands as a dynamic approach to fostering innovation and stakeholder engagement [10] and an effective means to avoid top-down approaches or mere stakeholder consultations [5].

There is a growing recognition of co-creation as a valuable methodology, yet, to date, there is no common practice or standardized approach [1,11]. Co-creation has increasing traction in terms of involving stakeholders, but the extent to which this creates a fundamental change in practices is still unclear, and there is a strong potential that it will remain tokenistic [12]. Major challenges remain and need to be confronted to make co-creation trustworthy and unlock its full potential [1,2,11-13].

Fragmentation of Co-Creation

A well-documented challenge in co-creation research is its fragmentation. Slattery et al [14] describe the literature as complex, contradictory, and poorly synthesized, noting that inconsistent terminology makes it difficult to retrieve and understand relevant studies. Agnello et al [1] further highlight this fragmentation, attributing it to inconsistencies in terminology and inadequate cross-referencing and knowledge sharing among co-creation researchers. Smith et al [15] found that researchers operationalize co-creation in various ways, while Grindell et al [16] emphasize the interchangeable and often ambiguous use of the co-creation, co-design, and coproduction terms. These issues hinder the identification of best practices and the establishment of robust evidence for co-creation.

Methods for Co-Creation

Research methods provide a structured and systematic approach to gathering and analyzing data, ensuring that findings are valid, reliable, and generalizable. Detailed insight into these processes is essential to truly understand and assess the quality of research [14,15,17-19]. Furthermore, well-documented research methods enable others to replicate studies and build on findings, which is crucial for advancing knowledge in any field [17]. Using appropriate methods allows researchers to control potential biases that might affect their results, making their findings more trustworthy and credible [20].

However, co-creation has been plagued with poor reporting of the steps involved in the process, in particular the methods used. Smith et al [15] urged the research community to improve reporting by clearly and consistently documenting methods. Similarly, Slattery et al [14] highlighted the need for better reporting on methods used in co-creation as a foundation for understanding its effectiveness and cost. An et al [13] also discovered limited reporting of methods in the co-creation literature and Lee et al [21] drew attention to the difficulty in evaluating co-creation due to a lack of systematic comprehension of methods. This challenge is also documented by Durugbo and Pawar [22], who highlighted the absence of a detailed description of the methods used to facilitate the interaction between the convener and the cocreators.

More than any other aspects of research, methods have the potential for adaptation or reuse across different contexts, research questions, and disciplines [6,17,23]. Consequently, poor reporting or restricted access to reliable methods creates inefficiencies and can slow progress. Given the numerous benefits of co-creation, it is surprising that there are no clear recommendations regarding methods appropriate for ensuring accurate, impactful, and trustworthy co-creation. The transferability of these methods suggests they could adapt the co-creation process to various contexts and research questions. However, poor reporting and limited access to trustworthy evidence about co-creation methods pose significant barriers, making it difficult to contextualize research, evaluate co-creation, replicate studies, or scale up co-creation research [1,14,15]. This lack of clarity also limits researchers' ability to build on existing knowledge and apply best practices [24].

While some studies have highlighted individual methods for co-creation, a comprehensive inventory or systematic overview of the full range of methods used in co-creation is lacking. Researchers striving to apply co-creation often lack the time to systematically search, retrieve, review, and compare all the available literature to develop a thorough and critical sense of the varied methods [1,25]. Therefore, a systematic methods overview could increase clarity and enhance collective understanding of which methods have been used in co-creation [25,26].

As Slattery et al [14] noted, there is considerable value in a greater synthesis and differentiation of the co-creation literature, highlighting that methodological and theoretical barriers in co-creation often prevent systematic comparison using traditional means. Consequently, this study aims to address this gap using a nontraditional means, by systematically inventorying and analyzing methods used in co-creation. By providing a comprehensive overview and analysis, this research will lay the groundwork for developing a robust taxonomy and compendium of co-creation methods in future research.

Methods

Definitions

We expanded on the definition of participatory methods by Vaughn et al [27] to establish a definition of methods used in co-creation: "Co-creation methods encompass a diverse range of tools, activities, approaches, and techniques strategically employed across the entirety of the co-creation process. These methods serve various purposes, including but not limited to data collection, facilitation, recruitment, reflection, data analysis, and dissemination, allowing for flexibility in achieving diverse objectives."

We defined co-creation according to Agnello et al [1]: "Co-creation is any act of collective creativity that involves a broad range of relevant and affected actors in creative problem-solving that aims to produce a desired outcome."

Systematic Methods Overview

Overview

Reviews on methods topics, known as methods overviews, are valuable for advancing research methods, making a systematic methods overview the ideal approach for thoroughly investigating methods used in co-creation [25,26,28]. This approach aims to synthesize guidance on methods from the literature; therefore, principles and strategies for a systematic approach were sourced from Gentles et al [25]. The strategies sourced from Gentles et al [25] and how they were applied in this study are described in Multimedia Appendix 1.

The first search sourced empirical research that provided examples of applying co-creation. The second search aimed to investigate gray literature to identify nonjournal publication types that provide guidance or information about co-creation methods, or include the use of co-creation methods.

Search 1: Empirical Research

Health CASCADE, a European Commission-funded network that aims to develop a coherent methodology for co-creation research in public health, created a peer-reviewed curated database of co-creation literature containing 13,501 papers [29]. Since this study investigated methods used in co-creation, it

was logical to source the methods from that database. However, since it contains a vast number of papers with different study types from various disciplines, a 2-step screening process was applied. First, a recursive search strategy was used to group the literature by method, reducing the number of papers for title and abstract screening. Second, title and abstract screening was conducted to categorize papers by study type.

The recursive search involved analyzing titles, abstracts, and keywords to identify relevant studies based on specific keywords, using Rayyan (Qatar Computing Research Institute), a systematic review manager [30]. This process included (1) screening titles and abstracts, (2) grouping by the method name, (3) screening grouped literature, and (4) iterating these steps until a stop rule was met. Details of this process are outlined in Multimedia Appendix 1.

Papers identified in the recursive search were extracted in Microsoft Excel and then reuploaded into Rayyan for classification by study type. We included empirical studies, protocols, exploratory studies, and case studies, while excluding evaluations and reflections on co-creation, to ensure the relevance of the extracted methods. This approach ensured that our inventory accurately reflects methods used in the co-creation process. For additional details, and the full set of inclusion and exclusion criteria, please refer to Multimedia Appendix 1. The classified literature was exported in a Microsoft Excel format and then taken to the analysis step.

Two approaches were used to analyze the final set of method names: one to deduce the frequency of the method names and one to validate the results. The first approach used pattern analysis, and the second approach used a more complex algorithm, commonly used by search engines. The pattern analysis provided initial frequency estimates, while the advanced algorithm validated these results by assessing the relevance of each method name in the context of the literature. This dual approach aimed to clarify which co-creation methods were most frequently used and which were less common. Further details can be found in Multimedia Appendix 1.

Search 2: Gray Literature Search

An initial step in a systematic methods overview is identifying and selecting relevant literature, which can be poorly indexed in standard databases [25]. To address this, we conducted a search in Google's Advance Search tool for co-creation guidelines, toolkits, books, and nonjournal publications, as detailed in Multimedia Appendix 1.

Search strategies were aligned with those used to create the Health CASCADE Co-Creation Database covering literature dating back to January 1, 1970 [1]. We targeted specific domains and used co-creation and methods terms. The gray literature search strategy is outlined in Table 1 and provided in Multimedia Appendix 1.

Table 1. Gray literature search strategy.

We applied inclusion and exclusion criteria in 2 rounds to determine relevance. Initially, we included papers, reports, guidelines, books, and web-based tools relevant to co-creation, as defined by Agnello et al [1], provided they were absent from the Health CASCADE Co-Creation Database version 1.5 [1] and were written in English. Materials such as conference proceedings, abstracts, dissertations, non-English content, or those already included in the database were excluded. In the second round, selected full-text documents were rescreened to ensure they introduced and described at least 1 co-creation method, including its application or guidance on its use. Nonrelevant texts were excluded. The snowballing approach was used to trace citations and references of included literature to identify additional relevant resources, continuing until saturation was reached.

Literature that met all criteria was processed using a predefined Microsoft Excel extraction table. Data were validated by cross-checking the extracted method names with those found in both academic literature and gray literature, and the results were discussed among the coauthors (DMA, AS, and SC). Once all the extraction tables were completed, a list of methods and frequency of appearances across the included literature was generated, to ascertain the relevant prevalence of each method.

Analysis

To analyze co-creation methods, we calculated method co-occurrence to understand how methods are combined in co-creation projects. The results were visualized using a Sankey diagram to illustrate the relationships between methods. We also conducted a bibliometric analysis of the included literature to investigate methodological trends and fields represented in the literature. Additionally, we examined the overlap between methods reported in academic literature and gray literature to determine if practitioners engage in co-creation similarly to those documented in academic research.

To understand how methods were combined, we analyzed co-occurrence in the academic literature by examining which methods appeared together in titles or abstracts. We used Python to map method names and count their co-occurrences, ensuring accuracy by marking and skipping already identified combinations. RAWGraphs (version 2.0; DensityDesign Research Lab) [31] was used to create Sankey diagrams that visualized these co-occurrences, removing method names with

no co-occurrence. For ease of visualization, methods were categorized into three groups: (1) qualitative; (2) participatory; and (3) quantitative, mixed, and ethnographic. Separate Sankey diagrams for each group were produced to simplify and clarify the visualization of method combinations and their prevalence in co-creation research.

To gain insights into the methodological paradigms and fields within the academic literature, we performed a bibliometric analysis using VOSviewer (The Centre for Science and Technology Studies) [32]. This tool helped us construct and visualize bibliometric networks to assess the prevalence of different methodologies and research areas. By analyzing the source landscape and methodologies, we aimed to identify dominant fields and approaches represented in the included academic literature. Detailed steps for this analysis using VOSviewer are provided in Multimedia Appendix 2.

To determine if co-creation practices differ between academic and gray literature, we compared methods from both sources using a Venn diagram. We identified overlaps and unique methods by comparing the 2 lists of methods in Microsoft Excel using Conditional Formatting. Methods were categorized into three groups: (1) exclusively in academic literature, (2) exclusively in gray literature, and (3) found in both. We calculated the number and percentage of methods in each group and visualized these findings in a Venn diagram. This comparative analysis highlighted similarities and differences in co-creation approaches between academic and practitioner-focused literature.

Results

Systematic Methods Overview

Search 1: Empirical Research

For academic literature, the full set of literature from the Health CASCADE Co-Creation Database version 1.5—a total of 13,501 papers—were identified as relevant for screening. There were 2 subsequent screening processes for this literature: (1) grouping the papers by whether a method was present or not (n=13,501) and (2) screening the papers by study type (n=6472). During this 2-step screening process, a total of 10,905 papers were excluded, and 2590 papers were included.

The extraction of methods from academic literature involved 2 steps: first, method names were identified through a recursive search in Rayyan, and then, these names were used to determine their frequency in the final set of included literature. The identified methods were then subjected to co-occurrence analysis.

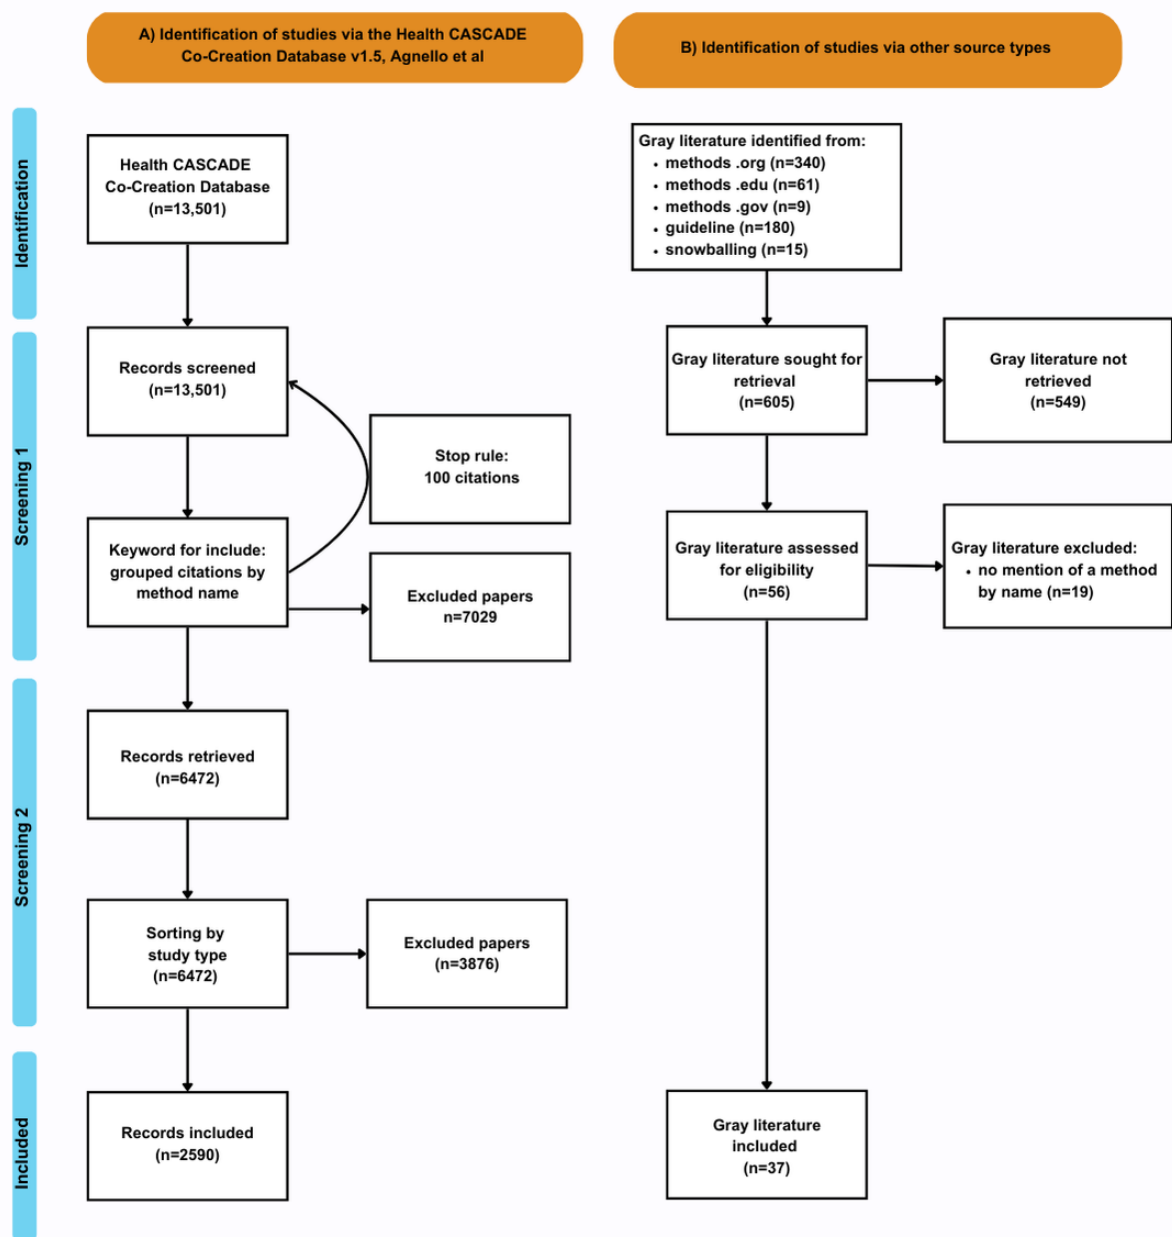
Search 2: Gray Literature Search

A parallel search was conducted in gray literature, and a total of 605 materials were identified. As shown in Figure 1, there were two steps to screening the gray literature: (1) screening for relevance based on 1 set of selection criteria (n=56) and (2) screening the extracted full text based on a different set of

selection criteria (n=37). These 2 screening steps resulted in the exclusion of 568 materials and the inclusion of 37 materials.

Method names from gray literature were manually extracted using a predetermined extraction form. The frequency of each method was calculated by counting its appearances across the included materials. For example, a method found in 5 different sources was assigned a frequency of 5.

A total of 2590 papers were included, and the gray literature search resulted in the inclusion of 37 materials. The adapted PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of this parallel process is shown in Figure 1, and a filled-in PRISMA checklist is provided in Multimedia Appendix 3.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the screening processes for the systematic methods overview with two sources as follows: (A) academic literature and (B) gray literature.


Analysis

We assessed the relative presence of methods in the different types of literature by examining their frequency of occurrence. In academic sources, the frequencies ranged from 349 to 1, reflecting the varying specificity of method names. For example, "interview" appeared in 124 papers, while the more specific "Lego serious play" method was found in only 1 paper. Examples of the most and least frequent methods in academic literature are listed in Table 2, with the full set of methods and their frequencies provided in Multimedia Appendix 4.

In terms of gray literature, frequencies were manually tallied based on the extraction tables, ranging from 12 to 1. Examples of the most and least frequent methods sourced from gray literature are listed in Table 3, with the full set of methods and their relative frequencies provided in Multimedia Appendix 5.

Of the 252 methods extracted from academic literature, 91.3% (n=230) co-occurred within the same title or abstract. The resulting Sankey diagram visualizing this co-occurrence is too large to include in this manuscript and is therefore presented as an open-access figure on Zenodo [33], allowing readers to delve into the detailed co-occurrences and gain a deeper understanding of methods used in co-creation research. The full dataset of co-occurrence is provided in Multimedia Appendix 6. For clarity, the methods were categorized into three groups: (1) qualitative methods; (2) participatory methods; and (3) quantitative, mixed, and ethnographic methods, which are each visualized in separate Sankey diagrams.

Table 2. Examples of the most and least frequent methods that were sourced from academic literature. The percentage represents the percentage of total method hits.

Method name	Values (n=3520), n (%)
Most frequent methods	
Survey	349 (9.91)
Focus group	337 (9.57)
Photo voice	189 (5.37)
Group discussion	150 (4.26)
Questionnaire	142 (4.03)
Semistructured interview	139 (3.95)
Interview	124 (3.52)
Least frequent methods	
Consensus workshop	1 (0)
Social mapping	1 (0)
Participatory theme elicitation	1 (0)
Lego serious play	1 (0)
User persona	1 (0)
Emotional touchpoints	1 (0)
Structured brainstorm	1 (0)

Table 3. Examples of the most and least frequent methods that were sourced from gray literature. The percentage represents the percentage of total extracted method hits.

Method name	Values (n=1151), n (%)
Most frequent methods	
World café	12 (1)
Focus group	10 (1)
Role playing	9 (1)
Persona	8 (1)
Brainstorming	7 (1)

What if brainstorming	1 (0)
Trigger storming	1 (0)
The blue sky vision exercise	1 (0)
System mapping	1 (0)
Sorting important to/for	1 (0)
Sky the limit brainstorm	1 (0)
Service safari	1 (0)

The co-occurrence analysis of the qualitative methods, shown in Figure 2, features 22 source methods (qualitative) on the left and 149 target methods (multiple types) on the right side of the Sankey diagram. This analysis revealed that focus group, one of the most frequently used methods, often co-occurs with other qualitative methods like group discussion, interviews, and in-depth interviews, as well as qualitative analysis such as content analysis and thematic analysis. Additionally, focus group commonly co-occurs with participatory methods like prototyping, photo voice, storytelling, and various ethnographic methods, including participant observation, field notes, and narrative.

The co-occurrence analysis of the participatory methods, visualized in Figure 3, includes 42 source methods (participatory) on the left and 132 target methods (multiple types) on the right side of the Sankey diagram. This analysis highlighted that some of the most frequently used methods, such as photo voice, and prototyping, often co-occur with other participatory methods like experience prototyping, concept mapping, and participatory mapping. Photo voice is also commonly linked to narrative and group discussion, and a mix of ethnographic and qualitative methods, including thematic analysis, field observation, and various types of interviews. Additionally, deliberative workshops frequently co-occur with other deliberative or participatory methods such as user committee, participatory budgeting, fuzzy cognitive mapping, and collective reflection.

The co-occurrence analysis of quantitative, mixed, and ethnographic methods is presented in Figure 4, with 24 source methods (quantitative, mixed, and ethnographic) on the left and 156 target methods (multiple types) on the right side of the Sankey diagram. This analysis showed that the most frequently used method, survey, often co-occurs with other high-frequency methods like questionnaire and narrative. Survey is also strongly linked to qualitative methods such as focus groups, group discussions, various types of interviews, and qualitative analysis methods. The ethnographic method, field notes, is associated with a combination of ethnographic and participatory methods, including participatory observation, participatory reflection, and group model building.

The VOSviewer co-occurrence analysis of keywords related to methodologies in the title and abstracts of the academic literature is visualized as a network map in Figure 5. This map includes 34 keywords, interconnected a total of 385 times, and organized by VOSviewer into 4 clusters [32]. Cluster 1 (in yellow) includes terms related to participatory research, community-based participatory research, and community engagement or participation. Cluster 2 (in teal) focuses on various forms of co-creation, value co-creation, and design methodology approaches. Cluster 3 (in pink) includes coproduction, co-design, public and patient involvement, and user involvement. Cluster 4 (in blue) groups together different forms of participatory action research and action research. The main terms across these 4 clusters are co-creation, coproduction, co-design, participatory action research, and participatory research. Further details about these clusters are provided in Table 4.

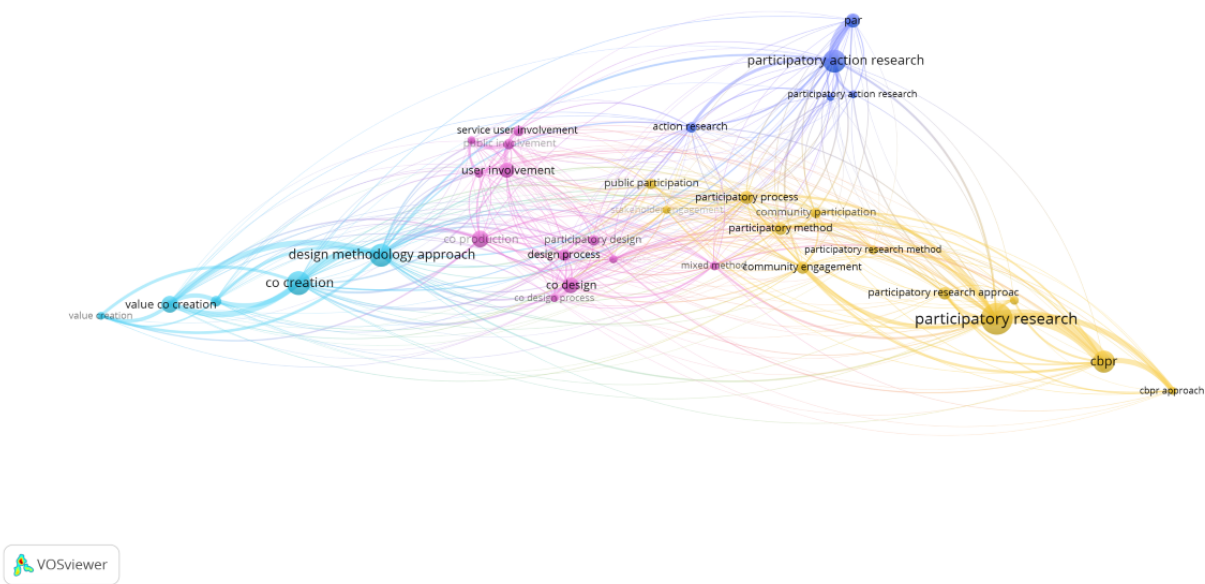
Figure 2. Sankey diagram illustrating the co-occurrence of qualitative methods with other research methods in academic literature. Source methods are displayed on the left side (n=22) and target methods are on the right (n=149). The thickness of the line indicates the frequency of co-occurrences across the literature, with thicker lines representing more frequent co-occurrences between methods.
Figure 3. Sankey diagram illustrating the co-occurrence of participatory methods with other research methods in academic literature. Source methods are displayed on the left side (n=42) and target methods are on the right (n=132). The thickness of the line indicates the frequency of co-occurrences across the literature, with thicker lines representing more frequent co-occurrences between methods.
Figure 4. Sankey diagram illustrating the co-occurrence of quantitative, mixed, and ethnographic methods with other research methods in academic literature. Source methods are displayed on the left side (n=24) and target methods are on the right (n=156). The thickness of the line indicates the frequency of co-occurrences across the literature, with thicker lines representing more frequent co-occurrences between methods.
Figure 5. VOSviewer generated an image representing the co-occurrence of keywords representing methodologies across the title and abstracts of the academic literature. The size of the keyword bubble represents its importance in the number of co-occurrences. Each line represents a co-occurrence of the terms. cbpr: community-based participatory research; par: participatory action research; ppi: public and patient involvement.


Table 4. Co-occurrence of methodologies in academic literature.

Methodology (Cluster)	Co-occurrence links (n=385), n (%)	Related methodologies
Participatory research (yellow)	31 (8)	Participatory process, participatory method, participatory research approach, participatory research method, participatory research project, community-based participatory research, community-based participatory research approach, public participation, stakeholder engagement, community engagement, and community participation.
Co-creation (teal)	29 (8)	Co-creation process, design methodology approach, value co-creation, and value creation.
Coproduction (pink)	28 (7)	Co-design, co-design process, design process, iterative process, mixed method, participatory design, patient involvement, public and patient involvement, public involvement, and user involvement.
Participatory action research (blue)	25 (7)	Action research, participatory action research, participatory action research project, and participatory action research approach.

The VOSviewer co-occurrence analysis of the keywords related to fields in the title and abstracts of papers in the database is visualized as a network map in Figure 6. This map includes 150 keywords, interconnected 181 times and organized by VOSviewer into 48 clusters [32]. Focusing on the 8 most prominent clusters, which contain at least 5 keywords each, cluster 1 (in red) includes health service research, community health services, medical education, occupational therapy, primary health care, and social work. Cluster 2 (in blue) covers health promotion, health policy, and school health services. Cluster 3 (in green) includes dementia, emergency nursing, home care services, home nursing, long-term care, and terminal care. Cluster 4 (in purple) features palliative care, emergency medical services, and hospital emergency services. Cluster 5 (in orange) focuses on women's health, maternal welfare, rural health, and supported employment. Cluster 6 (in yellow)

includes humanities, pediatric hospitals, organizational innovation, quality health care, and vaccinations. Cluster 7 (in brown) is centered on health and nursing education. Cluster 8 (in teal) covers family health, child development disorders, learning disorders, and self-evaluation programs. Full details on these clusters are provided in Table 5.

This study extracted a total of 956 methods used in co-creation, which were then categorized into 3 distinct categories based on their sources. Of these, 16% (155/956) were found exclusively in academic literature, 74% (704/956) were sourced solely from gray literature, and 10% (97/956) were identified in both academic literature and gray literature. The comparison of these categories is visualized in Figure 7, and a complete list of methods per source type is provided in Multimedia Appendix 7.

Figure 6. VOSviewer generated an image representing the co-occurrence of keywords representing fields across the titles and abstracts of the academic literature. The size of the keyword bubble represents its importance in the number of co-occurrences. Each line represents a co-occurrence of the terms.
Table 5. Co-occurrence of fields and diseases in academic literature.

Field (cluster)	Co-occurrence links (n=181), n (%)	Related topics
Health services research (red)	46 (25)	Community health services, medical education, health service accessibility, occupational health, occupational therapy, primary health care, social work, and substance-related disorders.

Discussion

Principal Findings

This study is the first systematic methods overview of co-creation, identifying and delving into both academic and gray literature to extract 956 methods from 2627 sources, analyzing these methods and their interrelationships within and across source types. This study can facilitate the identification of methods suitable for co-creation endeavors, while also highlighting discrepancies between co-creation in research and nonacademic contexts. By offering a comprehensive and reliable snapshot of co-creation and its associated methods, this research enhances transparency regarding how co-creation is executed in both research and practice in the health research fields. The study serves as a foundational resource, providing an evidence-based and systematic inventory of methods, as well as shedding light on which methods are commonly used in conjunction with one another across the health research fields. This innovative approach to conducting a systematic methods overview enables the comprehensive analysis of a vast amount of literature and methods, offering valuable insights into the landscape of co-creation practices and methods globally and across disciplines.

Principal Results

A notable strength of this study lies in its utilization of methods sourced from a published and high-quality database of co-creation literature spanning from 1970 to 2022. This literature represents the largest known dataset of methods used in co-creation. This study serves as a foundational work that can be used to elucidate the interrelationships between different co-creation methods and co-creation processes. This study adopts an unbiased approach by providing a comprehensive overview of current co-creation practices, without prescribing specific methods or recommendations. By providing an overview of current co-creation practices, this study establishes a platform for further research and analysis into the various ways in which people design and execute co-creation. Furthermore, this study reveals a stark difference between academic and practitioner approaches to co-creation, highlighting the importance of understanding and bridging these disparities.

Multimethod Approach

In the realm of research methodologies, each type has its unique characteristics and applications. Recently, Messiha et al [11] discussed how naïve realism (a singular objective reality) often favors quantitative methods, while relativism (multiple realities exist) tends to favor qualitative approaches. For instance, approaches such as qualitative, quantitative, and ethnographic studies offer different lenses through which to explore phenomena. Qualitative methods delve into the subjective experiences and perspectives of individuals, capturing rich narratives and deep insights; valuing methodological pluralism and diversity rather than universal truths [34]. Quantitative methods, on the other hand, focus on numerical data and statistical analysis to uncover patterns and relationships to uncover universal truths about reality. Finally, participatory methods emphasize collaboration between researchers and stakeholders; unlike traditional research methods, which prioritize objectivity, participatory methods prioritize engagement and collective decision-making [27]. Furthermore, Messiha et al [35] found that applying methodological principles of critical realism (recognizes independent reality and acknowledges multiple perspectives), namely using multiple method types to understand complex phenomena, enriched the evidence base for co-creation in public health research.

This study reveals that co-creation represents a fusion of various types of methods, and well-known methods for analysis, such as thematic analysis, are combined with qualitative methods like interviews. Co-creation combines methods for qualitative inquiry and analysis, quantitative analysis, ethnographic observation, and participatory collaboration. This amalgamation of methods offers great potential for generating innovative solutions, fostering stakeholder engagement, and addressing complex challenges. However, the convergence of multiple methods also introduces challenges, including potential divergences in processes and outcomes between co-creation projects. Overall, the mixed nature of co-creation presents both opportunities and challenges.

The Gap Between Academics and Practitioners

While analyzing the data within this study, a clear gap exists between the practices reported in academic literature and those used by practitioners in nonacademic settings. This divergence

may stem from various factors, including differences in reporting styles, publication platforms, and the emphasis placed on outcomes versus process documentation. Academic publications often prioritize the reporting of research outcomes and their impact, allocating limited space for detailing the intricacies of the co-creation process. Conversely, practitioners may opt to disseminate their co-creation endeavors through alternative channels, such as reports, case studies, or web-based platforms, where they have more flexibility to document their methods. However, this discrepancy in reporting practices poses a significant challenge for the scientific community, which is well documented by various researchers who are calling for researchers to transparently document the entire process of co-creation, including the methods [6,14,15]. Without detailed documentation of each method used in the co-creation process, replication and validation of findings become challenging. Furthermore, the lack of transparency in documenting co-creation methods hinders knowledge sharing and collaboration among researchers and practitioners. This gap underscores the importance of adopting standardized reporting guidelines and best practices for documenting co-creation, regardless of the publication platform.

One notable observation is the prevalence of co-creation methods outside of academic literature. While academic research may provide valuable insights into academic rigor, and application of theory, it appears that the majority of the co-creation methods are published on nonacademic platforms. This raises questions about the transparency and documentation of co-creation processes. Efforts to bridge the divide between academic and practitioner perspectives on co-creation are essential for advancing knowledge, promoting collaboration, and maximizing the impact of co-creation initiatives. By fostering greater transparency, documentation, and knowledge sharing, researchers and practitioners can enhance the rigor and reproducibility of co-creation.

Comparison With Prior Work

Grindell et al [16] underscore the distinctiveness of collaborative approaches like co-creation, co-design, and coproduction, contrasting them with traditional applied health research methodologies; emphasizing that these coapproaches are designed to foster meaningful engagement with a broader range of cocreators, including those not typically involved in research. However, the network analysis of the methodologies in the final dataset reveals a different story. While coapproaches and participatory research methodologies are prevalent, the actual methods used in these projects fall short of truly embracing collaborative engagement. This highlights a disconnect between the intended methodological goals and the practical application of collaborative methods.

Our findings align with recent work by Slattery et al [14] and Smith et al [15], who reported similar trends in the types of methods being used. Slattery et al [14] observed that the most frequently used methods were focus groups, interviews, and surveys, with less frequent use of methods like citizen juries and voting. Smith et al [15] also found that commonly reported methods included interviews, focus group discussions, surveys, discussion meetings, and workshops. This consistency across

studies is encouraging, as it underscores a broader trend in the field and validates our findings about the dominant reliance on certain qualitative methods.

Louise and Annette [12] highlight the significance of using participatory methods, emphasizing their potential applicability to intervention development and their capacity to transcend traditional boundaries. When executed effectively, participatory methods offer numerous benefits, including genuine stakeholder involvement, a holistic understanding of multiple perspectives, an iterative and investigative approach, and a commitment to enacting meaningful change for those directly affected by the outcomes [12]. Maenhout et al [6] also found that co-creation is feasible with adolescents with intellectual disabilities if the correct methods are selected, specifically creative methods. Furthermore, studies favoring creative methods found that design and participatory approaches effectively engaged cocreators with their emotions, and abilities, and retained their involvement throughout the process [16,36]. Prototyping methods were found to be valuable for translating knowledge into tangible objects, while visual design methods facilitated the rapid communication of ideas in an accessible manner. The utilization of creative methods was observed to promote a shared understanding of the problem and identify critical needs, thus addressing power differentials and fostering a sense of ownership among stakeholders [16].

Grindell et al [16] illustrated how researchers rely on qualitative research methods (such as focus groups, observations, and interviews) when other, more creative methods, can achieve the same aim (such as role-playing, personas, and user journeys). These findings underscore the importance of using participatory and creative approaches in co-creation processes to build trust, confidence, and collaborative solutions. Considering the documented benefits of using these types of methods, this study reveals that the way people are currently cocreating is leaning heavily on qualitative methods. While qualitative methods provide rich insights into individual subjective experiences and perspectives, incorporating diverse approaches such as creative or participatory methods could further enhance stakeholder engagement, understanding, and problem-solving in co-creation processes.

There is a growing concern regarding participation fatigue in co-creation, alongside the risk of heightened inequity when only specific demographic groups engage, potentially leading to disengagement [37,38]. Amundrud et al [38] stress that co-creation should empower individuals to participate actively as citizens with the chance to genuinely influence outcomes. Various methods, including focus groups, one-on-one discussions, and creative workshops, are utilized for involvement and engagement. However, patients increasingly advocate for greater autonomy in determining the extent and nature of their involvement in research processes. In contexts like coproduction and participatory action research, traditional distinctions between researchers and participants are challenged, resulting in blurred boundaries and a reassessment of power dynamics [12]. This study reveals that the multi-method approach to co-creation primarily integrates various qualitative methods, while more creative or participatory methods are often found in nonacademic gray literature. Consequently, academics appear

to rely solely on qualitative methods and rarely draw from nonacademic sources for guidance and inspiration. This heavy reliance on qualitative methods may increase the risk of disengagement, reassessment of power dynamics, or participation fatigue.

Consequences and Future Research

This systematic inventory of methods used in co-creation provides an interesting dataset that should be mined, for instance, to make further distinctions between the methods and their intended purpose and impact. We intend to use it to develop a taxonomy facilitating more consistent and better reporting, which other reviews highlighted as an important gap [14,15]. In turn, this could facilitate a more robust evaluation of the impact of co-creation, which is fundamental for the progression of this methodology [15,16]. Co-creation researchers could make use of such a taxonomy or apply our novel artificial intelligence and data science approach, to extract additional information about the methods used in co-creation, mirroring the approach of the Human Behavior Project for behavior change science [39]. This approach could help identify specific clusters of methods or sequences of methods that are particularly effective in certain contexts, for certain purposes, and in certain phases of the co-creation process. The data generated in this study also raises interesting questions about how and when collective intelligence and creative methods are best placed or used, and how scientific practices might have to change to provide room for effective collective creativity based on evidence.

Limitations

Although we achieved our objectives by conducting a systematic overview of methods, our approach has some limitations including single screening of the gray literature and the lack of full-text screening of the academic literature. However, we recognize that this work was conducted in a peer-reviewed, precurated database of co-creation literature, and the complexity of the screening of gray literature was not high enough to necessitate double screening and extraction.

Conclusions

This study has yielded the first systematic overview of methods utilized in co-creation, intending to provide researchers and practitioners with a comprehensive understanding of methods used in co-creation to date. By increasing awareness of methods used in co-creation, we seek to unlock the full potential of co-creation and contribute to its advancement as a transformative methodology for research and practice. The analysis of methods sourced from both academic and gray literature revealed a rich array of methods used in co-creation, spanning participatory, qualitative, quantitative, mixed, and ethnographic approaches. This diversity underscores the versatility of methods, which can adapt to varying study objectives, target groups, contexts, and other influencing factors. However, it also highlights the need for more detailed guidance on method selection, method grouping, and application to ensure co-creation remains effective and meaningful.

This systematic exploration of co-creation methods offers valuable insights for individuals currently involved in co-creation, as well as those aspiring to participate in it. By illuminating the diverse landscape of co-creation methods, this study aims to enable researchers and practitioners to make informed decisions and enhance methodological rigor and innovation in co-creation. Through continued research and collaboration, we can further advance co-creation as a dynamic and impactful approach for addressing some of the most pressing complex or wicked public health challenges.

Data Availability

The inventory of methods sourced from both academic and gray literature is available on Zenodo under the name "Co-Creation Methods Inventory: Sourced from Academic and Grey Literature" [40]. The Sankey diagram is available on Zenodo under the name "Co-occurrence of Methods in Co-Creation: A Sankey Diagram" [33].

Authors' Contributions

DMA, AS, and SC conceived the study, and DMA led the study. DMA wrote the manuscript. AS, DMA, GB, and SC edited the manuscript. DMA developed the search strategy. DMA conducted the search in academic and gray literature. DMA executed the screening steps, and extraction, conducted the bibliometric analysis, and generated all the figures. GB conducted the method frequency and co-occurrence analysis. The manuscript was then reviewed and approved by all authors.

Abstract

Background: Patient pathways (PPs) are presented as a *panacea solution* to enhance health system functions. It is a complex concept that needs to be described and communicated well. Modeling plays a crucial role in promoting communication, fostering a shared understanding, and streamlining processes. Only a few existing systematic reviews have focused on modeling methods and standardized modeling languages. There remains a gap in consolidated knowledge regarding the use of diverse visual modeling languages.

Objective: This scoping review aimed to compile visual modeling languages used to represent PPs, including the justifications and the context in which a modeling language was adopted, adapted, combined, or developed.

Methods: After initial experimentation with the keywords used to describe the concepts of PPs and visual modeling languages, we developed a search strategy that was further refined and customized to the major databases identified as topically relevant. In addition, we consulted gray literature and conducted hand searches of the referenced articles. Two reviewers independently screened the articles in 2 stages using preset inclusion criteria, and a third reviewer voted on the discordance. Data charting was done using an iteratively developed form in the Covidence software. Descriptive and thematic summaries were presented following rounds of discussion to produce the final report.

Results: Of 1838 articles retrieved after deduplication, 22 satisfied our inclusion criteria. Clinical pathway is the most used phrase to represent the PP concept, and most papers discussed the concept without providing their operational definition. We categorized the visual modeling languages into five categories: (1) general purpose–modeling language (GPML) adopted without major extension or modification, (2) GPML used with formal extension recommendations, (3) combination of 2 or more modeling languages, (4) a developed domain-specific modeling language (DSML), and (5) ontological modeling languages. The justifications for adopting, adapting, combining, and developing visual modeling languages varied accordingly and ranged from versatility, expressiveness, tool support, and extensibility of a language to domain needs, integration, and simplification.

Conclusions: Various visual modeling languages were used in PP modeling, each with varying levels of abstraction and granularity. The categorization we made could aid in a better understanding of the complex combination of PP and modeling languages. Standardized GPMLs were used with or without any modifications. The rationale to propose any modification to GPMLs evolved as more evidence was presented following requirement analyses to support domain constructs. DSMLs are infrequently used due to their resource-intensive development, often initiated at a project level. The justifications provided and the context where DSMLs were created are paramount. Future studies should assess the merits and demerits of using a visual

XSL•FO
RenderX

modeling language to facilitate PP communications among stakeholders and use evaluation frameworks to identify, modify, or develop them, depending on the scope and goal of the modeling need.

Introduction

Background

The concept of patient pathways (PPs) has been widely used to improve health system functions across a range of health conditions, care levels, and regions [1]. PP implementation spans from emergency care [2] to specialized fields such as cancer care [3,4], with recent adaptations to address conditions like the COVID-19 pandemic [5]. Effectiveness reviews of PP implementation indicated improved patient outcomes, reduced length of stays and cost of care, enhanced teamwork, and improved documentation [6-11]. Depending on the type of pathology and nature of the organization where the concept was introduced, the evidence on the effect of the outcomes is inconclusive. The confusion around the concept [12], the variability in its quality [13], and the deficiencies in the process of contextualization were among the implicated factors in the effectiveness studies that reported on patient, health system, and finance outcomes [14]. Seys et al [14] indicated the dual complexity, that is, the PP itself is a complex concept implemented in a complex health system. This calls for clarity in all aspects, including simplification of the description to facilitate communication and common understanding to enhance its effectiveness [15-17].

Multifaceted factors pose varying challenges to maximizing the benefits of PPs. Yet, there is an ongoing discussion on the unified definition and frameworks for their development, implementation, and evaluation [12]. Efforts are being made to synthesize and consolidate the various terms used and their definitions since the first identification of several alternative names is in action [18]. Furthermore, 84 different definitions along with the differing focus of pathways in the United States and the United Kingdom were identified shortly after their use [19]. One of the pioneering definitions, also adopted by the European Pathway Association, states that "A care pathway is a complex intervention for the mutual decision-making and organization of care processes for a well-defined group of patients during a well-defined period" with characterizing features [20]. To identify studies for an effectiveness review, Kinsman et al [21] proposed an operational definition, later refined by Lawal et al [22], and validated it in an emergency medicine review [23]. The use of terms evolved from merely clinical orientation of care provision (clinical pathways) to the inclusion of more stakeholders and from elements of care organization (care pathways) to the inclusion of multiple levels of care (integrated pathways or integrated care pathways) to develop a patient-focused systemic approach (PPs). Schrijvers et al [24] argued that adding qualifiers such as in "integrated care pathway" is unnecessary because the care pathways are integrated by definition. Such comments seem not to have held on because the most recent concept analysis paper proposed an even longer term, a "patient-centered care pathway," showing an increase introduction of terminologies [12]. Their proposed definition, "a long-term and complex managerial intervention adopting a systemic approach, for a well-defined group of patients who journey across the entire continuum of care, from prevention and screening to recovery or palliative care," with several attributes [12], however, is indicative of perspectives added toward comprehensive and patient-centric concepts. The key characteristics and elements were listed, and their importance was stressed beyond the proposed definitions in each article [12,19,21,22], with slight variations. In this review, we use "patient pathways" to represent the concept from a patient-centered care perspective [12] while using the criteria proposed for a Cochrane systematic review [21,22] to identify the articles. Patient journey studies, which focus on patient-centric mapping and analysis of health care delivery processes, are increasingly being introduced to the scene [25]. To simplify, we use "patient pathways" to represent a plan as a blueprint of the care process, while patient journey denotes an individual experience of the planned PPs revealed retrospectively. In this review, we used different terms interchangeably in the identification and review of articles. Confusion in the definition and conceptualization leads to variabilities in the analysis and modeling of PPs [12].

The rampant siloed and local productions with varying representations of a PP [1] call for more standardized ways to describe and communicate PP to have a shared understanding of the concept. This can be argued in the same manner as consensus frameworks have been proposed [12,14,26,27] in an attempt to standardize the stepwise development, implementation, and evaluation of PPs. The standardization process starts with the modeling languages that are used to describe and communicate PPs. Particularly, visual modeling "not only enables easy interpretation but moreover denotes a useful means for communication and understanding" [28] of a process. Graph-based formalism is one of the two most common process-modeling approaches [29]. The benefits of visual modeling over other forms of representation have been extensively discussed in business process modeling, although there remains a scarcity, particularly in the PP domains, of effectiveness studies using a traditional approach [29-31]. Lack of a common language also exacerbates the interoperability challenge in the increasingly digitized care processes, including digitized PPs integration to other electronic patient records and quality improvement digital tools [32,33].

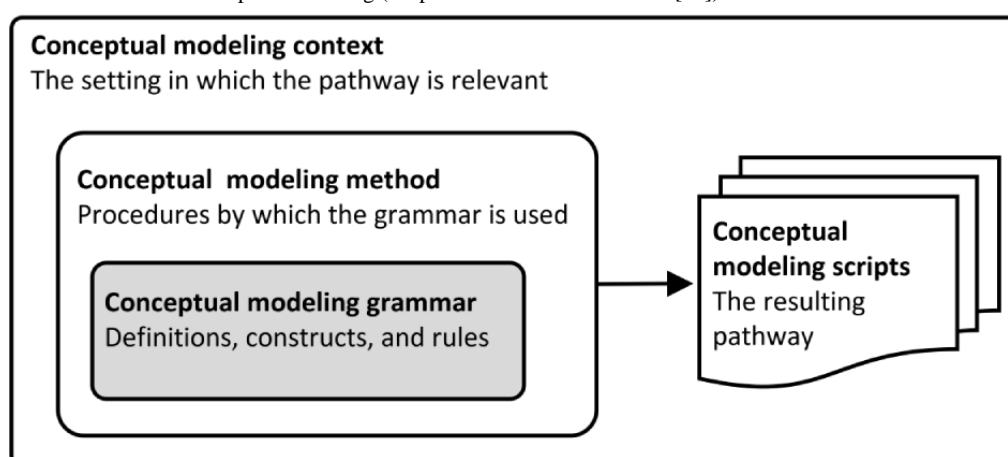
Prior Systematic Reviews on Modeling Languages

The modeling of PPs can be done to understand and analyze the current state, which is often referred to as an "As-Is" model, or a redesigned or improved PP modeling can be done in a "To-Be" model. The "As-Is" model is often "data-driven" modeling that uses clinical data from various electronic tools, for example, electronic health records (EHRs) and registers. Clinical data-based mathematical modeling often focuses on exploring the patient journey retrospectively, the focus being on simulation studies, data mining, machine learning, and artificial intelligence to predict the most efficient path for a care process [33,34]. The "To-Be" model considers PPs as a complex concept, which is prescriptive in nature and created by a multidisciplinary team. One of the challenges for this model is the absence of a common process-modeling language that is complex enough to incorporate all the necessary aspects in a model while being simple enough to be used by nonmodeling domain experts, either manually or digitally [35].

There are many different process-modeling languages coming from different scientific traditions, and their characteristics and intended use vary greatly [36-38]. However, the complex nature of health care delivery has led to a modest uptake of business process–modeling languages that are shown to be useful in sectors with predictable work processes [39]. Although choosing a modeling language has generally been a challenge [37,38], there are a few systematic reviews that have targeted specific modeling languages or notations in the care process [39-41]. Specific to PP-related concepts, there is a comprehensive review on modeling [42] while other reviews are more inclined toward data-driven pathway description and optimization [36]. The most similar review to our scoping review was conducted by Mincarone et al [37] in which only standardized modeling languages were included on the entirety of care process, which is wider in scope than PPs. To improve the domain expressiveness of a modeling language, extending or combining a general purpose–modeling language (GPML) or developing a domain-specific modeling language (DSML) can often be done. To our knowledge, the justification for and the "how" of such efforts have not previously been summarized. In addition, focusing on standardized languages and notations potentially excludes DSMLs, which are costly to develop but may display higher expressiveness than the GPMLs, including their domain-extended versions.

Goal of This Scoping Review

This review's scope is to include both DSMLs and standardized GPMLs with emphasis on how they were used to meet the domain-specific requirements. Our focus is on visual modeling languages but not on 1D textual languages as delineated by Moody [43]. Visual languages in this case include ontological modeling languages that depict terms and concepts with their relationships in a visual manner. Most of the PPs are described in natural languages, with flowcharts and tables accompanying for simplicity, but we did not include simple flowcharts and diagrams as a visual notation. Wand and Weber [44] introduced a framework for research on conceptual modeling consisting of 4 elements to ease communication. To reduce potential confusion around terms in this scoping review, we introduce an adapted version of this model (Figure 1, adapted from Wand and Weber [44]). The modeling *grammar* constitutes the inner core because it provides definitions, constructs, and rules to produce a model. The modeling *script* is the end product of the modeling process. The modeling *method* describes how grammar can be used to produce a script. The modeling *context* has a wider perspective and describes the setting in which the modeling occurs. We do not intend to provide a comprehensive review of the *script* because our focus lies at the core of the framework. While grammar is the core, modeling method and context are of interest in this review because this review aims to contribute to the different ways in which a modeling language is presented.

Figure 1. Framework for research on conceptual modeling (adapted from Wand and Weber [44]).


Review Questions

A scoping review was conducted to systematically identify and map visual modeling languages used to describe and communicate PPs. The review addresses the following review questions:

- Review question 1: Which visual modeling languages were used in the modeling of PPs?
- Review question 2: What are the justifications provided to adopt, adapt, or develop a visual modeling language to describe and communicate PPs?

- Review question 3: Within what contexts are the visual modeling languages applied in PP projects?

Methods

Overview

The reporting of this review follows the systematic review extension for scoping reviews PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) [45]. We followed the methodological framework proposed by Arksey and O'Malley [46], which was further improved by Levac et al [47] and the Joanna Briggs Institute [48], to conduct this scoping review. The review questions were proposed and refined after a thorough exploration of the existing synthesis on the topic, as presented earlier. The rest of the framework is integrated into the reporting format as presented in subsequent sections.

Eligibility Criteria

To be included in the review, papers needed to satisfy the operational definitions (Textbox 1) for both PP and a visual modeling language. The article's main aim could be either a theoretical discussion or empirical research on a modeling language that is created, adopted, adapted, or combined. Peer-reviewed journals, conference and congress proceedings, and gray literature that are accessible on the internet, regardless of the geographical location, type of health condition, and publication date up until the last systematic search dated November 21, 2022, were eligible. For papers published in a conference proceeding, we searched for and opted to include the more complete peer-reviewed publication in a scientific journal, if it existed, in expectations of detailed information. Only papers published in English were considered. No restrictions on study design, population characteristics, type of health care facility, or level of care were applied.

Papers were excluded if their focus was mainly on mathematical models, simulation studies, or machine learning without having information to report on the visual graphical presentation of a model for facilitating communications, including to nonmodeling expert stakeholders. Comprehensive reviews [35,36,42] have been done to cover modeling methods and languages applied in data-driven retrospective models. According to the conceptual framework proposed by Wand and Weber [44], we excluded papers that have primarily emphasized the presentation of a pathway using a known modeling language without an adequate description of how it is being used differently in the domain it is being applied to. Papers uniquely reporting modeling tools (software artifacts) without discussing the underlying modeling language used, or its semantics and ontologies for reasons of extension or visual presentation were excluded. Ontology-based and semantic modeling languages, with or without the inclusion of visual modeling as an output, were included in the review given the aim of this study is to facilitate communication of PPs among the stakeholders. According to a review by Zarour et al [49], representation of business process model and notation (BPMN) extensions can be of one of the 3 formats: metamodel, XML Schema, or graphical elements, and therefore, we included metamodels in this review.

We excluded simple flowchart presentation of pathways, which is the most common description and communication approach in medical domain but is now headed toward extinction [42] because the more mature notations were extensions of it and the relevance of including and discussing its use was perceived to be not adding to the standardization and wide acceptance of visual modeling for PP discussion. The enforcement of inclusion criteria began with the development of search strategies broadly and gradually narrowed down during the selection process. In the initial screening stage, articles were included if they mentioned or described 2 concepts, PPs and visual modeling language, in the abstract. The second stage involved a closer examination of these concepts. For instance, papers mentioning terms related to PPs but discussing broader concepts such as general care processes were excluded. Similarly, articles mentioning a visual modeling language but failing to describe how it was used in their research context were also excluded.

Textbox 1. Components and Definitions according to population, concept, and context framework proposed by the Joanna Briggs Institute.

Population and Participants

- Regardless of the professional background of the experts behind the modeling language; irrespective of the health condition and level of care. The paper can be a theoretical exploration of how existing process-modeling languages, particularly general purpose–modeling languages (GPMLs) applied to other domains, can be adopted or adapted. This extends to the development of domain-specific modeling languages (DSMLs) for describing and communicating patient pathways (PPs) to facilitate common understanding among intended stakeholders.

Concept

Two concepts are as follows:

- Patient pathways: We based the PPs concept definition on a refined operationalization criterium by Kinsman et al [21] and by Lawal et al [22] in that they used it to identify articles for a Cochrane systematic review. Articles primarily focusing on theoretical discussions of a modeling language without empirical studies (including a case study for the sake of demonstration) might not reflect the aforementioned criteria. Such articles were included as long as the authors clearly stated that the application is for patient pathway concepts. As the terms used have evolved through time and are sometimes used interchangeably, we relied on the concept definition and explanations by the authors. Papers containing terms and phrases that are often used interchangeably, such as care process, workflow, etc were excluded if the paper did not explicitly state the PP concept dealing both with the organization and clinical part of the care.

- Visual modeling language: general-purpose or domain-specific modeling languages that may or may not be standardized, can be graphical, rule-based, or combined presentations, aimed at describing a PP, regardless of the origin and the extent to which a given modeling language has been implemented. The modeling language can be adopted, adapted, combined (as in complementary combinations of stand-alone modeling languages), or developed to model a PP and can or cannot have digital applications and tools accompanying the language. Modeling languages used in mathematical models, simulations, artificial intelligence, and machine learning are outside the scope of this review

Context

- The modeling language applied regardless of disease or health condition, treatment and intervention options, clinical settings, and service delivery level (primary, secondary, or tertiary care facilities). No restrictions based on geographical location and scope within the location.

Information Sources

We conducted searches in the following databases: MEDLINE via PubMed, PsycINFO, Embase, CINAHL, and Scopus after iteratively developing search strategies. We used Joanna Briggs Institute [48] population, concept, and context framework to exhaustively list search terms under each component. The following initial search terms were used: "Patient Pathway*," "Care Pathway*, "Clinical pathway*," along with the Medical Subject Heading term "Critical pathway/" in MEDLINE and CINAHL databases to decide on what additional terms to combine with them to identify papers relevant to our inclusion criteria. For words describing modeling language and related concepts, terms like "language*," "model*," "framework*," "formalism*" were used and search was expanded by including additional similar terms from retrieved articles. We narrowed the scope of the terms by adding descriptors. The search strategies were drafted in consultation with an experienced librarian and customized to each database after iterative rounds of improvements. We limited our search strategy to the title and authors' keywords after discovering that including the abstract greatly increased the number of search hits. The final search strategies for each selected database are available in Multimedia Appendix 1. Gray literature search and hand searches of relevant articles referenced by included papers were done by the first author. After learning that the IEEE website has useful collections on the topic, we made searches in addition to the initial database search. As a forward search strategy, Web of Science and Google Scholar databases were used.

Selection of Sources of Evidence

The librarian used EndNote (Clarivate) to deduplicate the retrieved articles. After importing them into Covidence (Veritas Health Innovation Ltd) software, any remaining duplicates were identified and automatically removed using the software's built-in feature. In total, 2 reviewers independently screened publications in 2 stages after importing all the retrieved papers into the Covidence software [50]. To have consistency in the screening process, we defined and discussed the inclusion and exclusion criteria and documented them in the Covidence software for easy referencing and to use the automated word detection features of the software. Accordingly, the 2 reviewers conducted the screening of the title, index words, and abstract at stage 1 and full-text review screening at stage 2 guided by the predetermined inclusion and exclusion criteria. In case of discordance, a third reviewer voted the article as in or out in stage 1 screening, and a consensus-based resolution of disagreements was reached in stage 2 between the 2 reviewers.

Data-Charting Process

A data-charting form was developed by the first author and discussed with the second reviewer who participated in all the screening stages. The 2 reviewers discussed and iteratively improved the data-charting form while retrieving the results from the included papers. The data-charting form was developed to capture key information about the modeling language in addition to the identifying characteristics of the papers (author, title, date of publication, region or country, and journal or source). The form featured a free text section dedicated to capturing details about the modeling language including its name, descriptions, justification, and its application within the research context. In addition, categorical information, such as yes or no responses, was included accompanied by a follow-up free text area. For example, questions like "Is there an associated digital tool?" allowed for documentation of tool names, if applicable. Regarding the concept of PPs, we extracted the

phrases used to define or represent the concept, as well as any stated definitions within the document. All the data-charting process was conducted using the Covidence software and eventually exported to a Microsoft Excel spreadsheet.

Synthesis of Results

The synthesis of the results followed the review questions where we descriptively categorized the modeling languages into thematic groups. We also thematically analyzed the justification, purposes, and context in which the modeling language was created or implemented.

Results

Selected Articles

We imported a total of 1835 articles from the selected databases to Covidence after removing duplicates (Figure 2). In addition,

we discovered 5 more articles through hand searching, including gray literature searches from the Object Management Group (OMG). Of the 22 papers included in our review, half were published in conference proceedings and mainly retrieved from IEEE. The other half, except for 1 article from gray literature, were obtained from peer-reviewed scientific journals (Table 1). We included papers that were published as far back as 2008 to as recent as 2022. Most of the papers were from Europe (Germany and Italy), and almost all of them were from high-income countries. We found that more than 1 modeling language was contributed by similar groups of coauthors in another paper included in the review.

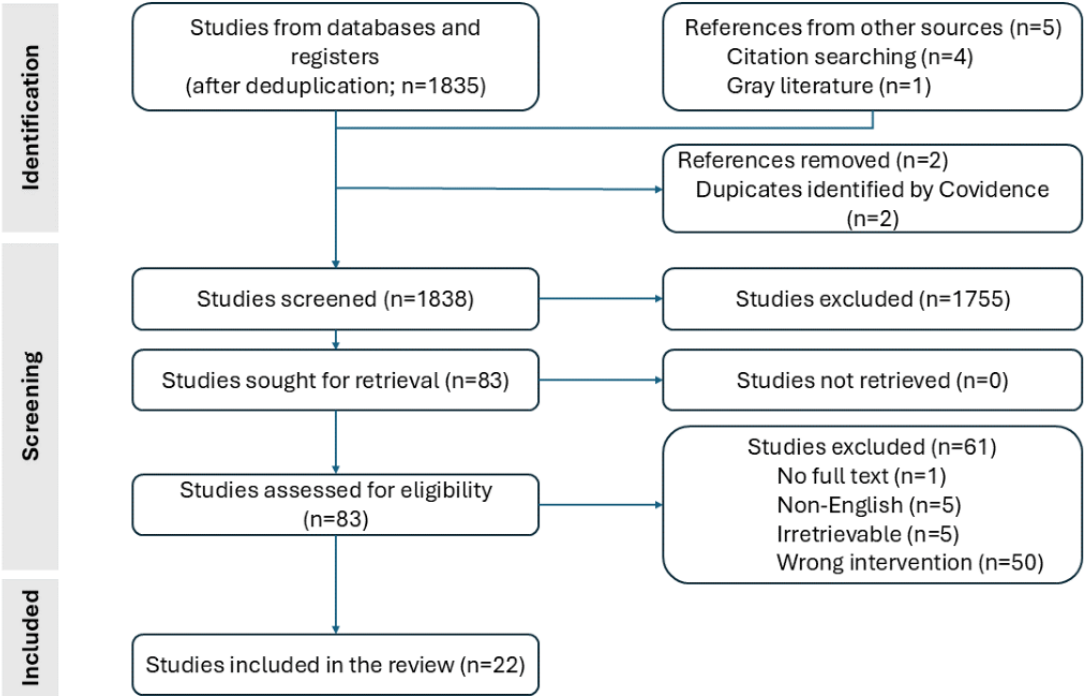
Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart.


Table 1. Summary information of the included publications.

Study	Country	Publication source (categorized)	Modeling language used	Case study or demonstrated on
Scheuerlein et al [51], 2012	Germany	Journal	*BPMN*[a] (*tBPM*[b])	Colon and rectum carcinoma (treatment of)
Barbagallo et al [52], 2015	Italy	Journal	*BPMN*	Multiple surgical conditions

[a]BPMN: business process model and notation.

[b]tBPM: tangible business process modeling.

[c]UML: unified modeling language.

[d]Includes congress, conference, symposium, and published papers mainly on the IEEE and IEEE Xplore websites.

[e]BPMN4CP 2.0: business process model and notation for clinical pathways 2.0.

[f]DMN: decision model and notation.

[g]COPD: chronic obstructive pulmonary disorder.

[h]BPM+Health: business process management for health care.

[i]LES: labeled event structure.

[j]EER: enhanced entity relationship.

[k]TP-VML: task planning visual modeling language.

[l]OWL: web ontology language.

[m]CPO: clinical pathway ontology.

[n]SWRL: semantic web ontology rule language.

[o]CHARM: convincing human action rationalized model.

Modeling Languages

Overview

Modeling languages that have their origin and wider uptake outside of the health domain and others developed within health domains were identified. We have collectively called the former GPML, and the latter DSML. In this context, GPML means a widely used modeling language or notation to visualize processes that transcend the health domain. These modeling languages can be used in the health care domain either (1) directly and without major extension or formal combination, (2) by extending the specifications following extension recommendations, or (3) by combining to enhance their expressiveness. On the basis of the presentation of the output, some can be formal notations and others visually presented concept relationships. To provide a detailed and simplified account, we grouped the included modeling languages into categories mentioned in subsequent sections.

GPMLs: Without a Formal Extension to the Domain Requirement

This category contains adopted process-modeling languages that are standardized and widely applied in other sectors. The 2 OMG standards, BPMN [51,56] and unified modeling language (UML) [53-55], were used without any demonstrated extension or modification to the original specifications. The methodology to enhance GPML uptake, especially to include nonmodeling experts in the modeling process, was not considered as a change to the modeling grammar and syntax. In the case of tangible business process management (BPM) [51], the authors used physical icons instead of digital tools that enhanced the participation of the domain experts. Zerbato et al [56] stated extending with additional time primitives to represent temporal constraints, which is not supported by the BPMN version that they have used. However, the details of the extension and its outcome were not provided. In the latest of the 2 papers [54], Ferrante et al [53] discussed the method around the modeling process to the original paper where UML is used to model the stroke rehabilitation pathway.

GPMLs: With a Formal Extension to the Domain Requirement

By adapting the widely used standardized notation, Braun et al [57] provided an extension formalism called BPMN4CP (business process model and notation for care pathways) to include care pathway—specific aspects. The revised BPMN4CP 2.0 covers additional domain-specific requirements to the original recommendations. Whereas Richter and Schlieter [58] extended BPMN to add the quality indicator specifications based on the BPMN4CP extension framework. Tehrani et al [59] extended the BPMN specification from the results of their norm analysis, together with organizational semiotic methods, which focus on describing the human behavior and conditions under which the human behaviors occur. In the notation, the extension was indicated by labeling (N#). In all 3 cases, it is imperative to take advantage of the widely used process models with their extension possibilities.

A Combination of Modeling Languages

To satisfy the domain requirements and specific needs that arise in the modeling processes, 2 or more visual modeling languages were used in combination, often complementing one another as required by the nature of each part in a given model. The OMG BPM+health provides a possibility to combine 3 independent modeling languages (BPMN, case management model and notation [CMMN], and decision model and notation [DMN]) [62], while Combi et al [60] and Sooter et al [61] combined BPMN and DMN in their respective studies. Extensive use of other modeling languages in combination, including the use of data modeling to identify comorbidity was presented in 2 instances [63,64]. One could argue that these may not be identified as visual modeling languages.

Developed DSMLs

Three articles [65-67] discussed the development of a DSML; one was called MedPath, which was specifically developed for the PP modeling process [66], and the other 2 radically improved [65,67] the base modeling language that inspired the development of specific DSML to model PPs.

Ontological Modeling Languages

This category is made acknowledging the differences between the promises of visual modeling and ontologies. While visual models do not intend to present a complete description of the domain and the constructs, rules should reflect some ontological commitments. Ontological models go beyond such restriction and cover a possible set of concepts and premises in a domain [72]. Ontology-based modeling languages were supported by other methodological approaches, such as semantic and norm analyses, and specifically dealt with terms and expressions to satisfy the PP requirements. Li et al [69] built an ontology chart that is presented in a diagrammatic visualization of the constructs following semantic and norm analysis. The widely used web ontology language and Protégé (a free, open-source ontology editor and framework for building intelligent systems) were used to personalize the pathways. To align institution-specific PPs in an automated solution, Abidi and Abidi [72] used semantic web-based modeling using web ontology language to align pathway ontologies. In another study, semantic web ontology rule language was used to represent the temporal relationship that was not covered by the time subontology of the clinical pathway ontology together with domain ontology [70]. Aimed at confirming the practical ability of convincing human action rationalized model to represent medical actions, promoting knowledge sharing, and inheritance in a computer-interpretable way, Nishimura et al [71] built the convincing human action rationalized model tree that contributed to finding the commonalities, variations, and reasons for differences among pathways.

Justification to Adopt, Adapt, Combine, or Develop Modeling Languages for PPs

The justification provided by authors for the identification, selection, use, and development of each modeling language varied across many different factors. These include but are not limited to the aim, level of analyses, the composition of the group behind the language, and when it was proposed during the progressive maturity of visual process languages.

Justification to Adopt a Visual Modeling Language

The justification given to adopt the GPMLs without extension was mainly to test the applicability of the modeling languages in health care domain and how the digitization process can be supported. The popularity and wider tool support made it easier to identify from the vast selection that already exists. Some authors provided comparative analysis to justify their choice.

Justification to Extend a Visual Modeling Language

To extend a modeling language, the main rationale emanates from the understanding of the deficiencies of GPMLs to meet the PP domain requirements. Apart from the popularity and resources around the modeling language, the presence of extension metamodel and the frameworks to guide the extension process are necessary to begin assessing whether the requirements can be met without extension (Table 2).

Table 2. The justification to extend a modeling language.

Study	Modeling language	Justification to adapt or extend
Braun et al [57], 2016	BPMN4CP[a]	• Domain requirements are not fully represented, and the extension procedure needs to follow a framework
Richter and Schlieter [58], 2019	BPMN[b], with quality indicator extension	• Widely accepted and established standard • Gives a metamodel, suitable for extension • Presence of extension framework [56] to build on
Tehrani et al [59], 2013	BPMN, with norm extension	• BPMN is "a rigorous method that provides a rich set of techniques and notations for process modeling" • Absence of techniques to describe human behavior and the conditions under which the behavior occurs

[a]BPMN4CP: business process model and notation for clinical pathway.

[b]BPMN: business process model and notation.

Justification to Combine Visual Modeling Languages

No single modeling language can adequately cover the requirements because the health care domain in general, and the PP modeling in particular, is a complex process. In this category (Table 3), the main rationale for combining modeling languages emerges from the conviction that complementing the deficiency of one model with the strength of the other is possible. In three of the cases, all the combinations were made progressively and included the specifications from OMG [60-62].

The health care Domain taskforce of the OMG has introduced a field guide called *shareable clinical pathways version 2.0* introducing amalgamation of their 3 standard notations for clinical pathway modeling [62]. Although not officially endorsed as a standard, it serves as a valuable discussion paper. The primary objective is to establish a modeling technique that is universally comprehensible among various stakeholders, including business analysts, health care professionals, and IT developers.

Implementing health information technology based on a care model that is universally developed and understood contributes to the efficiency, cost-effectiveness, and quality of health care delivery. The guide proposes the use of BPMN for prescribed models, CMMN as a complement for actual workflows, and DMN to address decision modeling, encompassing a complex set of factors to arrive at the most appropriate clinical decision. The suggested combination facilitates the creation of business flow diagrams and decision tables, offering coverage for clinical, administrative, and revenue cycle processes. This model, using a blend of these languages, addresses diverse aspects essential in the health care domain and is standardized for seamless sharing across organizations.

The BPM+ community of interest was assigned the task of examining the alignment between 2 OMG standard notations, namely BPMN and DMN. The focus was on bridging the gap between narrative guidelines and their digital representation with the aim of achieving a "true integration" of guidelines and pathways within electronic medical record systems. Sooter et al [61] illustrated the feasibility of modeling a clinical guideline for contraception in a standardized format suitable for digitization. Their approach involved listing and defining all data points using a spreadsheet, which subsequently indicated an area for extension to the BPMN 2.0 specification. The team showcased the challenges encountered in mapping SNOMED-CT (Systematized Nomenclature of Medicine–Clinical Terms) codes and presenting all terms in a summary chart. The decision logic and the business process aspects related to contraceptive choices and delivery were effectively modeled with a low level of abstraction using a modeling tool.

Combi et al [60] developed a framework using DMN to model decision-intensive care aligned with clinical practice guidelines directed at clinicians. Simultaneously, they used BPMN for modeling the care organization aspect. The authors rationalized the misuse of BPMN for modeling the entire pathway, including

clinical decisions, to conduct their research. However, they acknowledged the limitations of BPMN, particularly its shortcomings in fully supporting temporal relationships, domain knowledge, and the integration of complex structural data. The discussion explored the potential use of extensions to address these drawbacks. The steps outlined in the framework are more suitable for stakeholders with modeling expertise because the implementation of the modeling tool demands such skills.

Ardito et al [64] argued that finding a modeling language that is detailed enough to balance a machine-executable model yet simple enough to be human understandable is a challenging task. They proposed a modular approach for executing complex machine-level processes separately that uses a task-oriented chatbot approach based on the modeled pathways while interacting with the social media chatbot with the end user. The process used a stepwise approach and is method-intensive by nature, and it also includes patients, who are often forgotten as stakeholders in modeling efforts.

Table 3. The justification to combine modeling languages.

Study	Modeling languages	Justification to combine
Combi et al [60], 2017	BPMN[a] and DMN[b]	• Merely using a BPMN to model a decision-intensive care pathway is a misuse of the specification • Need for a framework that guides the use of DMN for a decision and BPMN for a structured process
Sooter et al [61], 2019	BPMN and DMN	• A "true integration" with electronic health records is not yet achieved • The compatibility of the 2 modeling languages to change narrative guidelines to digital instantiations is not checked
Object Management Group Healthcare Domain Taskforce [62], 2019	BPM+Health[c] (BPMN, CMMN[d], and DMN)	• Health care domain needs process models for prescriptive workflows, case models for reactive workflows, and decision models for complex business rules, hence appropriate modeling languages • Need to use accepted standards to make pathways shareable
Bowles et al [63], 2017	BPMN and LES[e]	• Other available presentations of CPsf for multimorbidity have inherent ambiguity. There is a need to resolve pathway conflicts using standardized, coordinated back-end and front-end models
Ardito et al [64], 2020	Metamodel; EER[g], BPMN, and UML[h]	• Finding a balance between modeling language expressiveness and the automated execution of modeled processes is difficult, and investing in it is unprofitable. To find the balance that does not require the domain experts to adopt a complex process-modeling language, what about dedicating the burden to an executing module—a chatbot engine?

[a]BPMN: business process–modeling notation.

[b]DMN: decision model and notation.

[c]BPM+Health: business process management for health care.

[d]CMMN: case management model and notation.

[e]LES: labeled event structure.

[f]CP: clinical pathway.

[g]EER: enhanced entity relationship.

[h]UML: unified modeling language.

Justification to Develop a DSML

Justifications to develop a modeling language included verbosity and issues related to customization and execution, limitations to cover PP domain requirements sufficiently, and needs such as integration. Furthermore, using domain-oriented existing languages was mentioned in this context (Table 4).

MedPath [66] is a process-based DSML that was developed to capture all the components in a clinical context while minimizing the verbosity challenges encountered by adopting the GPMLs. The language has syntax, semantics, and a visual notation. MedPath is a layer between the expert who develops a model and the engine that translates the metamodel into visual elements to be easily understood by the domain experts. The authors stated that the language is designed to be comprehensive

enough to capture all aspects of care organization, simple enough to be understood by health care domain experts and detailed enough to be integrated into the health information system.

The *openEHR* foundation strives for interoperable EHR systems and the use of standardized models in care processes and is also behind the task planning (TP) initiative. TP is a clinically oriented specification that also has a visual modeling language called task planning visual modeling language (TP-VML) [65]. The authors credit the BPMN extensions that are aimed at solving the temporal constraints to model clinical workflow. However, TP formalism can better represent the health care domain because it has a more domain-specific orientation than the extensions. The original TP-VML icons and semantics are not discussed, while the displayed visual notation in the paper

references its source to the tool that the authors used. Possible extensions of the TP specifications were presented after a thorough analysis following the stepwise methods. The authors concluded that following the extension procedures suggested for BPMN to pathways by Braun et al [57], TP can be extended to include domain requirements and can be used for complex PPs as demonstrated in the case study on the catheter-related bloodstream infection. Future work should focus on furthering the decision logic specification to evoke rules from TP supported by an expression language and a basic metamodel of openEHR.

Burwitz et al [67] developed a DSML named CP-Mod based on the clinical algorithms basic process-modeling concepts and extended to include evidence-based medicine and decision support, classification of treatment alternatives, and time events and waiting periods following the requirement they set for PP

modeling. The justification for using the base modeling concept and the need for extension in comparison to the widely used modeling languages were presented, and good arguments were made.

Icebricks [68] is a modeling methodology and digital tool that also provides a human-readable representation of care pathways. It meets the need for a notation that depicts activities, annotates information, and supports standardization while facilitating collaborative work with easy learning. The model can be exported to Microsoft Word with full process documentation, including diagrams (although not shown in the paper) and annotated information. The authors raised important questions that qualify a useful notation, but more emphasis was given to the methodology and the tool than to the core of the language.

Table 4. The justification to develop a modeling language.

Study	Modeling language	Justification to develop
Iglesias et al [65], 2022	TP-VML[a]	• More clinically oriented business process management standards can provide an adequate representation of the temporal orientation of clinical workflow than BPMN[b] or its extension.
Trajano et al [66], 2021	MedPath	• GPML[c] verbosity and not easily customized to medical context. • Also sometimes lack infrastructure for integration and execution.
Burwitz et al [67], 2013	CP-Mod	• Reviewed common modeling languages used against their set requirement and identified deficits. • Clinical algorithm can be used as a base and organizational aspect and individual data can be added.
Shitkova et al [68], 2015	Icebricks	• Generic modeling languages did not sufficiently cover PP[d] requirements. • A notation needs to allow the representation of activities and process flows, annotate relevant information, and represent knowledge on an appropriate level of abstraction.

[a]TP-VML: task planning visual modeling language.

[b]BPMN: business process model and notation.

[c]GPML: general-purpose modeling language.

[d]PP: patient pathway.

The Contexts in Which the Languages Were Applied

The context in which the modeling process occurred can take several aspects. Here, we focus on the profile of involved experts, the organizational structure, the coverage and scope, the tool support, the nature of the study, and the level of standardization, among other relevant information to a language. Additional discussion of the context is provided in Multimedia Appendix 2 [57-68] and for selected papers in the earlier section.

Almost all articles were method-intensive and primarily focused on theoretical discussion with empirical demonstration on selected medical conditions. Only 3 articles discussed the topic without demonstrating on a case [55,69,70]. While the majority demonstrated on a single condition, a few attempted the application on several conditions [52,63,66,68,71]. The field guide [62] and contraceptive guideline modeling [61] are meant to be applied widely at several levels of abstraction. One paper focused on interinstitutional care standardization [72], integration of PPs to deal with comorbidity [63], and that it can be applied at any level of abstraction.

The drivers of the modeling language creation or use are mostly modeling experts who attempt to involve novice modelers. The domain experts were also involved at some level in the presented concept or script ranging from design to the evaluation phases. Different techniques, such as making the vocabularies tangible [51] and producing a chatbot that facilitated the participation of novice modelers [64], were identified. The intention to simplify the modeling process for stakeholders with less modeling expertise was indicated by several authors. The use of modeling languages was tied to digitization in several of the cases, particularly to facilitate machine executability [52,64-66,68].

The OMG is responsible for UML, BPMN, as well as CMMN and DMN proposed for combination with BPMN [51-56,60-62]. Languages like TP-VML that have domain-specific engagement are linked to a foundation with a potential to be widely accepted [65].

Tool support is one of the main criteria for increasing the adoption and subsequent improvement of modeling languages. More than two-thirds of the modeling languages were accompanied by a tool or software artifact

[52,54,55,61-67,69-71] and the remaining did not specify in the report.

PPs: Terminologies and Concept Definition

The terms and operationalization of the concept synonymous with PPs varied among the included articles. The most frequently used phrase was "clinical pathways" alone or interchangeably with other phrases including "care pathways" or "integrated care pathways." There were no justifications provided as to why a given terminology was adopted. The phrase "patient pathways" appeared in only 1 paper [58]. In most of the papers, the concept of PPs (or their synonyms) was briefly discussed in the Introduction section. Almost all referenced the definitions forwarded by de Bleser et al [19], Vanhaecht [20], or Kinsman et al [21], among others. Almost all included papers lacked operationalization of the concept in relation to the context.

Discussion

Principal Findings

We identified and categorized visual modeling languages used in the representation of PPs. In addition to the direct adoption of standardized and widely used modeling languages originating outside of the health domain, there are extensions and combinations of languages proposed to meet the domain requirements. We identified DSMLs that are also important contributions to the discussion of PP modeling efforts. The justifications for selecting a visual modeling language varied depending on the modeling scope and goal. The rationale to propose any modification to the language evolved as more evidence was presented following requirement analyses to support domain constructs. The direct use of standardized modeling languages without any domain-specific adaptation was done mostly to test whether the standards can also be applied to the health domain. After having evidence regarding the deficiencies to fully represent the domain needs, extension by addition and combinations of more than 1 standardized visual modeling language were introduced. The presence of extension formalisms for widely used standard modeling languages, specifically BPMN, is promising, while the process of standardizing those extensions remains unclear. Standing on the shoulders of previous extensions would contribute to subsequently expanding the specification to the domain requirements with minimum effort. There are valid reasons put forward by the DSML developers, but these need further discussion considering the cost, rate of uptake, and likelihood of standardization. Given that there are more mature languages with already advanced tools, including the advantage of execution languages to automate the model, it is essential to conduct an exhaustive comparison of which languages to choose or whether there is a need to develop a new one before embarking on the long journey.

The taxonomy that we created corresponds to the approaches used to find the best possible ways to appropriately model PP. Similar approaches were used in other related reviews mainly to facilitate the ease of understanding of such a complex field [12,42]. The purpose of using a visual modeling language, otherwise stated as "the dependent variable/the design goal" by

Moody [43], was reflected in the included papers in various ways. It has been used to facilitate communication between designers and domain experts [51,66], involve patients to interact with their PPs [68], facilitate the digitization of the PPs [61-67], and facilitate integration with the EHR system [61]. The reviewed papers attempted to fulfill these purposes fully or partly.

The application of standardized modeling languages in the health care domain has previously been reported in systematic reviews [38,39]. This scoping review adds *the process* in which the GPMLs were being used to model PP-specific requirements. In this review, BPMN is categorized into GPMLs because its syntax can be used in various domains despite its business process–specific nature [56]. We believe that it is a good example to illustrate how GPMLs were being used to model PPs. From early experimentations to check for its suitability to model PPs [51,52,56], followed by the identification of domain-specific requirements resulting in extension approaches [57-59], to the recent recommendation to combine other specifications to overcome its inherent limitation [60-62], BPMN presented itself as a leading standardized process-modeling language for PP. Gartner et al [12] also reported in their review that the process nature is one of the most common attributes of care pathways and is modeled using BPMN or improved by combining with decision support modeling languages. The popularity, expressiveness and extensibility, and tool support with an execution language were presented as justifications for its use, which are parts of the parameters in most evaluation criterion frameworks [28,44,73]. According to a comprehensive systematic review, the relative simplicity of use with strong research and implementation experiences in nonhealth domains supported by OMG is convincing to agree to the notion that one should justify why they did not use BPMN over their chosen modeling language [74]. However, to fully represent the domain requirements, combinations of standards that cover aspects other than predefined and stable processes must be considered [62].

It is widely accepted that the use of DSMLs may boost the modeling practice and enhance the flexibility, maintainability, and sustained use of a model compared with using a GPML [74,75]. Developing a DSML is very costly and time consuming. It is premature to declare the impact and possibility of continued use of all the included DSMLs in this review because of their recent appearances [65,66]. However, the justifications for embarking on such a time-consuming and costly process need to be recognized to gain inputs to build the most expressive and simplified modeling language for the domain. For example, TP-VML aimed at replacing all the extensions to GPMLs that are not built to represent all the needs in the domain [65].

On the basis of the anatomy of visual modeling languages [43], a visual vocabulary (graphical symbols), grammar (a set of compositional rules), semantics (definitions of the meaning of each symbol), and its visual (concrete) syntax are included. Most articles included in this review did not specifically aim at the core aspects of a modeling language by discussing its grammar, ontologies, and semantics fully. As this scoping review aims at mapping but not quality appraising the modeling languages, we did not seek out further information for those

developed or traced back to the original specifications for those adopted, adapted, or combined known visual modeling languages. There are frameworks with comprehensive evaluation criteria to measure the quality of a modeling language, although the criteria confuse the script with grammar [44]. A few papers included in this review also presented their criteria for selecting one modeling language over another. Future studies need to find a good framework and evaluate all modeling languages used in PP in general and DSMLs in particular. As clearly recommended by Gemino and Wand [73], a comparison of modeling languages should be based on their grammar (constructs and rules) rather than the scripts (specific models and end product of a modeling process).

The modeling and selection of the appropriate modeling language go in line with the data sources. Aspland et al [42] stated that there are 2 common ways of obtaining data: either data-driven approaches or through collaboration with those who interact with the pathway. They recommended coordinating both sources to advance on the advantages of each. The increasing presence of digital technology presents the opportunity to use a data-driven approach, which also gives the opportunity to evaluate progress in a dynamic manner [12,33,40]. More emphasis is being placed on the presence of an EHR to have access to reliable data at all phases to "identify the relationships between the context, the mechanisms, and the results obtained" [12]. Of note is the extensive use of other modeling languages that are more relevant to the modeling methods categorized as stochastic, data mining and machine learning, simulation, and optimization and heuristics by Aspland et al [42]. Our review encompasses the use of modeling languages for pathways created by multidisciplinary teams in a prospective manner.

With the increasing use of patient-centric pathway development [12], modeling languages that reflect the patient perspectives are of interest. The patient journey concept, or customer and user journey in a wider context, is getting more attention; although, the literature on the subject is incoherent [76]. One such language that covers the perspective of patients is the customer journey modeling language (CJML), which is making its way to the health domain [77] targeting novice modelers [78]. CJML is developed from the human end user's perspective, as opposed to the software-centric UML and the business-centric BPMN (refer to the diagrams of CJML from one of the authors' previous works for illustration purposes in Multimedia Appendix 3). This modeling language has been explored to support the design, management, and analysis of patient journeys. CJML is designed to capture both planned (prescribed) and actual patient journeys, allowing for the analysis of deviations and the inclusion of the end-users' experience [79]. CJML provides vocabulary, a metamodel, and a visual notation. It is easy to learn and does not require complex technical competence to use. CJML provides a graphical notation for the planned and actual journeys with specific constructs such as journey phases, experience, channel, and actor information, which is limited or lacking in other process-modeling languages [77-79].

Limitations of This Scoping Review

We restricted our inclusion criteria based on several factors. Although this has merits to focus this review on modeling languages that emphasized description and communication of PPs, our narrow focus, including restrictions of the search strategies to the title and keywords only, might have excluded papers that have relevance regarding how the modeling languages were used to address domain issues while used in the modeling of data-driven pathways. Our effort to include DSMLs, which are not yet standardized, posed a challenge as to where to draw the line in the abundance of modeling languages [38,74] with varying levels of abstraction and granularity. We excluded simple flowchart and diagram presentations, the most common visual notations, because the scope of this review includes advanced languages. However, a few matured visual presentations with less structured description of the language might have been excluded. We did not include all the standards and accompanying modeling languages and methods that focus on standardizing interoperability between different IT systems, such as HL7 (Health Level Seven International), and textual languages that support international or interinstitutional coding to classify and standardize terminologies, such as SNOMED-CT [80]. We excluded the so-called task-based modeling languages commonly used to digitize clinical practice guidelines [81], because they lie outside of our inclusion criteria. This complexity is exacerbated in the overall confusion of the PP definitions, as also presented in the Result section of this review.

Identifying the operational definitions of the PP by the authors has been challenging. We filtered articles based on their emphasis on defining and explicitly stating where the focus of their work mainly targets. However, there is a fine line between closely similar concepts, such as workflow and clinical practice guidelines, which were understood as synonyms in a few original papers and previous reviews [12,37,42]. In contrast, even though terms that are used to represent similar concepts with PPs (those that were highlighting the organizational aspects of a care delivery) are presented in the title of the paper, the definition and the emphasis given to the concept in the body of the paper did not demonstrate the intention. These papers were excluded. We did not include patient journeys in the search strategy because it differs from the PP concept definition (in 1 review included synonymously [12]), which resulted in excluding modeling languages that are patient centric, such as CJML.

We have not conducted ontological analysis to check for the correspondence of ontologies and notations [28] or any other quality appraisal frameworks [73]. The use of such tools would have excluded a few papers that are more focused on scripts and are more method-intensive where limited information on the core modeling language and notations were presented. We have not stated a strict definition of a modeling language that implicates the need for a quality appraisal. Identifying the known and standardized modeling languages was simple. Applying strict operational definitions to those lesser-known DSMLs was complex and required careful analysis. Therefore, we considered the authors' description of the modeling language to accommodate in this scoping review. This resulted in the inclusion of papers focused on techniques and methods with

less information about the modeling languages that were used. Some raised important questions about a modeling language but used a more generic description in the part where they described the tool [68].

The variability in extractable data from each paper significantly influenced the focus of our discussion. Despite using the Wand and Weber framework [44], the lack of detailed information within each manuscript constrained our ability to engage in deeper discussions within this review. While the aim of this scoping review was not to conduct quality appraisal, the limitations in available data impeded our ability to thoroughly identify research gaps in a more nuanced manner.

Gaps Identified for Future Research

Finding effective ways of describing and communicating a PP is essential to enhance its impact. It is as important as having a framework for its development and implementation. A considerable number of frameworks suggesting a standardized development of a PP to set common and shared practices do exist [12,27]. However, less focus has been given on how to simplify and optimize the description and communication of a model beyond the use of customary box-and-arrow type flowcharts and narrative text descriptions. Given the amount of locally made PPs, the effort directed toward the use of visual modeling language is very scarce. A report from PPs in oncology care research group [82] found that many of the cancer care pathways were presented in the form of flowcharts and texts. We also reviewed the national websites where the popular standardized cancer care pathways, for example, locally known as "pakkeforløp for kreft" in Norway, are presented in Scandinavian countries [83-85]. The pathways for several cancer cases were presented in a flowchart, a narrative text, and a table format. We have not explored how they are presented at each institution level, including the process of integration with EHR systems. As per the process steps of the cancer care pathways, the need for a standardized visual modeling language may not be argued provided that the intended goal is achieved by the current representations. This example and the overall limited adoption of visual modeling languages suggest that despite the inherent ambiguity and lack of precision and consistency associated with narrative and text descriptions [62], many institutions still rely on these representations over visual models. This reliance may stem from factors such as organizational culture, lack of awareness, and apprehension about the complexity of modeling languages. However, raising awareness and fostering a better understanding of the benefits and drawbacks of visual models, particularly in the context of specific PP projects, could help shift attitudes and reshape organizational culture regarding the choice of process representation.

Efforts to develop simplified visual modeling languages accessible to nonmodeler domain experts can help alleviate concerns about complexity and encourage broader adoption. While balancing ease of understanding with the expressiveness of modeling languages poses challenges [65], it is essential for all contributions in this field to prioritize this as a principle. In addition, as digital technology plays an increasingly prominent role in this domain, emphasis should be placed on visual languages equipped with execution engines and tools, facilitating integration with existing digital tools, and streamlining the modeling process.

In larger projects intended for widespread implementation, such as those aiming to serve as common documents for local implementations, incorporating visual models of business processes benefits the project while normalizing the use of such representations. For instance, the World Health Organization's smart guideline documents have integrated visual representations of business processes [86]. However, further research is needed to thoroughly evaluate the advantages and disadvantages of visually modeling such projects using an accessible and expressive modeling language.

Using the decision model to select the most appropriate process-modeling language for a given modeling task is proposed for research modelers, which can be applied in the PP domain as well [74]. Guizani and Ghannouchi [75] argued that none of the languages that they reviewed fully supported the following 7 criteria: expressiveness, flexibility, formality, readability, support tools, usability, and ease of learning. Therefore, multicriteria decision support analysis is suggested as the most appropriate approach for comparison. We recommend that modelers and PP developers should exhaustively scrutinize the suitability of existing standards to model their PP before embarking on developing a DSML from scratch. However, reviews are needed to avail comprehensive knowledge of the gaps in the existing potential candidate languages and weigh the merits of developing new ones in relation to whether all requirements in a PP concept are covered or not.

Extension of existing languages, especially extension by addition, is a good approach to cover domain requirements but the standardization process of the extensions is a challenge [39,49]. By contrast, the latest OMG-recommended combinations of modeling languages have to be tested in different contexts as it is a promising approach to cover all the domain needs [62]. With the move toward a more patient-centric nature of pathways, more research is needed on how to reflect the patients' views in the modeling product [12,25,87].

Conclusions

Diverse visual modeling languages were used to model PPs fully or partially. The GPMLs were used directly without any modification to the grammar, extended following extension protocols, or combined with other languages to complement the inherent limitations of each language. We identified a few attempts of developing DSMLs in this review. A limited number of papers presented a DSML that is developed to meet the specific requirements of the PPs. Purely ontological modeling languages were also identified. We have shown the need to consider the rationale, context, and the ways in which the identified visual modeling languages were used. This provides additional useful information to stakeholders in the process of selecting a modeling language. Furthermore, one should use quality appraisal tools to check the conformity of a modeling language to their specific pathway project before deciding to use, extend, combine, or develop a visual modeling language.

Abstract

Background: Nations of considerable wealth and sophisticated health care infrastructures have experienced high rates of illness and death from COVID-19. Others with limited economic means and less developed health systems have achieved much lower burdens. To build a full understanding, an appraisal of the contribution of social relationships is necessary. Social cohesion represents a promising conceptual tool.

Objective: This study aimed to examine scholarship on social cohesion during the COVID-19 pandemic: specifically, the constructions of social cohesion being deployed, the variables chosen for representation, and the effects of and on social cohesion being reported.

Methods: The PubMed, Scopus, and JSTOR databases were searched for relevant journal articles and gray literature. A total of 100 studies met the inclusion criteria. Data were extracted and analyzed from these using spreadsheet software.

Results: Several constructions of social cohesion were found. These concerned interpersonal relationships, sameness and difference, collective action, perceptions or emotions of group members, structures and institutions of governance, locally or culturally specific versions, and hybrid or multidimensional models. Social cohesion was reported to be influential on health outcomes, health behaviors, resilience, and emotional well-being, but there was some potential for it to drive undesirable outcomes. Scholarship reported increases or decreases in quantitative measures of social cohesion, a temporary "rally round the flag" effect early in the pandemic, the variable impacts of policy on social cohesion, and changing interpersonal relationships due to the pandemic conditions. There are numerous issues with the literature that reflect the well-documented limitations of popular versions of the concept.

Conclusions: Social cohesion has been used to express a range of different aspects of relationships during the pandemic. It is claimed to promote better health outcomes, more engagement with positive health behaviors, and greater resilience and emotional well-being. The literature presents a range of ways in which it has been altered by the pandemic conditions. There are significant weaknesses to this body of knowledge that greatly impede its overall quality.

Introduction

Overview

The COVID-19 pandemic has offered a challenge to those seeking to understand the operation of social relationships and patterns of health and illness. Throughout what is likely the first truly global pandemic to begin in the information age, humans have had access to real-time data from across the globe. What we have seen has frequently surprised us. For example, the 2019 Global Health Security Index positioned the United States and the United Kingdom in the top 2 positions in the league table of pandemic preparedness [1], yet these nations have experienced among the highest rates of illness and death from

COVID-19 on the planet [2]. The same report placed, for example, Aotearoa–New Zealand (Aotearoa-NZ) and Singapore much lower in the rankings, but these nations have managed to limit their burdens of this kind [2].

Analyses have sought to explain unequal COVID-19 outcomes between populations using, among other independent variables, features of physical geography [3], previous experiences of infectious disease outbreaks [4], ethnic composition [5], and even leaders' gender [6]. Although some of these may make important and valid points, none tell the whole story: an understanding of the patterns of health and illness cannot be complete without attention to social determinants. After all, it is physical, in-person interaction between humans that allows the virus to spread. In most cases, a nation's ability to slow or stop the spread of the virus has depended on collective action from a large majority of its population. More fundamentally, the ability of a government to enact policy for protection of public health in the face of COVID-19 is contingent on there being political infrastructure to permit it and, following this, the likelihood that the policy will be adhered to at the population level. At every juncture, the progress of the disease is contingent on social relationships.

Social Cohesion

One useful tool for the examination of social relationships is social cohesion. Comprehensive accounts of social cohesion have already been written recently [7-9]; however, a brief discussion here may provide context to the current work. Most basically, it is a tool for the analysis or characterization of social relationships. There are several theoretical lineages underpinning social cohesion as it currently appears, their relative presence in different incarnations of the concept being frequently noted in the more critical literature [10-14]. The inception of social cohesion into academic inquiry is usually attributed to Durkheim [15], who sought to understand what brings and holds societies together in the context of the rapid industrialization of the 19th and early 20th centuries. His answers to this question—shared values and culture and functional interdependence—are at the foundation of one theoretical lineage, present through Parsons' [16] and the functionalists' scholarship and are a notable feature of more recent work by Jenson [10]. Attention to the Marxian theory of capitalist socioeconomics, the division of labor and wealth inequality is also frequently present, with inequality presented as an impediment to social cohesion, which in such accounts is largely synonymous with order and stability [17].

Some scholars, such as Green and Janmaat [11], indicate the importance of the state in the operation and maintenance of social cohesion and, in doing so, draw attention to the work of political theorists. Liberal, contractarian, romantic conservative, and French republican thought traditions are each cited in this work. Such ideas are carried through into the contemporary social cohesion scholarship from policy, development, and political science fields. In this general area, social cohesion is again a question of a social order, underpinned by particular understandings of the nature of the human condition and sociality, for which the state is ultimately responsible.

Another influential theoretical lineage, though one that has seen rather less explicit acknowledgment in the more recent social cohesion literature, grew from roots in social psychology. The pioneering work by Le Bon [18] on behavioral contagion paved the way for a range of contributions, including those from Freud [19], Lewin [20], and the field theorists and group identity scholars, such as Hogg and Turner [21]. Although this work was primarily small-group experimentation, some of its principles and lexicon have become established in the social cohesion scholarship seeking to characterize larger groups, of course in those from psychological fields making reference to the topic [22], but also notably in the characterization of intergroup relationships, identification with the local or national community, and in the nature and operation of trust.

The more recent construction of social capital concepts adjacent to social cohesion has also been influential. Building in part on the work of social network analysts [23], Bourdieu [24], and Coleman [25] each introduced their own versions of social capital. This concept draws attention specifically to interpersonal relationships and the opportunities and resources these may offer to the individual. In this form it had relevance to social cohesion but still remained reasonably distinct: where social cohesion was, for the most part, to operate at the population level, social capital was concerned with individual-level social networks. However, with the popular version of social capital from Putnam [26-28] the boundaries between the two became less clear. Putnam's work departed from the use of the individual as the unit of analysis to focus on groups' and communities' extent and practices of civic engagement and the operation of social norms, the implications these have for population-wide trust, and, following this, the effectiveness of democracy and successful economic growth. Putnam's social capital thus began a literature trajectory that appraised variables and conditions that would have found a comfortable home under the social cohesion banner as social capital, and in many cases that treats the two as synonymous (eg, Kawachi and Berkman [29]).

Most recently, policy and development scholars, and, following them, those from several other fields, including public health, economics, and geography, have brought these theoretical lineages of social cohesion and its fraught relationship with social capital into dialog with contemporary social and political problems or change and have sought to operationalize them quantitatively. The manner in which social cohesion is represented in such work is often contingent on the problems or processes of change under scrutiny. For example, scholars seeking to draw attention to the human casualties of the neoliberal dismantling of the welfare state, tend to foreground the problems of inequality [30]; those looking to solve the problem of ethnic intergroup tension frequently look to explanations around shared culture, values, and interpersonal connection [31]; and those concerned about the social order and operation of democracy can commonly be found emphasizing the role of the state and the quality of its institutions [32]. It has been used to represent or understand—among many other sets of relations—collective action [33], relationships between populations and the state [24,34], trust [29], and neighborhood networks' resilience to hardships or shocks [35].

The diversity of the lineages of social cohesion and contexts in which it has been deployed have produced significant diversity within the concept. In practice, there are many different social

cohesions, and there is rarely any basis to claim one of them more valid or useful than the next. This has long been observed in the literature: Bernard [17] famously referred to social cohesion as a "quasi-concept," imbued with "a vagueness that makes [it] adaptable to various situations...to follow the meanderings and necessities of political action from day to day," and Cheong et al [36] suggested that it is "a moveable feast, aligned with the political and ideological positions of policy makers, practitioners, and academics." Despite the currency it has come to hold in both policy and academic debates, it is rare that all parties to a conversation on the topic are talking about the same thing.

Although this ambiguity has produced definitional and conceptual confusion, it may also lend the social cohesion concept a flexibility that can be a source of strength in examining human sociality. Given the collective nature of the problems of COVID-19 and the requirement for collective solutions, it appears to be especially promising in the analysis of social relationships in such a context. This work is an initial step into such a line of inquiry. Beyond this specific topic, and as the direct impacts of the COVID-19 pandemic diminish in magnitude, the accumulation and persistence of further wicked problems, such as environmental degradation and climate change, poverty and inequality, recurring financial-economic crises, etc, the imperative for understanding collective behaviors becomes ever more pressing. Social cohesion is a concept that might be of use to human endeavors therein.

The Current Work

As part of a broader research project using social cohesion to understand the operation of social relationships within and upon the COVID-19 pandemic, a review of what others have contributed is necessary. Reported here are the processes and results of an integrative review on the topic. Given the definitional ambiguity and broadness of the scope of the social cohesion concept, in addition to its effects, it was of interest to investigate the different ways in which social cohesion has been constructed. It is thus not the intention of this work to seek solutions to its ambiguity and vagueness, or indeed to imprint its own framework or claims as to the nature of social cohesion onto the endeavor. Rather, reported here is an exploratory mission to seek out how social cohesion has been deployed by others: which versions are being used, how they are being used, and the effects on and of the experience of the pandemic being claimed.

Methods

Search Strategy

A computerized search strategy was conducted on the PubMed, Scopus, and JSTOR databases on October 10, 2022, then repeated on August 8, 2024. The dual purpose of the review—to explore the range of versions of social cohesion being deployed to characterize the social relationships in operation during the COVID-19 pandemic and the effects thereon and thereof—necessitated the casting of a broad net in the literature search. This need was magnified by the newness of the topic. Given the slippage between social cohesion and such adjacent concepts as social capital, it was worthwhile to maintain singular

interest in those accounts specifically and explicitly using the social cohesion concept as an important component in the analysis. The following search string was used: "social cohesion" AND ("coronavirus" OR "Covid").

Searches were limited to journal articles and gray literature published since 2020 to exclude results from before the COVID-19 pandemic. For the PubMed search, the search parameters were set at title and abstract. For the Scopus search, this was widened to also include keywords, and for the JSTOR search, to include the whole text as initial title and abstract searches alone yielded limited results.

From an initial return of 698 results, 89 (12.75%) were reviewed. A further 11 (1.5%) articles and reports were included from the reference lists, bringing the total number of papers to 100 (14.3%). Inclusion criteria were as follows:

1. Social cohesion formed a substantial part of the analysis. Across social scientific scholarship, the term is frequently used without a definition or significant discussion. Including papers where social cohesion was present in this manner would not be of value to the task of generating detailed knowledge on social cohesion during the COVID-19 pandemic.
2. Discussion was present on COVID-19 outcomes or social cohesion in the context of the pandemic. The purpose of this review being to understand the relationships between COVID-19 and social cohesion meant that any papers not dealing with these were not relevant.
3. The full text was available through the associated database.
4. The full text was available in English.

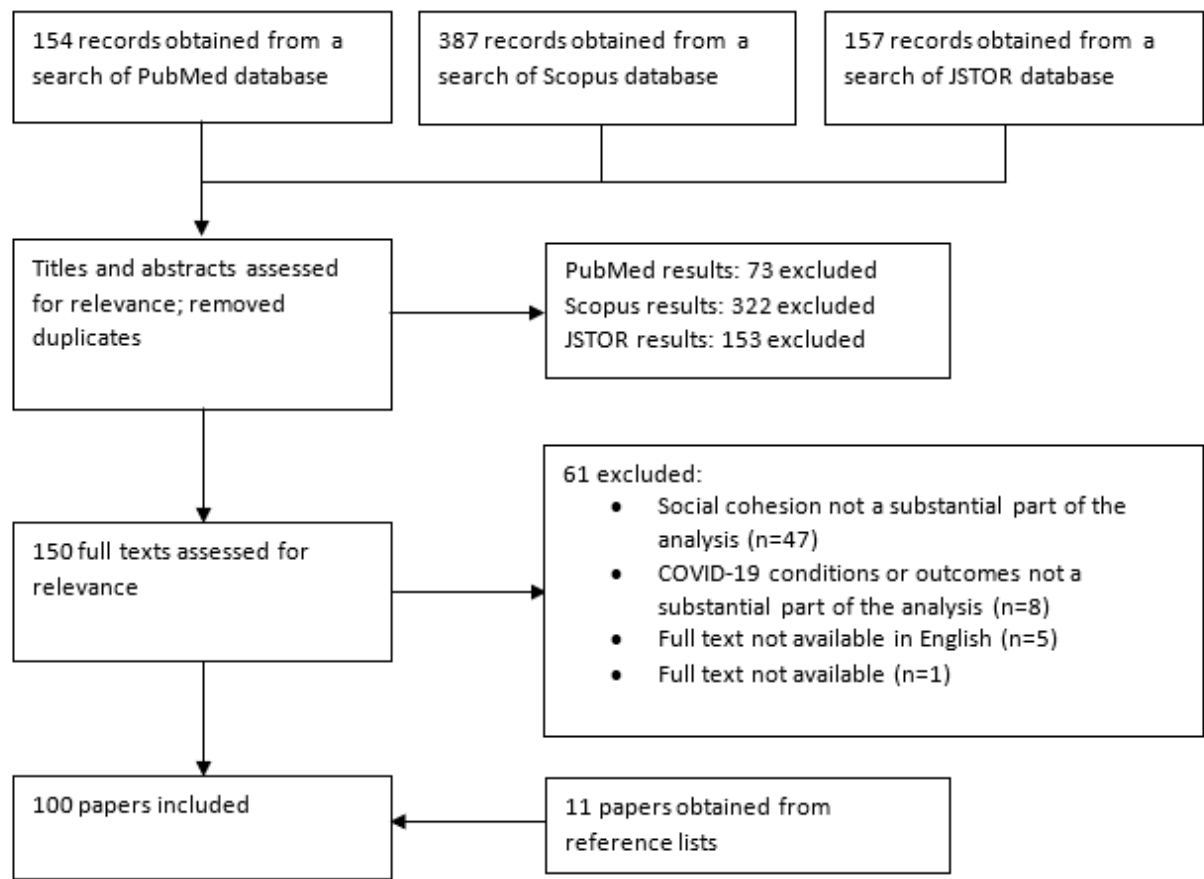
Data Extraction

All 100 studies were accessed electronically. In each case, PDF files were downloaded from the database on which they were found. Data were extracted using the integrative method from Whittemore and Knafl [37], which was chosen for its capacity to draw together a range of methodologies. This consists of data reduction and coding, display, comparison, and the drawing of conclusions. A coding matrix was developed using the Microsoft Excel spreadsheet software. During initial coding, the literature was arranged by methodology and discipline. Following this, through an inductive process, it was organized by further categories becoming salient during a second pass. These included the nature of the work (empirical, analytical, or theoretical), the units of analysis, the objects of focus, the construction of social cohesion being deployed, and the outcomes being described. A third pass over the literature informed by this was then conducted, which yielded the thematic structure described in the following section. The extraction focused in particular on the manner in which social cohesion was conceptualized, the components or indicators thereof proposed, and the argument being presented regarding its operation during the pandemic.

Results

Selection and Exclusion Process

The selection and exclusion process is shown in Figure 1.

Figure 1. Literature selection and exclusion diagram.


Study Features

Tables 1 to 3 provide details of the papers reviewed relating to location of interest, the methodological approach, and the effects on or of social cohesion being investigated.

Table 1. Reviewed papers and their locations of interest (N=100).

Different Models of Social Cohesion

A range of constructions of social cohesion were presented. These may be sensibly organized as clusters of objects that are used to represent social cohesion one way or another. These clusters commonly describe the same or similar sets of behaviors or situations using different terminology. In total, 7 categories are proposed for the papers reviewed: interpersonal relationships, sameness and difference, groups' collective action or members' choosing to act toward the overall benefit of the group, the sum of the perceptions or emotions of group members, and the operation of structures and institutions of governance. The sixth category is a small one that contains locally and culturally specific constructions of social cohesion, and the seventh consists of accounts presenting large hybrid and multidimensional models incorporating several other categories. In each case, the chosen version of social cohesion is represented by particular constructs or variables that act as a representation of the whole. Table 4 contains a summary of this information.

Each model of cohesion naturally implies the units of analysis between which relations are being characterized. The interpersonal group measures characteristics of the individual human, and in its purpose to appraise the operation of their social networks, often resembles what has been more commonly characterized as social capital. The individual is also used as the unit of analysis in the process of calculating the sum of emotions and perceptions. Analyses of sameness and difference tend to span the individual and group. A common example of this practice is the measurement of individual group members' characteristics to make inferences about the group. The same general practice is also apparent in the working together category. Analysis of institutions and governance usually situates the particular structures under scrutiny as the units of analysis.

The Different Effects of Social Cohesion

Health Outcomes

Those works presenting social cohesion as a determinant of health most commonly held it to be producing comparatively positive population health outcomes from COVID-19. Such reporting included the negative association of social cohesion (frequently referring to social capital, either explicitly or implicitly, as a proxy) with the likelihood of death [54,123,129,130]; or the spread of infections of COVID-19 in groups and populations [53,56,127,129,130]; hospitalization [62]; or antibody response to vaccination [39]; or, in the case of some analytical and theoretical work, a less precisely defined and more general "health outcomes" [111]. For example, Gallagher et al [39] used a 5-item questionnaire to measure frequency of contact with neighbors, and perceptions of neighborhood trustworthiness, willingness to help, similarity and friendship; and vaccination-related blood antibody concentration among 676 people from the United Kingdom, finding a positive association between their measure of social cohesion and blood antibody concentration.

Some works sought to isolate the effect of different components or variables within their model of social cohesion on health outcomes from COVID-19 [53,54,119] or different effects of the same components on different populations [53]. For example, Elgar et al [119] drew on existing data from surveys across 84 countries and used a Putnam-inspired construct measuring trust in other people, membership of community groups, civic activity, and confidence in the state (thus resembling social capital) to investigate a hypothesized association between social cohesion and COVID-19 deaths in the early days of the pandemic. They reported that while mortality was positively associated with interpersonal trust and group affiliations, it was negatively associated with civic engagement and confidence in the state. Ransome et al [53] measured feelings of belongingness, trust in neighbors, perceptions of neighbors' willingness to help, civic and social participation, and collective engagement across a selection of neighborhoods in Philadelphia, looking for any associations with rates of COVID-19 diagnosis. They found that social cohesion operated differently in different places: neighborhoods predominantly occupied by African Americans found some of their indicators of choice to be associated with higher rates of diagnosis, while those in which African Americans were the minority saw the same indicators associated with lower rates.

Information for and Practice of Health Behaviors for the Prevention of COVID-19

Several studies described the effects of their chosen construction of social cohesion on the promotion of health behaviors intended to prevent transmission of SARS-CoV-2. These included commentary on those behaviors made compulsory by legislation and access to or transmission of information around them. This body of work includes notable contributions from those who deployed qualitative methods to explore in detail the motivators and barriers for practicing recommended and required public health behaviors [38,60,85,121,122]. Each of these introduced social cohesion at the latter stages of their analyses to draw together a collection of influences on opinions and behaviors into a single explanation. In keeping with the qualitative approach, these presented a more complex arrangement of forces than the single-axis scales or binaries commonly expressed by quantitative work. For example, Zimmerman et al [122] used social cohesion to explain those behaviors informed by feelings of togetherness, commonality, empathy, and compassion, linking this to the spread of uptake of health-promoting behaviors across a group. They noted that these can encourage closer adherence to public health guidelines through care for the collective, while at the same time may cause people to deviate from guidelines and regulations when doing so is perceived to benefit another or others who may be in need.

Others produced quantitative analyses using self-report surveys to capture the practice of specific sets of COVID-19–related health behaviors [55,75,93,96]. For example, Cheng and Lo [55] surveyed older adults from the United States on the number of preventative behaviors from a given list in which they engaged and a 3-item Likert scale measuring social cohesion at the neighborhood level. They reported a positive association between the two. Cárdenas et al [75] surveyed a large sample of Australians to investigate whether engaging in physical distancing and hand hygiene behaviors were susceptible to sociopolitical determinants. They used a model of social cohesion incorporating social identification, confidence in government, and social relations captured by a 14-item tool. They reported a complex set of findings in which their measures relating to social cohesion are spread across being positively associated with these health behaviors, negatively associated with them, evidencing no apparent relationship, or associated with one and not the other.

The place of social cohesion in the distribution, provision, and accessing of good-quality health-related information has also been of interest to scholars [38,72,104]. The interview research by Burton et al [38] and Healey et al [72] presented the sharing of health information as a form of social support and, in turn, as a component of social cohesion. Machida et al [104] suggested that the offering and uptake of health information between groups bound by ethnic and cultural sameness may be an explanation for the positive relationship they found between social cohesion and rates of vaccination.

Some authors engaged in commentary on relationships between social cohesion and whether people choose to become vaccinated against COVID-19 [40,78,92,104]. For example, Machida et al [104] in a cross-sectional study in Japan found social capital (in their Putnam-derived construction containing social cohesion) to be associated with both previous vaccination and intent to receive a booster vaccine.

Social Cohesion Promoting Resilience and Emotional Well-Being

The effects of social cohesion on resilience and mental and emotional well-being have seen significant attention in the literature. These works commonly noted the heightened states of stress and anxiety brought about by the pandemic and the isolating effects of the physical distancing measures that were used to prevent transmission of SARS-CoV-2. There are those who referred to the resilience of groups in this respect, proposing that their chosen model of social cohesion is supportive of this [49,59,60,63,64,70,72,76,77,89,96,97,103,107,109,110,117,128,131]. For example, Rela et al [89] offered an analysis of the action of a Putnam-influenced fusion of social cohesion and social capital in Indonesia. An argument is presented for social cohesion as a determinant of community resilience, defined as the capacity of a group to cope with changing environments while continuing to improve the living conditions of its members. Garcia-Rabines and Bencich [97] and Healey et al [72] both argued that within-group cohesion in marginalized communities (transgender women and ethnic minorities, respectively) can act as a source of resilience in times of crisis in the forms of practical and moral social support. Group resilience is also, by some, explicitly held as important for groups' protection against psychosocial distress and clinical versions of this [67,96]; and groups of health care professionals' ability to maintain stability and the provision of care [107,128]. Most commonly, however, the various constructions of social cohesion at the group level are offered as a resource for individuals' protection from poor mental health outcomes [51,65,73,81,86,91,95,100,105,132,135]. For example, Best et al [95] surveyed 1381 Canadians on perceptions of social cohesion in their neighborhoods and levels of panic, depression, emotional stability, and worry, alongside a range of other variables. They found that the COVID-19 pandemic and the restrictive responses to it were responsible for heightened distress, but that their social cohesion indicators were unequivocally negatively associated with all measures thereof. O'Donnell et al [73] reported, based on longitudinal research with Australian informants, that neighborhood-level social cohesion was associated with lower levels of depression during periods of high infection rates and restrictions on social activity; but that there was no effect on anxiety and loneliness.

The Negative Effects of Social Cohesion

Some authors offered commentary on the opposites of social cohesion, or its less-desirable effects. These include social cohesion or elements of it as a driver of increased infection or death rates. Ransome et al [53], using data collected from across the United States, and Thomas et al [56], in a San Francisco–based simulation, suggested that social cohesion, viewed as collective engagement or frequency of interpersonal

connection respectively, may offer a mechanism by which increases in social cohesion may explain ethnic differences in infection rates. Brief commentary was also made by Hangel et al [121], Zimmermann et al [122], and Schneiders et al [46] on how demands made by commitments to the cohesion of a larger social group might come to negatively impact the well-being of those in one's close circle. One example of this is in the demands for physical distancing to stop the population-level spread of SARS-CoV-2, meaning that some family members experience isolation.

Some works presented commentaries suggesting that social cohesion may operate to produce in-group versus outgroup orientations or sharpen existing ones in populations in the pandemic environment and explored some of the implications [58,80,82,90,98,114]. Comment was made on group constructions that preexisted the pandemic and their boundaries and operation in its context: age [82], ethnicity [62,65,79,82,86,106,130], gender [114], wealth [79,130] and neighbors versus "outsiders" [58,90]. Others suggested that new groups have formed in response to the pandemic and the requirements of the public health response [80,98]. Ergler et al [80] offered an analysis of the procession of groups that have become marked as outsiders because of the Aotearoa-NZ pandemic response, which included political efforts to generate national unity in opposition to the virus. Schuessler et al [98] measured the extent to which compulsory vaccination policy in Denmark brought into being group boundaries that excluded those resisting vaccination from some aspects of social life.

Changing Social Cohesion During the Pandemic

"Increasing" and "Decreasing" Cohesion During the Pandemic

Some commentators suggested that the pandemic conditions facilitated increases in social cohesion in the manner in which they constructed it. These suggestions were based on observations of increases in the provision of social support [52,74,82,109]; the fruitful interaction between pandemic conditions and previous policy efforts to bolster social cohesion at the local level [48,76]; and perceptions of increases in local unity and solidarity [13,43,44,71,94]. For example, Morgan et al [82] conducted in-depth interviews with older people following the first wave of the COVID-19 pandemic in Aotearoa-NZ and found participants feeling a greater sense of belonging in their communities due to the help they received from family and friends during a difficult time, this being experienced in different manners by different ethnic and age groups.

Some (including some of the same authors) also painted the opposite picture: the pandemic environment bringing about a reduction in social cohesion. Such evidence presented includes declining trust in others from the population under investigation [48,60,71], and in politicians and political institutions [43,44,70,71]. Perceptions of declining national unity are also referenced in this respect [13,43,44,70]. Others, as covered above, reference the action of policy responses to the pandemic to create division [67,80,98]; and the occasional failure of national policy approaches to cater to and include all groups

[82,108]. Also raised in this respect is the sometimes polarizing effects of pandemic politics and public health responses and the interplay thereof with social cohesion, adherence to public health measures, and population health outcomes [98,102,123,126]. Three contributions, characterizing social cohesion as mutual support and trust between neighbors, reported no change [57,79,105].

Several works presented social cohesion and division as antithetical and offered broad commentaries on the operation of the latter [13,43,44,115,126,129]. For example, Bisiada [126], in a theoretical discussion of social life in Germany and Spain over the course of the pandemic, countered the argument that social divisions have been primarily ideological in nature and presented another, that socioeconomics have been the major axis. Abrams et al [43,44] presented data to show that the United Kingdom's experiences of the COVID-19 pandemic have been marked by increasing perceptions of unity at the local level but of disunity at the national level.

"Rally Round the Flag" and Its Diminishing Returns

An observation that is made frequently across the literature, especially in works that have engaged in longitudinal research or ongoing analysis, is that there was a moment of increased cohesion in the early stages of the COVID-19 pandemic, which gave way to a return to form—or worse—toward the end of 2020. This was characterized by the British Academy [13] as a "rally round the flag" effect. This effect has been described occurring in relation to a range of different constructions of social cohesion and their indicators: interpersonal interaction, social support, and feelings of togetherness [13,52,87]; trust in "most people" [66], those in one's neighborhood [42] and government [13,43,96]; political polarization [102]; feelings of national and local unity [13,42-44]; commitment to a common goal [101]; and collaboration between nations [118]. The British Academy's [13] UK-based narrative suggested preexisting division and declining cohesion in the years before the COVID-19 pandemic, followed by a "coming together" during the first wave, in which people were brought to trust each other more, have increased perceptions of local and national unity, identify more closely with their communities, and offer both emotional and practical support to others. The authors suggested that this moment had come to an end by September 2020, at which point almost all indicators returned to prepandemic levels. Perceptions of local unity in some cases remained higher, and trust in government declined to still lower levels, the latter effect being most pronounced in socioeconomically deprived communities and "key" workers, such as those used in frontline social care, who were concentrated in these lower socioeconomic strata and who experienced the greatest exposure to risk of contracting the virus.

The Effects of Policy

A smaller body of work looked into the effects of policy on social cohesion in pandemic conditions. There have been those already mentioned who held vaccination policies [98] and a framing of collective action against the virus [80] as responsible for driving division. Others pointed to the greater levels of social cohesion experienced by nations that focused policy toward fostering it in their pandemic response—including those

emphasizing solidarity and agency [114]; "we-ness," that is, feelings of unity [115]; and the swift rollout of generous social protections [116]. Contrary to this, Strupat [99], in an analysis of the Kenyan response, considered that the burden placed on the nation by the COVID-19 pandemic was too great for the welfare approach overseen by the government to have any real effect. In the study by Di Giulio et al [108], the extended critique of Bolsonaro and the central government's role in the pandemic response in Brazil shows it to have damaged a version of social cohesion centered on political trust and civic engagement, and, in turn, to have led to worse population health and widened inequality. A further set of commentaries, all from the early stages of the COVID-19 pandemic, offered analyses and advice for policy authors toward prioritizing social cohesion in the pandemic response [50,117,124,125].

Changing Interpersonal Relationships

A significant thread in the literature, involving those constructions of social cohesion where interpersonal relationships are at the center, is analysis of how changes in relationships brought about by the COVID-19 pandemic have affected social cohesion. Such accounts include the suggestions that frequency of contact and quality of relationships with people from outside the family circle have diminished [41,43,44,68,84,120]; and that bonding with those in one's close environment has strengthened [42-44,46,82,120]. Other interesting observations on the changing nature of interpersonal relationships includes their becoming politically polarized or depolarized over time [46,102]; and the manners in which the requirements of remaining physically distant can function in cultures of communal sociality [88,112].

A common suggestion is that the conditions of the COVID-19 pandemic have produced a fundamental reformation of the manners and practices by which social relationships are enacted—and therefore a change in a cohesion that is reliant on these. These range from, most simply, the observation that the novel social conditions of the pandemic may bring new conditions for the construction of personal identity, group identity, and thus group interactions [134], that the extent of disruption to established practices has required a conscious and intentional reformation of relationships [46], to the idea that times of crisis bring the requirement for specific sets of practices of interaction [69,73,97]. More specific observations include those on details of the large-scale shift of interaction to remote communication technologies [52,74]; the use of outdoor singing as a communal negotiation of grief and solidarity [100,133]; and signing up to volunteer programs as an expression of commitment to the collective and a means of engaging in meaningful interpersonal interaction [45,47,68]. There are numerous commentaries dealing with the changing practices of interaction of different groups, including the changing construction of oldness in relation to older people's increased vulnerability during the pandemic and how this has affected intergenerational relations [74,82,113]; the "closing ranks" of transgender people in expectation of heightened oppression [97]; increasing victimization experienced by ethnic minorities [43]; the increase in disconnection and isolation felt by key workers [45]; and the disproportionate decline in quality and frequency of social relations felt by socioeconomically

marginalized peoples [13,115,116,126] and those of lower formal education levels [68].

Of particular interest due to their novel nature are the accounts that identify the intersection between local culture and pandemic environment to create conditions of possibility for new practices of interaction. Schröder et al [69], upon their aforementioned theoretical model in which cohesion arises in a space of latency from an underlying milieu of social relations, noted that in Germany these practices took different forms in different geo-cultural regions. These authors held the distribution of socioeconomic resources and values to be of special importance. Villalonga-Olives et al [90] described a "bounded solidarity" on the island of Menorca in which there was an increase in solidarity and support in the communities of the island but a tension between mistrust of outsiders as potential carriers of disease and the reliance on the same outsiders to bring in capital to maintain islanders' financial well-being.

Critique

The literature on social cohesion and the COVID-19 pandemic contains numerous weaknesses. A large proportion of these limitations are a function of the already well-documented issues with the social cohesion concept. The broad diversity of definitions and constructions of social cohesion have long been the subject of discussion and appear to be no closer to a resolution [7,8,12]. In respect of the current work, this means that there is such a spread of versions of social cohesion in circulation that its explanatory power is weakened and it is difficult to make stable comparisons across the body of knowledge. In general, the observation by Bernard [17] remains apt: social cohesion appears as a "quasi-concept," amenable to the imprinting of any political-ideological or discipline-bound framework within which those using it are working.

The presence of such diversity within social cohesion and its value-laden construction would logically require explicit theoretical engagement and clear justification of choice for the version of the concept being deployed. With some notable exceptions [69,82], this work is not—beyond an acknowledgment of diversity—undertaken with detailed attention in the literature reviewed. As such, social cohesion does not carry as much explanatory strength in analyses of the conditions of the pandemic as it might: a model built without theoretical justification leaves its conclusions open to question and becomes open to such criticisms as that from Schröder et al [69]: that the concept is in danger of becoming an "empty signifier." This issue is compounded by the use of measures that do not appear to be a good operationalization of the definition of social cohesion provided. It is a frequent occurrence in the literature that the diversity across constructions is acknowledged, a brief summary given, and a particular definition settled upon, following which a measure is chosen for its previous validation or its ease of administration rather than its reflection of the construction of social cohesion offered.

In this body of literature, social cohesion is, as mentioned, situated among a group of concepts clustered around a set of behaviors, orientations, and situations. Social cohesion is frequently not precisely defined or distinguished from those adjacent concepts. This is especially true in respect of social

capital, where the two are often treated as synonymous [72,89] or where social capital is used as a proxy for social cohesion without a detailed justification [40,96]. There is also frequent unacknowledged definitional imprecision across social cohesion and "solidarity" [50,121]; engagement with democratic processes [123]; the social contract [66,116]; and activity in the civic space [103,104]. Where these concepts are not defined and differentiated with care and clarity, analyses become unclear as to the networks of cause and effect being invoked, and, again, explanatory power is impeded.

It is possible that a large portion of the imprecision across social cohesion, social capital, and civic engagement is a consequence of the broad influence of Putnam's [26,28] work on the field and the use of this and other models derived from it. Putnam's framework, nominally of social capital, incorporates several diverse elements. It situates social cohesion in part as a product of interpersonal connections and individuals' access to resources (finance, support, etc); a notion present in other constructions of social capital [24,25]. However, it also measures political and civic engagement and uses whole groups as the units of analysis—practices that might sit more comfortably under the social cohesion banner. This may invite conflation of these concepts. The frequent use of Putnam's framework also means that the body of knowledge focusing on social cohesion during the pandemic is heavily skewed toward a cluster of constructions of social cohesion kept inside its boundaries: at the local or neighborhood level, contingent on its specific set of indicators and its knowledge produced by quantitative inquiry. One common consequence of this is a self-fulfilling deficit orientation by which social cohesion is held to be reliant on face-to-face interpersonal interaction and trust and is measured quantitatively with models designed for normal conditions. However, in the context of stay-at-home and physical distancing requirements, this leads to an inevitable conclusion that there are problems for social cohesion as a result.

Inattention to theoretical justification and the overrepresentation of quantitative models are made more problematic by an overreliance on older self-reported measures of social cohesion that impede the quality of knowledge in the area. Although the complexity and local specificity of social relationships and the unprecedented nature of the pandemic environment are well recognized, the measurement of social cohesion using, for example, Likert scales with ≤5 items—sometimes one alone—is common. This is unlikely to be sufficient to describe the complexity of the relationships across groups and the populations under scrutiny, especially in novel circumstances. One such frequently deployed tool is the scale by Sampson et al [137]. This was devised in 1997 to measure disorder and collective efficacy (over and above social cohesion) in the suburbs of Chicago and measures a small number of perceptions of the neighborhood on a 5-item Likert scale. Aside from the potential problems with validity in the novel pandemic context, the problems with making firm conclusions on self-reported data of this kind are well documented [138]. Even when cultural specificity and the newness of the pandemic environment are explicitly acknowledged, the complexity and diversity of social relations are recognized, and the ongoing issues with the social

cohesion concept engaged with, some still fall back on such limited manners of measurement.

At the other end of the spectrum, there are some models that appear to be so large and all-encompassing that social cohesion becomes the basic determinant of almost all psychosocial life and culture. For example, the construction by Godara et al [135] includes social connections (capital), interaction, inclusion, civic engagement, identity, social structures, norms and values, loyalty, solidarity, human rights, trust, conflict management, equality, and order; across micro-, meso-, and macro-levels; involves both structures and groups of various sizes; and includes vertical and horizontal relationships. Scholarship of this kind creates a version of social cohesion that becomes deterministic, mechanistic, and inattentive to local difference, while at the same time being too large to make work within the limits of the capacities of knowledge-production apparatus. Its broadness also, again, weakens its explanatory power. There may be a sweet spot between reductionism, expansionism, and the particular that few contributing to this body of knowledge have managed to achieve, although there are some notable examples, predominantly using qualitative or mixed methods [13,43,82,90].

Two further problems with the literature reviewed here are also noted by commentators on the social cohesion literature more generally. The first, in relation to the quantitative work, and described previously by Janmaat [139] and Green and Janmaat [11], is that the indicators contained within commonly deployed constructions of cohesion almost always do not covary [75]. This calls into question the validity of the construction of a concept that aims to provide a single coherent explanation—or independent variable—for social life. The second is that there is some ethical concern with works [53,56] that apply closed-ended quantitative approaches to identify ways in which social cohesion may be driving higher rates of sickness and death from COVID-19 in marginalized populations and minorities. As has been pointed out elsewhere [140], this comes with the danger of blaming the victims of structural violence for its effects.

A final comment here relates to the quality of data regarding COVID-19 outcomes. Such was the speed at which the pandemic achieved great size, the data collection infrastructures were overwhelmed, and the quality of data describing its effects is not currently of a quality most would hope to have. This means that commentaries on effects on population health outcomes, especially those relying on quantitative data, should be treated with caution until better data are produced. This effect is most prominent in those commentaries undertaken early in the pandemic when the quality of data was at its worst. Furthermore, a number of those accounts authored in the early stages of the pandemic may have produced different conclusions if they were undertaken with a longer period of experience, evidence, and context from which to draw.

Discussion

Principal Findings

It is valuable to understand the ways social relationships have influenced and have been influenced by the COVID-19 pandemic. This work reviewed the body of literature that has made use of the social cohesion concept in this endeavor. A range of different constructions of social cohesion were found and can be categorized into the following broad groups:

1. Those considering it a product of interpersonal relationships
2. Those claiming a reliance on sameness
3. Social cohesion as collective action or acting for the benefit of the collective
4. The accumulation of individual subjective perceptions or emotions relating to togetherness
5. The operation of structures of governance
6. Locally or culturally specific arrangements
7. Hybrid models

Some commentaries center on the effects of social cohesion on other objects or processes of interest. In these, the following broad themes are present:

1. Cohesive groups or societies are generally said to see lower burdens of ill-health during the pandemic, depending on how social cohesion is constructed and the population under study.
2. Cohesive groups or societies are generally said to engage in better health-related practices in the context of COVID-19, though there are some tensions identified between the requirements of the larger collective and smaller groups.
3. Social cohesion is said to be a resource for resilience, emotional well-being, and protection against clinically diagnosable mental states during the pandemic.
4. There are indications of an emergence of novel social groupings in relation to the demands of the pandemic and related policy and evidence of in-group–outgroup dynamics.

Some work describes social cohesion itself during the pandemic. In such scholarship, the following broad themes are present:

1. Changes to social cohesion claimed during the pandemic depend on the way it is constructed and the groups under investigation. Changes are distributed and experienced unequally.
2. There was a "rally round the flag" moment early in the pandemic where many populations exhibited higher social cohesion by many different appraisals. This gave way to a return to type—or worse—toward the end of 2020.
3. Government policy before and during the pandemic has been of real importance to the operation of social cohesion ongoing.
4. There have been significant and fundamental changes to the practices around interpersonal relationships. These changes have not been distributed equally across populations.

Problems identified in the literature by and large reflect the wider and well-documented issues with the social cohesion

concept and the diversity of forms it takes [12,17,36]. This makes comparison across the literature and the development of coherent thematic structures somewhat problematic. There is an overreliance on long-established quantitative tools of measurement, which are likely not appropriate for such a new and complex situation. One of the major issues in this respect is the reduction of a complex and diverse arrangement of culturally bound relationships to a limited number of closed-ended measures.

Much of what has been reported here aligns with previous relevant scholarship. Interrelationships between social cohesion and health have been studied extensively, usually suggesting a positive association and a health-promoting effect [29,141]. The importance of social cohesion in preparing for and responding to times of difficulty effectively has also been the topic of extensive scholarship, including violent conflict [142], significant social change [143], natural disasters [144,145] and pandemics [146,147]. Moreover, the transmission of social cohesion to individual psychological and emotional resilience against distress is well studied [148]. The situation-specific forms of bonding, collective action, and support in response to moments of increased need (the "rally round the flag" effect [13]) have also been studied previously under the banner of social cohesion (eg "emergent social cohesion" [149]), such that scholars early in the COVID-19 pandemic engaged in hurried efforts to set out how this effect might be promoted and harnessed [150].

However, new knowledge has been produced by this literature. Obviously, some of this is in relation to COVID-19, which is, of course, itself new, but there has also been novel insight and development of existing ideas on how social cohesion may be conceptualized, its operation, and important considerations therein. A good portion of the more notable insights are raised by qualitative work, which is well-represented in the body of work reviewed here and which is untypical of the social cohesion scholarship in general. One of the more significant directions taken up by the literature reviewed is the acknowledgment of a diversity of potentialities for social cohesion. These included the new arrangements of identities, group membership, relationships, and manners of interaction demanded by the pandemic environment and policy responses [46,47,66,134]. Positions maintaining that distinct locally and culturally bound arrangements of cohesion exist, were also forwarded, taking up Green and Janmaat's [11] somewhat neglected invitation to investigate the idea using a particularist lens [69,90,103]. Commentaries also extended the understanding of the temporal nature of certain expressions of cohesion [13,43,116].

Another area of interest where significant new ground was broken was the place of information and communication technology in the functioning of social relationships and therefore social cohesion, an area identified as neglected by Bayliss et al [9] in their 2019 review. Commentaries highlighted the importance of communications technology (and, of course, having possession of it and necessary skills to make use of it) for maintaining relationships over distance and therefore for the strengthening of cohesion [52,82]; and thus, by implication calling into question the usefulness of constructions of the

concept that rely heavily on the occurrence of face-to-face interaction. In addition, scholarship drew attention to the technologically mediated processes of in and out group formation and political polarization [98,102,126].

This review has several limitations. First, although as broad a net as possible was cast intentionally, the knowledge being produced is bounded by the limits of the search terms deployed. There are, for example, relevant literatures dealing with social capital (without mention of social cohesion), communitas, "tight and loose" cultures, and more that are not captured by the singular focus on social cohesion. Second, there are likely relevant works that were not held by any of the 3 libraries searched here and which have thus been omitted. Third, as has been suggested in the findings section, during the period from which literature was obtained the situation and knowledge on it developed—and in many cases misunderstandings and errors were corrected—at a great pace. This means that those published earlier in the pandemic did not have the benefit of the developments, context, corrections, and hindsight that those published later did. This means that the knowledge being produced here is, at least in part, also subject to this issue. Fourth, related to the third, data quality relating to COVID-19 (especially on morbidity and mortality and, again, especially from early in the pandemic) is still not of the standard one would wish to have to make robust claims. Finally, the great diversity of forms and manners in which social cohesion has been conceptualized, constructed, and measured means that it is frequently difficult and problematic to make broad and sweeping statements on the body of literature. Indeed, as is common across social cohesion literatures, much of the scholarship uses similar nomenclature but is commenting upon and measuring a surprisingly diverse range of phenomena, experiences, and subjectivities.

Future Work

Overall, there is a need for work in this field to use more care and precision when deploying the social cohesion concept. Perhaps the single most compelling piece of evidence from the current review to support this notion is the large number of papers returned that were excluded due to their neglect to offer a definition of the term or any real detail on what it might add to the analysis. It is introduced all too frequently as if there were consensus as to its conceptual stability and as a public good whose benefits are self-evident—and as such without need for any explication. As has been demonstrated by this review and a long lineage of critical work, there is no such consensus, stability, or grounds for presumption of goodness. It appears that, in the face of the uncertainty and imprecision that have long plagued the concept, any scholarship seeking to make use of it must necessarily undertake important groundwork if it is to be of real value to the body of knowledge.

There are a number of areas where such care and precision might be focused. First, and most importantly, there is an immediate need for engagement with and development of the theory underpinning the range of constructions of social cohesion to sharpen them and make them more useful—both for understanding the pandemic and other aspects of social life. There are some promising beginnings offered by those, such as

Schröder et al [69], which engage in robust theoretical justification for their choices in their process of model construction, allow for flexibility of group boundaries, and seek to capture important context-specific features of social life. Such works may be built upon and put to use in improving the concept, its components, and ways of measurement toward understanding the social world. Theoretical work currently appears especially necessary for establishing the robust connections between constructions of social cohesion and the variables chosen for its representation, which are currently largely sorely lacking. Such work will help both to sharpen the concept and end the overreliance on older and more limited measures. This will also necessarily involve considered and explicit disambiguation of the cluster of concepts that have thus far been confused—especially social cohesion and social capital.

Following this, there is a need for more qualitative research to generate new knowledge on the ways social cohesion may be understood to operate in the context of COVID-19 and beyond. Work, such as that from Morgan et al [82], appears to push at the boundaries and demand evolution of the older model of social cohesion selected for use. This is a demonstration of the usefulness of detailed and in-depth qualitative work for understanding the unprecedented social conditions and relationships operating during the pandemic and of the opportunity to develop the existing quantitative frameworks toward greater depth of understanding. Scholarship in both arenas will assist both in improving the social cohesion concept and the social cohesion scholarship on the COVID-19 pandemic in relation to contextual specificity. The importance of this line of inquiry has been noted by Green and Janmaat [11] for social cohesion generally and by Schröder et al [69] on the pandemic environment, but work of this nature remains thin on the ground. Work to explore subjective perceptions of togetherness, the reorganization of priorities and practices taking place during the pandemic, and the effects of swift and radical new policy directions would all be of value.

The literature contains an overrepresentation of analyses conducted at the neighborhood level and, relatedly, a preponderance of constructions of social cohesion that may more comfortably be called social capital. This is true of both the COVID-19–related scholarship and the wider social cohesion field [140]. More work is needed to understand the operation of societies at the national level. The ongoing project conducted by Abrams et al [42-45] in the United Kingdom offers an excellent example of the value of such scholarship. There is also room for more (and more detailed) analysis at the small-group level under the social cohesion banner; for example, what are the subjective mechanics of togetherness and identification with the group in the pandemic environment? The operation of information and communication technology in respect of social cohesion also represents a promising avenue for future research offered by the work reviewed: in the pandemic's requirement for physical distance, what does the replacement of interpersonal interaction with technologically mediated modes mean for the nature of togetherness? This may also provide interesting and useful insights around the notion of cohesive transnational groups and populations connected by such technologies beyond the pandemic environment.

Abstract

Background: Clinical decision support systems (CDSSs) are designed to assist in health care delivery by supporting medical practice with clinical knowledge, patient information, and other relevant types of health information. CDSSs are integral parts of health care technologies assisting in disease management, including diagnosis, treatment, and monitoring. While electronic medical records (EMRs) serve as data repositories, CDSSs are used to assist clinicians in providing personalized, context-specific recommendations derived by comparing individual patient data to evidence-based guidelines.

Objective: This targeted literature review (TLR) aimed to identify characteristics and features of both stand-alone and EMR-integrated CDSSs that influence their outcomes and benefits based on published scientific literature.

Methods: A TLR was conducted using the Embase, MEDLINE, and Cochrane databases to identify data on CDSSs published in a 10-year frame (2012-2022). Studies on computerized, guideline-based CDSSs used by health care practitioners with a focus on chronic disease areas and reporting outcomes for CDSS utilization were eligible for inclusion.

Results: A total of 49 publications were included in the TLR. Studies predominantly reported on EMR-integrated CDSSs (ie, connected to an EMR database; n=32, 65%). The implementation of CDSSs varied globally, with substantial utilization in the United States and within the domain of cardio-renal-metabolic diseases. CDSSs were found to positively impact "quality assurance" (n=35, 69%) and provide "clinical benefits" (n=20, 41%), compared to usual care. Among CDSS features, treatment guidance and flagging were consistently reported as the most frequent elements for enhancing health care, followed by risk level estimation, diagnosis, education, and data export. The effectiveness of a CDSS was evaluated most frequently in primary care settings (n=34, 69%) across cardio-renal-metabolic disease areas (n=32, 65%), especially in diabetes (n=13, 26%). Studies reported CDSSs to be commonly used by a mixed group (n=27, 55%) of users including physicians, specialists, nurses or nurse practitioners, and allied health care professionals.

Conclusions: Overall, both EMR-integrated and stand-alone CDSSs showed positive results, suggesting their benefits to health care providers and potential for successful adoption. Flagging and treatment recommendation features were commonly used in CDSSs to improve patient care; other features such as risk level estimation, diagnosis, education, and data export were tailored to specific requirements and collectively contributed to the effectiveness of health care delivery. While this TLR demonstrated that both stand-alone and EMR-integrated CDSSs were successful in achieving clinical outcomes, the heterogeneity of included

studies reflects the evolving nature of this research area, underscoring the need for further longitudinal studies to elucidate aspects that may impact their adoption in real-world scenarios.

Introduction

Clinical decision support systems (CDSSs) are designed to assist health care professionals (HCPs) in making evidence-based decisions using patient information, clinical knowledge, and other health care data [1]. CDSSs are typically developed as computer-based tools or software applications and can function independently (termed stand-alone) or be connected to an electronic medical record (EMR) database (termed EMR-integrated systems). According to regulations for software as medical devices in Canada and the United States and a medical device regulation in the European Union [2,3], a CDSS can be classified as a medical device or can be exempt from regulations as a nonmedical device, depending on its specific functions and intended purpose; however, the specific criteria and regulations may differ across countries or regions.

CDSSs are used to provide support across a spectrum of health care activities, including early disease detection, diagnosis, data interpretation, treatment planning, patient care, monitoring, and prognosis [4]. These functions can be enabled via specific CDSS features, such as the ability to estimate treatment efficacy or level of risk, recommend a treatment regimen or a referral, predict drug-drug interactions and dosing alerts, flag potential aspects for further monitoring, and facilitate shared decision-making [5,6]. CDSSs can be knowledge based, using predefined clinical decision rules (such as reinforcement-based methods), or non–knowledge based, relying on data-driven approaches like artificial intelligence, machine learning, or statistical pattern recognition, instead of being programmed to follow expert medical knowledge [7]. CDSSs can integrate data from multiple sources such as clinical guidelines, peer-reviewed literature, historical patient data, and EMRs [4]. In integrated CDSSs, input data (ie, relevant patient information) are acquired from an EMR database, such as Epic [8], Allscripts [9], Aifred Health [10], and Eclinicalworks [11], which serve as primary platforms for clinicians to check patient laboratory results, clinical documentation, and reports [4]. In contrast, stand-alone systems require manual data entry such as Epocrates [12], a CDSS that provides accurate, reliable, and actionable clinical tools to support clinicians in making point-of-care decisions [4].

CDSSs aim to improve health care delivery by enhancing medical decisions and tailoring patient care with targeted clinical knowledge and multidimensional medically relevant health indicators. These indicators can span across several dimensions of patient health and include but are not restricted to vital signs (eg, blood pressure and heart rate), laboratory values (eg, blood glucose levels and cholesterol levels), diagnostic test results (eg, electrocardiogram and magnetic resonance imaging), disease-specific biomarkers (eg, tumor markers and hemoglobin A_{1c} [HbA_{1c}]), patient-specific data (eg, allergies and medications), and predictive models (eg, Framingham risk score). Since CDSSs first originated in the 1970s, a manifold of systems has been developed and implemented using different modalities (eg, PC and tablet) as EMR-integrated or stand-alone systems for the management of numerous conditions at different stages, with a vast scope of functions (flagging, drug control, shared decision-making, etc), users (eg, HCPs, patients, and nurses), and settings (eg, ambulance, surgery room, and general practitioner's office) to address unmet needs of a given region or country [13]. In the context of ongoing digital transformation in the health care sector, the potential of CDSSs for improving the quality and efficacy of care has been increasing. Indeed, CDSSs have been associated with a positive impact on the quality of clinical practice and patient adherence in the management of chronic diseases [4,6,14]. It is noteworthy that while some CDSS significantly improved clinical practice, some yielded limited results, and others failed to meet expectations [15-17]. To date, a body of research sheds light on the reasons behind the lack of success or adoption of CDSSs from both theoretical and practical standpoints [6,16]; however, while previous research addresses clinical practice in general terms for both computer-based and manual systems, this review aims to complement previous work by focusing on the studies that address electronic and guideline-based CDSSs for the management of chronic, noncommunicable diseases in a primary care setting. Specifically, we aim to identify features and characteristics that impact the efficacy of CDSSs based on the outcome measures, consequently contributing to several value areas. We sought to gain a deeper understanding of the various value areas where improvements could be made through these systems, as well as the features that contributed to positive outcomes in the studies evaluating the benefits of CDSSs for HCPs.

Methods

Overview

This targeted literature review (TLR) was conducted to identify features of stand-alone and EMR-integrated CDSSs that positively impacted multiple value areas (Multimedia Appendix 1) and overall success (as measured by respective clinical outcomes) as reported in peer-reviewed literature. The TLR was conducted using multiple sources, including the Embase, MEDLINE, and Cochrane databases, and searches were limited to literature published from January 2012 to October 2022. The searches were performed using a combination of free-text search terms and controlled vocabulary terms specific to each database (Tables S1-S4 in Multimedia Appendix 2). Only studies

published in the English language were eligible for inclusion. The TLR searches were conducted with no geographical restriction. All conferences indexed in Embase were searched to identify relevant abstracts published within a 2-year timeframe from January 2020 to October 2022. The search strategies are detailed in Tables S1-S4 in Multimedia Appendix 2.

The eligibility criteria were developed based on population or scope of interest, intervention, comparators, outcomes, and study design (Table 1). The scope of interest was all health care providers. The TLR included studies on computerized,

guideline-based CDSSs with a focus on chronic disease areas. Clinical trials, as well as observational studies (ie, cohort, case-control, cross-sectional, and case series) conducted using CDSSs with HCPs across chronic noncommunicable disease areas were included in the TLR. Narrative reviews, conference abstracts published before 2020, and any CDSSs that were not computerized (based on software application) or not based on guidelines were excluded. Studies reporting evidence for CDSSs from the patient benefit perspective or studies in patient-oriented, self-management tools [18] were out of the scope of this review.

Table 1. Study selection criteria.

	Inclusion criteria	Exclusion criteria
Population or scope of interest	• Guideline-based CDSS[a] for care and treatment management • Disease area: chronic, metabolic, or noncommunicable etiology • Use group (including but not restricted to PCPs[b], nurse practitioners, nurses, specialists, pharmacists, medical students, educators, patients, and caregivers)	• Decision support systems that are not computerized or guideline based • Disease areas (duration of disease [acute], natural course of disease [curable], and non–disease-specific CDSSs) • User group is out of scope (eg, patients)
Intervention or approach of interest	• CDSS	—[c]
Comparator	• Any or none	—
Outcomes or variables of interest	• Features of CDSSs that impact the successful adoption of these systems (including but not restricted to system type: stand-alone or incorporated in an EMR[d]) • Value areas (clinical benefits, patient safety and risk, workflow improvements, educational aspects, user satisfaction, quality assurance, guideline adherence, and patient behavioral change or self-management) • Investigational or marketed device? • Main function of the CDSS in disease management (treatment management only or treatment management + combined diagnostic) • Study setting (primary health care setting, hospital outpatient setting, community health care setting, or rehabilitation clinic)	• Intended purpose of the CDSS is out of scope (blood transfusion, antibiotics treatment, treatment of attacks [including stroke, management of infections, fractures or pain, and support for organ transplants], or systems used in diagnostic purposes exclusively [eg, screening or testing only]) • Diseases are out of scope (eg, dermatology and rheumatology) • Study setting (inpatient, ICU[e], or emergency department)
Study design (full-text publications only)	• Observation studies (ie, cohort, case-control, cross-sectional, or case series) • Randomized and nonrandomized studies • Database studies • Modelling studies • Economic evaluations • SLRs[f] (for reference chasing only)	• Qualitative studies (eg, interviews) • Conference abstracts • SLRs • Narrative reviews • Methods or protocol papers
Geography	• Global, with a specific focus on Canada, the United States, and Germany	• No restriction
Timeframe	• 10 years (from January 212 to October 2022)	• Studies published before January 2012

[a]CDSS: clinical decision support system.

[b]PCP: primary care provider.

[c]Not applicable.

[d]EMR: electronic medical record.

[e]ICU: intensive care unit.

[f]SLR: systematic literature review.

Study Selection

Following the searches, all identified studies were screened for inclusion by a single reviewer and verified by other CDSS domain experts (KG and PS) by reviewing the title and abstract, based on predefined study eligibility criteria (Table 1). Selected studies then underwent full-text screening by a single reviewer, followed by CDSS domain expert (KG and PS) verification. The TLR used a comprehensive approach by tagging information at the full-text screening stage to help narrow the scope and prioritize key evidence needed to answer the research question. Tagging captured information on categorical variables such as disease area, CDSS features, value area or areas (as shown in Table 1), methods used to implement CDSS, target user groups, product category (investigational or marketed CDSS), function of CDSS in disease management, and environment of use. All categories of tagging are detailed in Table S5 in Multimedia Appendix 2. The tagging information was quality-checked for accuracy by 2 other reviewers (CR and KG). Any disagreements between reviewers about screening decisions were resolved by CDSS researchers (KG and PS). Studies that met all inclusion criteria and none of the exclusion criteria were eligible for inclusion in the review.

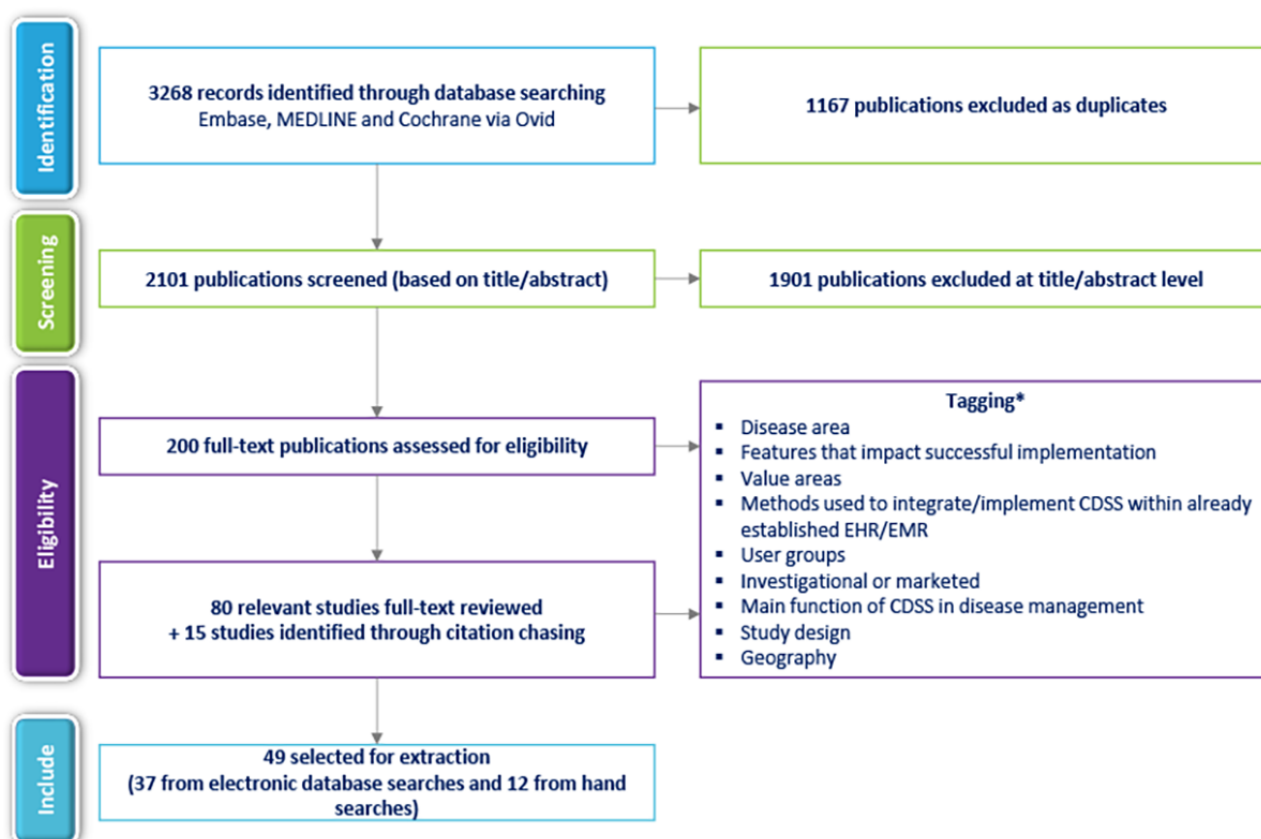
Data Extraction

A data extraction form was designed and developed in Excel (Microsoft Corp), which included key variables such as study objectives, study design, CDSS tool details, disease area, outcome measurement, CDSS value areas, CDSS features, methods of CDSS integration, and study conclusions, among others. An exhaustive list of all data of extracted variables is provided in Table S6 in Multimedia Appendix 2. The design of the data extraction form, selection of variables for extraction, classification of value areas (Multimedia Appendix 1), classification of features (Multimedia Appendix 3), and classification of disease areas (Multimedia Appendix 4) were iterative processes supported by literature classification frameworks within existing CDSS literature and inputs from CDSS domain experts (PS, KG, and AA). Furthermore, in alignment with available literature [6,16], the selected CDSS studies were heterogeneous in terms of architecture, modality, setting, input and output data, functionalities, type of integration, and intended user group, which provided additional insights into identifying the variables of interest. To compare the included CDSSs in an unbiased manner, we screened all studies for common differentiators, which, in addition to the established criteria, further informed the design of the data extraction framework. CDSSs evaluated in the reviewed studies were classified as successful or unsuccessful. Success was defined as having achieved the study outcomes and met the study objectives. To evaluate the performance of CDSSs as reported in the identified studies, we extracted information pertaining to their "objectives" and "success" for each study. We defined 3 criteria of success based on whether a given study met primary and secondary objectives (ie, successful study), did not meet any objectives (ie, unsuccessful study), or met some of the goals (ie, partially successful study). An example of meeting set objectives includes rejecting the null hypothesis in the case of randomized controlled trials (RCTs) by showing improved cardiovascular risk associated with the utilization of a CDSS [19] or acquiring desirable scores on satisfaction scales or positive qualitative feedback from HCPs in the case of an observational study [20]. While not fully explored in this review, another measure of the success of a CDSS is adoption (or uptake), as it indicates whether the system is fulfilling its intended purpose in practical, everyday health care settings. Data were extracted into the form by one investigator (SP) and further verified by a second investigator (CR). The completed data extraction form was validated for accuracy and completeness by two additional domain experts (PS and KG). The results of the validated data extraction were analyzed using a narrative approach to synthesize the findings of the review.

Results

Literature Search Results

The electronic database searches yielded 3268 records. After removing 1167 duplicates, 2101 unique records were screened by reviewing titles and abstracts. Of these, 80 publications met the eligibility criteria for full-text screening (Figure 1). Figure 1 summarizes the complete screening process in a TLR flow diagram. Following a full-text review, 49 unique records met the study eligibility criteria and were included in the review (Multimedia Appendix 5 [19-67]). Of these, 37 full-text publications were identified from electronic searches, and 12 were identified through manual searches of reference lists of journal studies.

Figure 1. TLR flowchart. CDSS: clinical decision support system; EHR: electronic health record; EMR: electronic medical record; TLR: targeted literature review. *Examples of categories are provided in Table S5 in Multimedia Appendix 2.


Study Characteristics

The TLR included RCTs (n=24, 49%), nonrandomized studies (n=2, 4%), and observational studies (n=23, 47%). The studies were performed in various environments of use, and primary care settings (n=34, 69%) were represented most frequently, followed by specialty clinics (n=7, 14%), and hospital outpatient settings (n=7, 14%); one study did not report study settings. The disease areas of CDSSs varied across studies, and cardiorenal diseases were reported most frequently (n=32, 65%), followed by diabetes (n=13, 56%) and atrial fibrillation (n=5, 10%).

Stand-alone Versus EMR-Integrated CDSS

Of the 49 included studies, 32 (65%) studies evaluated CDSSs integrated into EMRs, while 17 (35%) studies were on stand-alone CDSSs (ie, operating independently).

Geographic Distribution

The included studies were conducted across diverse geographical locations, spanning a total of 15 countries (Figure S1 in Multimedia Appendix 2). Of the 17 studies on stand-alone CDSSs (17/49, 35% of all studies), 6 (35% of the 17 stand-alone studies) were conducted in the United States, and the others originated from Austria (1/17, 6%), Brazil (1/17, 6%), Canada (2/17, 12%), China (1/17, 6%), Iceland (2/17, 12%), India (1/17, 6%), the Netherlands (1/17), and the United Kingdom (1/17, 6%; Figure S2 in Multimedia Appendix 2). One stand-alone study was a multicenter study conducted in Austria, Germany, Italy, and the United Kingdom. Of the 32 EMR-integrated CDSS

studies (32/49, 65% of all studies), 15 (46% of the 32 EMR-integrated studies) were conducted in the United States, followed by Canada (3/32, 9%), the Netherlands (2/32, 6%), and China (2/32, 6%); 1 (3%) study originated from each, Australia, Sweden, Brazil, Belgium, India, Spain, Sri Lanka, United Kingdom, and Singapore (Figure S2 in Multimedia Appendix 2), and 1 (3%) EMR-integrated CDSS study was a multicenter study conducted in India and Pakistan.

Disease Areas

Stand-alone CDSSs, as well as integrated CDSSs, were widely used in the management of type 2 diabetes (stand-alone: 5/17, 29%; integrated: 8/32, 25%). Additionally, both types of CDSSs were used in managing cardiovascular diseases (CVD), such as atrial fibrillation (stand-alone: 1/17, 6%; integrated: 4/32, 13%). Stand-alone CDSSs were used to manage CVDs such as heart failure (1/17, 6%) and cardiac rehabilitation (1/17, 6%; Figure S3 in Multimedia Appendix 2), while integrated CDSSs were used in managing CVDs such as atherosclerotic CVD (2/32, 6%; Figure S4 in Multimedia Appendix 2). Only a limited number of CDSSs were used in cancer management (stand-alone: 1/17, 5.9%; integrated: 4/32, 13%). Fewer CDSSs focused on disease areas including mental health (stand-alone: 2/17, 12%; integrated: 3/32, 9%), respiratory (stand-alone: 1/17, 6%; integrated: 1/32, 3%), musculoskeletal (stand-alone: 2/17, 12%; integrated: 0/32, 0%), and neurogenic conditions (stand-alone: 0/17, 0%; integrated: 2/32, 6%). One CDSS supported multiple chronic conditions such as hypertension, diabetes mellitus, and depression (stand-alone: 0/17, 0%; integrated: 1/32, 3%).

Environment of Use

Both CDSS types were extensively used in primary care settings in 69% (34/49) of studies (stand-alone: 11/17, 65%; integrated: 23/32, 74%), followed by specialty clinics in 14% (7/49) of studies (stand-alone: 4/17, 23%; integrated: 3/32, 10%), and hospital outpatient settings in 14% (7/49) of studies (stand-alone: 2/17, 12%; integrated: 5/32, 16%). One study did not report the study settings.

Modality of Use and Data Sources

Both types of CDSS used various modalities, ranging from desktop applications on computers to smartphones and tablets. Several integrated CDSSs, as well as stand-alone CDSSs, were only accessible via desktop computer platforms (stand-alone: 11/17, 65%; integrated: 29/32, 90%). Stand-alone CDSSs were delivered as smartphone apps across 23% (4/17) of studies compared to 6% (2/32) of studies with integrated CDSSs. One stand-alone CDSS was also deployed on a tablet (6%); however, no tablet-based EMR-integrated CDSS was reported. Across studies, combinations of manual, automated, and mixed input data types were reported. The majority of EMR-integrated CDSSs were interpreted as being fully automated (25/32, 78%), and in some cases, they combined both manual and automated data entry (6/32, 19%); one study reported on a manual CDSS that included a form of a questionnaire to be filled by patients, whereby the data were processed to the CDSS by HCPs to generate recommendations. In a large proportion of stand-alone CDSSs (9/17, 53%), data were provided by the HCPs who manually entered relevant information into the system to generate recommendations. Finally, 18% (3/17) of CDSSs were automated systems continuously monitoring patient data to provide real-time decision support, and some were a mix of manual and automated systems (4/17, 23%; one study did not provide this information).

Information on whether the CDSS was still in the research-and-development phase or fully developed and commercially available was lacking in 78% (38/49) of the studies (stand-alone: 17/17, 100%; integrated: 21/32, 66%). Overall, only 12% (6/49) of CDSSs, especially those integrated with EMRs (stand-alone: 0/17, 0%; integrated: 6/32, 19%), were understood to be commercially available or ready to be used in health care settings.

User Groups

CDSSs were found to target diverse user groups based on a broad spectrum of roles and accountabilities across the health care ecosystem. The key user groups identified through the TLR were combinations of physicians, nurses or nurse practitioners, medical assistants, and care coordinators in 55% (27/49) of studies. Primary care physicians were the sole users of CDSSs in 33% (16/49) of CDSS studies. Meanwhile, other studies indicated exclusive use by specialists, including cardiologists (1/49, 2%), nephrologists (2/49, 4%), and oncologists (2/49, 4%). This pattern of mixed CDSS users was reflected across stand-alone and integrated types of CDSSs (mixed users: stand-alone CDSSs 11/17, 65%; EMR-integrated CDSSs 16/32, 50%). Among mixed user groups, a group of physicians and nurses (stand-alone: 5/17, 46%; EMR-integrated: 11/32, 65%) was most frequently reported across both stand-alone and EMR-integrated CDSS studies. Primary care physicians were the exclusive user group in 29% (5/17) of stand-alone and 34% (11/32) of EMR-integrated studies.

Value Areas

CDSSs provide value across the diverse domains of health care systems, including quality assurance, clinical benefits, guideline adherence, user satisfaction, patients' safety or risk management, workflow improvement, patient behavior, educational aspects, and financial aspects (Table 2). Value areas in the TLR were linked to the outcome measures reported in the studies. The studies evaluated the effectiveness of CDSSs by assessing their impact on a range of value areas. These value areas collectively demonstrated the broad range of CDSS benefits across all studies identified in the TLR. The value areas are described in Multimedia Appendix 1. Quality assurance stood out as a prominent value area reported across 69% (35/49) of studies, followed by clinical benefits (20/49, 41%) and user satisfaction (20/49, 41%). The primary value areas were similar in stand-alone and integrated CDSS, which most frequently were reported to contribute to improving quality assurance, clinical benefits, user satisfaction, and guideline adherence.

Table 2. Value areas identified across stand-alone and integrated CDSSs[a].

	EMR[b]-integrated studies (n=32), n (%)[c]	Stand-alone studies (n=17), n (%)
Quality assurance	23 (72)	12 (71)
Clinical benefits	15 (44)	5 (29)
User satisfaction	14 (44)	6 (35)
Guideline adherence	9 (28)	5 (29)
Workflow improvements	7 (22)	3 (18)
Educational aspects	4 (13)	1 (6)
Patient behavior or self-management	3 (9)	2 (12)
Patient safety and risk	2 (6)	4 (24)
Financial aspects	2 (6)	0 (0)

[a]CDSS: clinical decision support system.

[b]EMR: electronic medical record.

[c]Percentages indicate the proportion of studies reporting on the respective value area. The percentages do not add up to 100%, as one study may report on more than one value area.

CDSS Key Features

CDSSs offer a variety of features, each contributing to key value areas (Multimedia Appendix 1). These features include the ability to flag potential issues for screening and follow-up; ensure safety by monitoring for incorrect indications; and provide support for treatment management, including estimating efficacy, recommending dosages, and suggesting pharmacotherapy options. The features of CDSSs may also facilitate shared decision-making, allow for result exporting, offer screening recommendations, support monitoring, provide referral recommendations, estimate risk levels, aid in diagnosis, contribute to patient education, and enable audits to identify deviations from recommended clinical pathways. Features pertaining to treatment recommendation and flagging were interpreted to be most used across all value areas identified in the TLR. Across stand-alone CDSSs, the most used feature was treatment recommendation by way of assisting HCPs in selecting appropriate pharmacological options; however, across integrated CDSSs, the features of flagging related to noncompliance to guideline-directed therapy [21], treatment eligibility [22], and screening with follow-up [23] were the most beneficial in enhancing all value areas.

Key Features of Successful and Unsuccessful CDSSs

Successful CDSSs

Over two-thirds (34/49, 69%) of all CDSSs identified in the TLR achieved the study outcomes and met the study objective, thus they were categorized as successful in the TLR. Approximately 8% (4/49) of CDSS studies were found to have achieved some (≥1) study outcomes and fallen short in other areas and were considered partially successful. The majority of stand-alone CDSSs (13/17, 76%), as well as EMR-integrated CDSSs (21/32, 66%), achieved their objectives. For the stand-alone CDSSs, 12% (2/17) were deemed unsuccessful and another 12% (2/17) were classified as partially successful. These were reported as 16% (5/32) and 19% (6/32), respectively, for the EMR-integrated CDSS.

Of the 34 successful CDSSs, positive impacts on value areas were reported across all studies, and quality assurance was reported most frequently (n=24, 71%), followed by user satisfaction (n=13, 38%), and clinical benefit (n=15, 44%). Other value areas such as guideline adherence (6/34, 18%), workflow improvement (6/34, 18%), patient safety and risk (4/34, 12%), educational aspects (2/34, 6%), patient's behavioral change (3/34, 9%), and financial aspects (2/34, 6%) were less frequently reported across successful CDSSs. Treatment recommendations and flagging were the features that emerged as the most frequent for successful studies across all the value areas (Figure S1 in Multimedia Appendix 6). Flagging typically involved the CDSS highlighting specific information or events to the attention of the HCPs. Flagging across included CDSS studies encompassed various types, such as flagging to notify of best practice advice, clinical guideline adherence, eligibility for preventative screening and follow-up, glycemic target deviation in diabetes, safety monitoring, out-of-range patient data, and flagging for incorrect indications. The flagging feature played a more important role in patient safety and risk than in any other value area across all successful CDSSs (Figure S1 in Multimedia Appendix 6). Similarly, treatment recommendation was also a frequently used feature in ensuring guideline adherence across all successful CDSS studies included in the TLR (Figure S1 in Multimedia Appendix 6). Other frequently reported features included risk level estimation, diagnosis, education, data export, and monitoring (Figure S1 in Multimedia Appendix 6).For successful stand-alone CDSSs, the most frequent feature was treatment recommendation, which was crucial across all value areas except educational aspects (Figure S1 in Multimedia Appendix 6). This feature played a central role in assisting health care systems and impacting multiple value areas such as patient behavior or self-management, guideline adherence, quality assurance, and user satisfaction. CDSS features such as referral recommendations and screening recommendations were less commonly used than other features (Figure 2).

Across studies on successful EMR-integrated CDSSs, the flagging feature was particularly notable as the most reported feature that contributed to multiple value areas such as quality assurance, clinical benefits, user satisfaction, and patient safety and risk management (Figure S2 in Multimedia Appendix 6). Additionally, alongside flagging, studies on successful EMR-integrated CDSSs also reported treatment recommendations, especially to ensure guideline adherence (Figure S3 in Multimedia Appendix 6).

Unsuccessful CDSSs

Unsuccessful CDSS studies were reported to have achieved neutral or negative study outcomes across measured value areas. Only a small number of CDSSs (7/49, 14%) failed to meet the study objectives, including 16% (5/32) of integrated CDSSs and 12% (2/17) of stand-alone CDSSs. Across unsuccessful CDSS studies, flagging and treatment recommendations were also the features most frequently reported across value areas (Figure S5 in Multimedia Appendix 2). The flagging feature was present across value areas comprising patient safety and risk management, quality assurance, and guideline adherence. The treatment recommendation feature was reported in relation to guideline adherence, quality assurance, patient safety and risk management, and patient behavior. Table 2 summarizes the study characteristics of 49 CDSS studies.

Discussion

Key Findings

This TLR aimed to provide a comprehensive assessment of CDSSs reported in peer-reviewed literature. The specific objective was to identify features of CDSSs that positively impact medically relevant value areas and the overall study success as measured by corresponding clinical outcomes.

According to our findings, in most studies, the application of a CDSS was associated with added clinical value for HCPs. A positive impact of CDSSs was reported for quality assurance in patient care, in particular by improving adherence to clinical guidelines, as well as better diagnostic support, monitoring practices, and additional opportunities for preventative screening and treatment. Using CDSSs was also associated with important clinical benefits, including improved accuracy in diagnoses, clinical decision-making, treatment selection, and thereby, enhanced patient outcomes.

Studies examined in this TLR offered valuable insights into the functions of an effective CDSS depending on its intended purpose. Besides features of successful CDSSs, the studies frequently reported that irrelevant and interruptive alerts led to so-called "alert fatigue" and low use rates, consequently leading to the failure of CDSSs [21,24,25]. These insights underscore the importance of prompting clinician action, integrating CDSSs seamlessly into workflows, and mitigating alert fatigue, all of which are crucial factors for the successful adoption of a CDSS [21,24,25]. A study by Ballard et al [68] found that incentivizing HCPs to use the tool through financial bonuses and other promotional incentives resulted in an increase in CDSS use rates. While the design of a CDSS is a fundamental criterion, other factors such as the organizational and technological infrastructure of the primary care system can also markedly influence the success of a CDSS [24].

The review found that the type of CDSS was not a crucial factor for its success, as both integrated and stand-alone CDSSs contributed to improved outcomes and were identified as beneficial for use in health care. While EMR-integrated CDSSs may have the advantage of ongoing access to patient data in real-time, stand-alone CDSSs offer the flexibility of operating independently from other systems, portability, and faster deployment (ie, the process of making the CDSS available and operational across the health care system) [69-71]. Therefore, the choice between a stand-alone or integrated CDSS should be guided by the needs and preferences of HCPs, intended use and application settings, regulatory considerations, and goals for improving patient care.

Successful CDSSs

Flagging was a feature in 59% of the studies reporting successful CDSSs and emerged as a pivotal feature, especially in the context of patients' safety and risk management (Figure S1 in Multimedia Appendix 6). Flagging features were used in a

variety of scenarios including notifications of best practice advice or clinical guideline adherence, eligibility for preventative screening, glycemic target deviation in diabetes, screening and follow-up, safety monitoring, out-of-range patient data, and incorrect indications. Other value areas such as clinical benefits, user satisfaction, and quality assurance were also frequently enhanced by the flagging feature. In addition to flagging, treatment recommendations (including recommendations for pharmacotherapy, dosage optimization, and nonpharmacological therapy) also played a notable role across multiple value areas, especially regarding guideline adherence. Although less frequently reported, successful CDSSs offered a range of other features beyond flagging and treatment recommendations, including risk level estimation, diagnosis suggestions, and the ability to export information. The popularity of these features may be explained by the specific needs of health systems, health care providers, or disease areas. Therefore, the effectiveness of a CDSS may often rely on a combination of features that collectively contribute to improved patient care, safety, and clinical status. Developers of CDSSs should consider the specific needs and priorities of HCPs in terms of target value areas when designing and implementing a CDSS to ensure that it addresses the unmet need and is effectively and seamlessly integrated within the HCPs' workflow.

Unsuccessful CDSS

Only 7 (14%) studies identified in this review reported CDSSs to be unsuccessful, that is, failing to fulfill study outcomes, compared with conventional approaches to disease management. Similar to successful studies, unsuccessful studies commonly reported the utilization of flagging and treatment recommendation features. Flagging was most often reported to address patient safety and risk management, while treatment recommendation was reported to address guideline adherence in unsuccessful studies. There were no recognizable aspects among unsuccessful CDSS studies that may have contributed to their failure. While unsuccessful CDSSs did not achieve the study objectives, it is important to note that the efficacy of a CDSS may vary depending on various factors, which this review found very little data on (only 7 CDSS studies failed). The included publications did not provide sufficient granularity to fully understand the reasons for which the CDSSs were not successful; however, the authors suggested that the failure of a CDSS was mostly attributed to ineffective design, low use rate, organizational challenges, and issues with CDSS alerts. The authors also highlighted the importance of rigorous testing and undertaking quality improvement initiatives to ensure the effectiveness of a CDSS.

Importance of the Findings

The findings of our review suggest that CDSSs can improve screening for CVD risk factors, such as diabetes, as well as quality assurance and user satisfaction, resulting in clinical benefits for the management of cardio-renal-metabolic diseases. This is of particular interest to the development of novel CDSSs in this disease area such as Exandra, a tool supporting Canadian HCPs in the management of type 2 diabetes by offering individualized, patient-specific recommendations based on the

Diabetes Canada Clinical Practice Guidelines [72] (Exandra as a product has been decommissioned; however, the recommendation engine that supported Exandra is being used under different names in Canada and other countries).

The success of a CDSS may not always result in its adoption across studies. Adoption measures for the uptake of a CDSS in health care settings were largely underreported and inadequately described across successful CDSS studies. Only two studies reported some plans in place for the successful adoption of CDSS in health care settings. A single-arm, longitudinal, observational study conducted in Brazil on HealthRise, a CDSS designed for diabetes and hypertension management in primary care, reported plans to expand the CDSS to primary care units in other towns, include more diseases, and implement it in various settings. Efforts were also underway to address the challenge of integrating the CDSS with the Brazilian public health system's Electronica-Sistema Unico de Saude. Further, a retrospective study conducted in the United States included a CDSS prototype built on the drools platform that can interpret Papanicolaou test (Pap) reports and provide cervical cancer screening and management guidelines. The authors reported that after physician validation, the developed CDSS would be deployed in the Mayo Clinic's outpatient departments with user feedback collected on its performance. The CDSS will integrate with an EMR interface listing all preventive care reminders. An impact analysis was also planned to compare screening and referral rates before and after deployment. It should be noted that the assessment of the successful adoption of a CDSS, as well as the identification of key attributing factors, may have been compromised by the heterogeneity of outcomes evaluated across studies and by the study design (ie, RCTs, whereby participants were incentivized to use a given system). RCTs in the TLR focused predominantly on the efficacy of CDSSs in improving quality assurance and other value areas as the primary outcome, with less emphasis on reporting planned adoption measures for their CDSSs. In contrast, a few observational studies noted challenges with CDSS adoption related to scaling, portability, generalizability of results, limited transferability to different settings, and resource constraints. Among the CDSS studies included in the review, only two observational studies confirmed adoption to health care settings. The primary reasons for the deployment of CDSSs included a high level of CDSS accuracy, user satisfaction, and the potential to improve guideline adherence. Deployment included essential measures to optimize CDSS performance such as user feedback, impact analysis, and intervention monitoring and refinement. Therefore, real-world evidence from marketed or integrated CDSSs, as well as insights from longitudinal observational studies encompassing diverse perspectives, may shed further light on features that contribute to long-term adoption. It is important to note that successful CDSS adoption depends on a combination of factors, including alignment with objectives of HCPs, workflow integration, clinical relevance, usability, customization, training and support, interoperability, technical expertise, resource constraints, financial viability, and multi-level engagement, as well as governmental regulations and barriers [5,73-75]. Active engagement and collaboration by the end users, and in particular, HCPs, to address challenges are vital to ensure that a CDSS meets its objectives [76].

Comparison With Previous Reviews

Our findings show that CDSSs improved quality assurance and user satisfaction, and they provided clinical benefits in cardio-renal-metabolic conditions, though heterogeneity in population characteristics, interventions, and outcomes limits the generalizability of these findings. A recent systematic review on the impact of CDSS on clinical and patient-reported outcomes in patients with chronic disease found inconclusive evidence, primarily attributed to the heterogeneity and methodological biases of included studies. Similarly, a previous review on the effect of CDSS on cardiovascular risk factors found no definitive clinical benefits but highlighted the clinical relevance of CDSS in enhancing shared decision-making [77]. Both reviews emphasize the heterogeneity of studies and methodological differences that reflect the immaturity and the evolving nature of research in the field [77,78].

Previous reviews on the impact of CDSSs in multiple disease areas including CVD and diabetes report a positive effect on physician performance, such as adherence to clinical guidelines and prescription of drugs, whereas they had no impact on other outcomes [4,79,80]. Evidence demonstrating the positive impact of CDSS on prescribing treatments, facilitating preventative care services, and ordering laboratory tests across diverse venues was reported in another review [81]. This study builds on previous findings and has identified key features, such as flagging and treatment recommendations, which are associated with improved patient outcomes. This is in agreement with a previous review assessing features of CDSSs, which identified that features that provided support as part of clinician workflow and those that provided actionable recommendations were strongly associated with CDSS's ability to improve clinical practice [6].

Study Limitations

The TLR followed robust, protocol-driven methods, ensuring a structured and rigorous review process. However, it should be acknowledged that there are no standardized gold standard methods for conducting a TLR; reviews can range from very rapid and targeted searching to comprehensive mimicking a systematic review (but using only one reviewer), which was the case with this TLR. While single screening may increase the potential risk of bias, this was effectively mitigated by leveraging the expertise of subject matter experts to validate the decisions. In addition, it is important to note limitations within the evidence itself. CDSS studies exhibited a high degree of heterogeneity in terms of architecture, modality, setting, input and output data, functionalities, type of integration, and intended user group, which can pose limitations in terms of the generalizability of our findings. On a similar note, the absence of an organized framework outlining all value areas required the research team to develop their own set of value areas building on existing classification frameworks from the CDSS literature, by adding common value areas identified in the reviewed literature. Although this approach may also introduce a possible risk of bias, the potential impact was minimized through expert review and validation. Another limitation was the lack of granularity provided in the publications regarding the factors contributing to the limited success of certain CDSS implementations. While some authors mentioned factors such as suboptimal design, low adoption rate, organizational challenges, and issues with CDSS alerts, more detailed insights would greatly benefit future CDSS development.

Conclusions

The utilization of CDSSs varied globally, with substantial application in the United States and within the domain of chronic cardio-renal-metabolic diseases. Overall, both integrated and stand-alone CDSSs have been successful in providing benefits to HCPs, regardless of the integration type. Our findings suggest that CDSSs have an important role in quality assurance in patient care. Flagging and treatment recommendation features are commonly used in CDSSs to improve patient care, while other features, tailored to specific requirements, collectively contribute to the efficiency of health care delivery. Due to a lack of granularity, as well as extensive heterogeneity in the evidence available, there remains uncertainty around the role of specific factors contributing to the success of CDSS. There is a need for real-world evidence from longitudinal studies to identify the challenges of the adoption and deployment of these systems.

Authors' Contributions

Maria Dvorkina (Evidera, United Kingdom) contributed to the writing of the manuscript. All named authors meet the International Committee of Medical Journal Editors criteria for authorship for this manuscript, take responsibility for the integrity of the work as a whole, and have given final approval to the version to be published. All authors participated in data analysis and interpretation and contributed to the development of the manuscript.

Conflicts of Interest

KG, JM, and AA are employed by Boehringer Ingelheim International GmbH, Ingelheim am Rhein, Germany (and may own Boehringer Ingelheim International stock or stock options). PS is affiliated with Adivus Medical Consultancy, a contractor providing medical consultation to Boehringer Ingelheim International GmbH, Ingelheim am Rhein, Germany. JG has received speaking honoraria and has been on advisory boards of Abbott, Amgen, Astra Zeneca, Bayer, Boehringer, Eli Lilly, Dexcom,

Abstract

Background: Depression is a highly prevalent psychopathological condition among older adults, particularly those institutionalized in nursing homes (NHs). Unfortunately, it is poorly identified and diagnosed. NH residents are twice as likely to fall as community-dwelling older adults. There is a need for more knowledge about the mechanisms and relationships between depression and falls.

Objective: This study aims to identify, analyze, and synthesize research on the relationships between depression and falls among NH residents.

Methods: A literature search was conducted in October 2023 in the following bibliographic databases: MEDLINE ALL Ovid, Embase, CINAHL with Full Text EBSCO, APA PsycInfo Ovid, Web of Science Core Collection, the Cochrane Database of Systematic Reviews Wiley, and ProQuest Dissertations & Theses A&I. Clinical trials were searched for in the Cochrane Central Register of Controlled Trials Wiley, ClinicalTrials.gov, and the World Health Organization International Clinical Trials Registry Platform. Additional searches were performed using Google Scholar, the DART-Europe E-theses Portal, and backward citation tracking. The Newcastle-Ottawa Scale and the Appraisal tool for Cross-Sectional Studies were used to evaluate study quality.

Results: The review included 7 quantitative studies published in 7 different countries from 3 continents; of these, 6 (86%) were cross-sectional studies, and 1 (14%) was a prospective cohort study. Results suggested high frequencies of depressive symptoms and falls among older adults living in NHs, and depressive symptoms were considered a risk factor for falls. The 15-item and 10-item versions of the Geriatric Depression Scale were the most commonly used measurement tools, followed by the Cornell Scale for Depression in Dementia and the Resident Assessment Instrument-Minimum Data Set 2.0. The prevalence of depression was heterogeneous, varying from 21.5% to 47.7% of NH residents. The studies used heterogeneous descriptions of a fall, and some considered the risk of falls, recurrent fallers, and near falls in their data. The prevalence of fallers was disparate, varying from 17.2% to 63.1%. Of the 7 retained studies, 6 (86%) reported a relationship between depression and falls or the risk of falls. Among the 19 other risk factors identified in the review as being associated with falls among NH residents were a history of falls in the last 180 days, >1 fall in the past 12 months, and respiratory illnesses.

Conclusions: There is a paucity of research examining falls among older adults with depressive symptoms in NHs. These findings should alert nurses to the need to consider depression as a risk factor in their work to prevent falls. More research is needed to gain a comprehensive understanding of fall risk among NH residents with depressive symptoms.

Introduction

Background

The demographic transition to older societies is occurring worldwide [1]. The World Health Organization (WHO) predicts that the number of people aged ≥65 years will double from 703 million in 2019 to 1.5 billion in 2050, rising from 6% to 16% of the planet's population [1]. The number of people aged ≥80 years is expected to rise from 143 million to 426 million during the same period [1]. Aging exposes people to a variety of health problems and debilitating chronic diseases that can result in functional dependency. Unfortunately, many older adults experiencing multiple chronic conditions of different etiologies can no longer remain at home and must transition to a nursing home (NH) [2]. Depression or other mental disorders also represent a substantial risk of NH admission [3].

Depressive disorders are characterized by depressive mood or loss of pleasure, accompanied by other cognitive, behavioral, or neurovegetative symptoms that persist for at least 2 weeks and significantly affect an individual's ability to function [4,5]. The *International Classification of Diseases, 11th Edition* defines a depressive episode as having at least 5 out of a list of 10 symptoms, and these must manifest themselves most of the day, nearly every day, or for at least 2 weeks [6,7]. Despite its elevated prevalence of approximately 50%, depression among NH residents is often underdiagnosed and consequently undertreated [8]. With a characteristic pattern of cognitive deficits, mainly affecting executive function, attention, and processing speed, depression affects everyday life [9,10]. NH residents with depressive symptoms often have less ability to perform basic functions, and the condition sometimes speeds them toward functional disability, with an increased risk of falls [11].

Falls are frequent among NH residents, who often already have diminished functional capacities [12]. The WHO defines a fall as "an event in which a person inadvertently lands on the ground or any other surface at a lower level than that at which he was previously standing" [13]. The incidence of falls in NHs is estimated to be twice as high (at 1.7 falls per resident-year) as in the community, and residents are 10 times more likely to sustain a significant injury [14,15]. Indeed, a recent systematic review and meta-analysis estimated the incidence of falls among older adults in NHs to be 43% (95% CI 38-49) [11]. The consequences of falls among NH residents can extend beyond immediate physical harms. Falls can result in serious injuries such as long-standing pain, fractures, and head trauma, which often lead to transfer and admission to hospital, increasing medical costs and impacting the residents' quality of life [16-18]. Falls increase disability, and injured older adults frequently fail to recover their previous level of function [19]. Hip fractures are associated with high morbidity rates, often leading to a reduced ability to perform daily activities [20-23].

Falls are responsible for a significant number of deaths, making them the second leading cause of death by unintentional or accidental trauma worldwide [24,25]. In addition to being costly for both older adults and the health care system, falls can cause anxiety among health professionals and lead to family complaints [26].

Physical injuries and falls also have psychological consequences [27]. Many people who have experienced a fall are afraid of falling again, leading to immobility, followed by pressure ulcers, pneumonia, weakness, and an increased risk of falls [28]. Excessive fear of falling, which is frequently associated with depression, increases the risk of falls [29]. Both depression and fear of falling are associated with impaired gait and balance, an association that is mediated along cognitive, sensory, and motor pathways. A systematic review and meta-analysis by Gambaro et al [29] highlighted the association between depression and the fear of falling, which in turn increased the likelihood of falls.

Depression has been reported as an independent risk factor for falls and has been shown to increase the risk of future falls [30-32]. Four determinants of recurrent falls are reported: postural sway, history of falls, handgrip strength, and depressive symptoms [33,34]. The relationships between depression, cognitive performance, motor performance, and the risk of falls were also illustrated in a recent study that also found that depression slowed choice stepping reaction time, mediated by quadriceps strength and executive function [35]. Vascular disease and its related burden of white matter lesions may produce concurrent changes in balance, gait, and mood [36]. The interaction between depression and falls may also be self-perpetuating among those who are recurrent fallers, inducing the demoralizing effect of repeated falling.

Although antidepressant medication can mitigate depressive symptoms, which should lower fall risks, it also increases fall risk independent of depression. Recent studies reported that people using antidepressant medication no longer experienced depressive symptoms (with only 18% scoring ≥5 on the 15-item Geriatric Depression Scale [GDS-15]), and the use of antidepressants was an independent risk factor for falls [37,38].

A multifaceted approach is crucial for fall reduction, which includes staff training, systematic use of decision support tools, and implementing falls prevention actions [39]. A recent study demonstrated that a program combining individually prescribed progressive resistance training with balance exercises significantly reduced fall rates and improved physical performance among NH residents [40]. To ensure equitable access and guarantee high-quality care precisely when and where needed, new care models incorporating technological advancements are proving effective and well accepted [41]. Given the evidence that NH residents are particularly susceptible to both depression and falls, this study aims to enhance

XSL•FO

RenderX

understanding of these issues within this setting. This is crucial for developing tailored care strategies that address their specific needs effectively.

Objectives

This integrative review aimed to focus on and synthesize the literature from studies on the relationship between depression and falls among NH residents. The review's guiding research question was "What is the relationship between depression and falls among NH residents?" The review also sought to briefly report on the factors contributing to falls identified in the retrieved studies.

Methods

Design

This study used an integrative review design to synthesize published papers on the relationship between depression or depressive symptomatology and falls among NH residents receiving or not receiving treatment with antidepressant medication. It reported factors contributing significantly to falls based on the guidelines developed by Toronto and Remington [42]. The review rigorously applied the 6 steps of the integrative review process by (1) formulating a review question, (2)

systematically searching for and selecting literature, (3) assessing the quality of the studies selected, (4) analyzing and synthesizing studies retained, (5) discussing new knowledge, and (6) proposing further steps for a dissemination plan [43]. Regarding the protocol for this integrative review, published in *JMIR Research Protocols* (ISSN 1929-0748) [44], the authors modified the exclusion criteria for article types and the statistical analysis. In line with the concepts of an integrative review, which impose no restrictions on the designs of the studies evaluated, we considered some study designs other than primary studies, including literature reviews. In addition, no meta-analysis of the results on the relationships between depressive symptoms and depression and falls was computed.

Inclusion and Exclusion Criteria

This review considered papers reporting on falls and their relationship with depression or depressive symptoms among older adults with a mean or median age of ≥65 years living long term in NHs. NHs were considered institutions providing 24-hour room and board services and assistance with the activities of daily living (ADLs) or the instrumental ADLs, as well as health services for the management of the chronic conditions of older adults with physical and cognitive or mental impairments [45]. Textbox 1 presents the complete inclusion and exclusion criteria.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Population: older adults aged ≥65 years

- Depression: depression (diagnosed by a medical professional) or depressive symptoms (assessed by health care professionals using validated tools)

- Falls: incidence of falls, prevalence of falls, and reported or assessed risk of falls

- Health care setting: nursing homes and geriatric or psychiatric nursing homes

- Article types: original prospective research studies with a descriptive, correlational, or cohort design; retrospective cohort studies; mixed methods studies; and literature reviews

- Language: no restrictions

Exclusion criteria

- Population: adults below the age of 65 years

- Depression: antidepressant medication prescription without diagnosed depression or recognized depressive symptoms

- Falls: near falls

- Health care setting: intrahospital units, older adults' houses or apartments, community care living, and assisted living apartments

- Article types: meeting abstracts, conference abstracts, posters, guidelines, commentaries, editorials, opinion papers, book reviews, and case reports

---

Information Sources and Search Strategy

A literature search of the following bibliographic databases was conducted in October 2023 in collaboration with a medical librarian (JRA): MEDLINE ALL Ovid, Embase, CINAHL with Full Text EBSCO, APA PsycInfo Ovid, Web of Science Core Collection, the Cochrane Database of Systematic Reviews Wiley, and ProQuest Dissertations & Theses A&I. Clinical trials were searched for in the Cochrane Central Register of Controlled Trials Wiley, ClinicalTrials.gov, and the WHO's International

Clinical Trials Registry Platform. Searches were performed without language or date restrictions. Additional searches were performed using Google Scholar, the DART-Europe E-theses Portal, and backward citation tracking. Multimedia Appendix 1 provides details of the search syntax, keywords, and index terms used.

Selection Process

The initial search yielded 2345 references, and after the removal of duplicates, 1337 unique citations were identified and imported

into EndNote (Clarivate) software. Two reviewers (AMQ and HV) independently screened the titles and abstracts to identify documents to be included in the second phase. Disagreements over whether studies met the inclusion and exclusion criteria were resolved by discussion between the reviewers. A total of 105 studies were identified as suitable for a full-text review and were independently assessed by 2 reviewers (AMQ and HV).

Backward citation searching identified 6 further studies, but they failed to meet the inclusion criteria. The coauthors discussed and resolved disagreements over inclusion (AMQ, AvG, MMM, AML, and HV). Finally, 7 studies were identified as thoroughly matching the inclusion and exclusion criteria. These studies then underwent a quality appraisal and, finally, continued to the data extraction step. The 2020 PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) standards were followed for reporting information from each step of the review selection process [46].

Data Extraction

Two reviewers (AMQ and HV) developed the data extraction process using a specific, structured data extraction matrix. The following variables were included to answer the research question and meet the integrative review's aims: (1) authors, year of publication, country location, and study duration; (2) study design and sample size; (3) participants' characteristics, including sex, mean or median age, and SD or interquartile 25th to 75th percentile; (4) information about depression or depressive symptoms, depression evaluation tools, information about falls; (5) statistical results about the relationship between depression and falls; and (6) factors contributing to falls.

Assessment of the Risk of Bias in Included Studies

The quality of studies retained was assessed using the Newcastle-Ottawa Scale (NOS) [47] and the Appraisal tool for Cross-Sectional Studies (AXIS) [48]. The NOS comprises 2 different scales designed to evaluate cohort or case-control studies [47]. The NOS scale enables the attribution of scores, up to a total maximum score of 9, in 3 different domains: selection (maximum score 4), comparability (maximum score 2), and outcome (maximum score 3). The AXIS was developed by a panel of experts using a Delphi methodology, and it focuses principally on studies' published methods and results [48]. Two authors (AMQ and HV) performed the evaluations independently. Each study's 3 evaluation domains were meticulously analyzed to evaluate each domain and item based on the reported information. Any assessment score disagreements were resolved through discussion until a consensus was reached, and no third author had to be solicited.

Statistical Analyses

Descriptive statistics of the population's median age, the distribution of men and women, and the number of falls recorded in the studies retained were computed. Additional descriptive statistics on the prevalence of falls and depressive symptoms were computed to report differences between NH residents' profiles and types of NH.

In line with integrative review methodology, which focuses on the comprehensive analysis and synthesis of research findings, a meta-analysis was not conducted, given the substantial heterogeneity among the retained studies [42,49]. Data were analyzed using SPSS software (version 29.0; IBM Corp).

Results

Overview

The selection process (Figure 1 [46]) identified 7 eligible articles that rigorously met the review's inclusion criteria, including a description of the study population, measures of depressive symptoms, fall measures, and statistical results for the relationship between depression or depressive symptoms and falls, summarized in Tables 1 and 2.

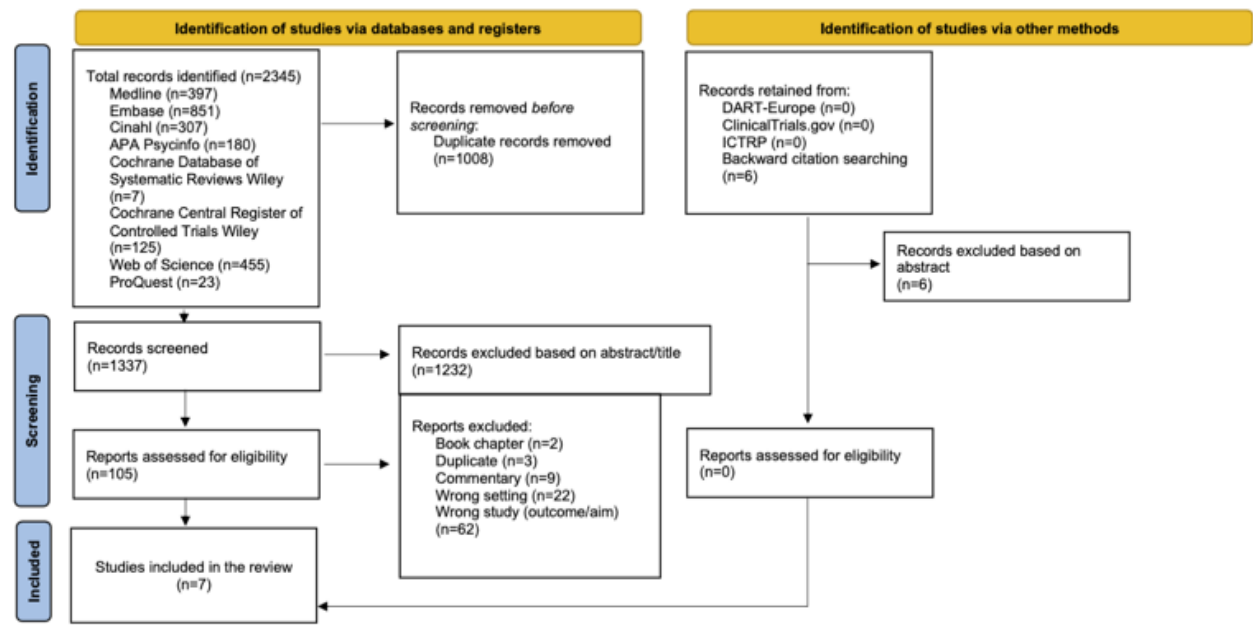
Figure 1. The integrative review flow diagram. ICTRP: International Clinical Trials Registry Platform.


Table 1. Characteristics of the studies retained.

Study	Country	Study aims	Design, data, and period	Sample size, N	Sex	Age (y)	Scales of depression assessment
Kioh and Rashid [50], 2018	Malaysia	Determine the prevalence and risk of falls and their associated factors among nursing home residents	Cross-sectional study collected data from October 2016 to July 2017 in 10 nursing homes	354	Female=230 (65%); male=124 (35%)	Age groups: 60-69, n=47 (13.3%); 70-79: n=162 (45.7%); 80-89, n=145 (41.0%)	GDS-15[a]
Damian et al [51], 2013	Spain	Measure the frequency of falls and associated factors among older adults living institutions	Cross-sectional study collected data from June 1998 to June 1999 in 55 living institutions	733	Female=408 (76%); male=325 (24%)	Mean 83.4 (SD 11.5% ; 95% CI 82.6-84.1)	GDS-10[b]
Khater and Mousa [52], 2012	Egypt	Evaluate the incidence of falls and the risk factors among nursing home residents	Prospective cohort study collected data from June 2009 to May 2010 in 3 nursing homes	84	Female=48 (57.1%); male=36 (42.9%)	Mean 71.9 (SD 7.2)	GDS-15
Ku et al [53], 2013	Taiwan	Investigate the prevalence and frequency of falls and identify factors of falls among older adult men in Taiwan	Cross-sectional study collected data from December 2009 to December 2010 in 4 long-term stay veterans' settings	940	Male=940 (100%)	Mean 85.5 (SD 5.72)	GDS-15
Wang et al [54], 2012	China	Examine the combined effects of medical conditions and depression status on fall incidents among institutionalized older adults	Cross-sectional study collected data over 1 year in 4 long-term care institutions	286	Female=193 (67.5%); male=93 (32.5%)	Mean 81.9 (SD 6.16)	GDS-15
Sylliaas et al [55], 2012	Norway	Examine whether the severity of dementia, behavioral and psychological symptoms, and depression can predict falls among nursing home residents	Cohort study with a 1-year follow-up collected data from November 2004 to January 2025 in 20 nursing homes	1147	Female=839 (73.1%); male=308 (26.9%)	Mean 84.8 (SD 6.86)	Cornell Scale for Depression in Dementia
Kron et al [56], 2003	Germany	Identify individual predisposing risk indicators for falls in a sample of institutionalized, frail older adults	Prospective observational study collected data from October 1998 to September 1999 in 3 long-term care institutions	472	Female=363 (77%); male=109 (33%)	Mean 84.0 (SD 7.0)	Minimum Data Set of the Resident Assessment Instrument, version 2.0.

[a]GDS-15: 15-item Geriatric Depression Scale.

[b]GDS-10: 10-item Geriatric Depression Scale.

Table 2. Depressive symptomatology and falls or risk of falls among nursing home residents.

Study	Statistical results of depression and depressive symptoms	Statistical results of falls	Statistical results for the relationship between depression or depressive symptoms and falls or risk of falls	Other findings on the relationship with falls or risk of falls	Main findings about the relationship between depression or depression symptoms and falls
Kioh and Rashid [50], 2018	Depression (GDS[a] score) n=76 (21.5%)	• Fallers: n=116 (32.8%); 1 fall: n=68 (19.2%); >1 fall: n=48 (13.6%); • Risk of fall (Fall Risk Assessment Tool): low risk: n=307 (86.7%); moderate-high risk: n=47 (13.3%)	• Depression and falls: OR[b] 1.71, 95% CI 1.00-2.91; P<.05 • Depression and risk of falls: OR 1.83, 95% CI 1.06-4.23; P<.05	• Respiratory illnesses and falls: OR 3.38, 95% CI 1.11-10.30; P<.05 • History of >1 fall in the past 12 months and risk of falls: OR 3.90, 95% CI 1.72-8.8; P<.05	Depression was strongly associated with the prevalence of falls and the risk of falls. Respiratory illness was also significantly associated with falls. A history of >1 fall in the past 12 months was significantly associated with the risk of falls.
Damian et al [51], 2013	Depression (disease) n=154 (21%) Depressive symptoms (GDS score) n=193 (33%)	• Fallers: n=88 (12%; 95% CI 9-15), 1.5 falls/person-year • Falls: n=146, 2.4 falls/resident-year (95% CI 2.04-2.82); 1 fall: n=60 (68%); 2 falls: n=18 (21%); ≥3 falls: n=10 (12%) • 1-year risk of falling=0.78	• Depression and falls: RR[c] 2.49, 95% CI 1.38-4.50; RR 1.55, 95% CI 0.95-2.5 • Depressive symptoms (GDS score) and falls: RR 1.06, 95% CI 0.95-1.19; RR 1.01, 95% CI 0.92-1.1	• Number of diseases ≥1: RR 1.40, 95% CI 1.27-1.54; RR 1.32, 95% CI 1.17-1.50 • Urinary incontinence: RR 2.89, 95% CI 1.48-5.65; RR 2.56, 95% CI 1.32-4.94 • Arrhythmias: RR 3.36, 95% CI 1.80-6.30; RR 2.00, 95% CI 1.05-3.81 • Antidepressants: RR 3.40, 95% CI 1.65-7.04; RR 2.32, 95% CI 1.22-4.40	Depression was associated with falls when adjusted for age, sex, cognitive status, and functional dependence. Multimorbidity, urinary incontinence, arrhythmias, and antidepressants were the most relevant factors for falls.
Khater and Mousa [52], 2012	Depression (GDS score): n=39 (46.4%) GDS score: mean 4.61 (SD 2.55)	• Fallers: n=53 (63.1%) • Falls: n=163, 5.3 falls/1000 resident days; 631 fallers/1000 resident-years; 1940 falls/1000 resident-years)	• GDS • Fallers: mean 4.8 (SD 2.5); P=.51 • Nonfallers: mean 4.4 (SD 2.7); P=.51	• Frailty: OR 2.340, 95% CI 1.542-16.746; P=.01 • Timed Up and Go test: OR 3.271, 95% CI 1.287-19.539; P<.001	Depression did not differ significantly between fallers and nonfallers. Frailty and poorer results in Timed Up and Go tests were the only independent risk factors for falls.
Ku et al [53], 2013	Depression (GDS score) n=334 (35.5%); GDS: mean 4.3 (SD 4.05)	• Fallers: n=162 (17.2%); 1 fall: n=97 (59.9%); 2 falls: n=31 (19.1%); 3 falls: n=17 (10.5%); 4 falls: n=7 (4.3%); 5 falls: n=6 (3.7%); 6 falls: n=1 (0.6%); ≥7 falls: n=3 (1.9%) • Fall incidence: mean 3.6 (SD 2.5)	• Depression and falls: OR 1.05, 95% CI 1.01-1.10; P=.01	• Advanced age: OR 1.04, 95% CI 1.01-1.07; P=.02 • Stroke: OR 2.16, 95% CI 1.18-3.96; P=.01 • Gout: OR 1.96, 95% CI 1.36-2.81; P<.001 • Cataract: OR 1.48, 95% CI 1.03-2.15; P=.04	Depression was an independent variable for predicting falls, as were increasing age, stroke, gout, and cataracts.

Study	Statistical results of depression and depressive symptoms	Statistical results of falls	Statistical results for the relationship between depression or depressive symptoms and falls or risk of falls	Other findings on the relationship with falls or risk of falls	Main findings about the relationship between depression or depression symptoms and falls
Wang et al [54], 2012	Depression (GDS score) n=68 (23.8%)	• Fallers: n=81 (28.3%)	• Depression and risk of fall: OR 1.92, 95% CI 1.00-3.64; P<.05	• Ancillary device use and risk of falls: OR 2.70, 95% CI 1.50-4.86; P<.01 • Medications ≥4 and risk of falls: OR 3.23, 95% CI 1.44-7.26; P<.01 • Depression, ancillary device, and risk of fall: OR 6.52, 95% CI 2.62-16.3; P<.01 • Depression, neural system diseases and risk of fall: OR 11.3, 95% CI 1.96-65.2; P<.01 • Depression, medication ≥4 and risk of fall: OR 5.28, 95% CI 1.46-19.1; P<.05	Depression status, using ancillary devices, and multiple medication use were significantly associated with the risk of falling.
Sylliaas et al [55], 2012	Cornell Scale for Depression in Dementia: mean 5.35 (SD 5.1)	• Fallers: n=459 (40%); 1 fall: n=459 (40.0%); ≥2 falls: n=379 (33.0%)	• CSDD[d] and falls: RR 1.37, 95% CI 1.13-1.65; P=.001	• NPI[e]: RR 1.15, 95% CI 1.08-1.19; P<.001 • Age: RR 1.03, 95% CI 1.01-1.04; P=.002 • CDR[f] Scale: RR 1.06, 95% CI 1.03-1.08; P<.001 • PADL[g]: RR 0.95, 95% CI 0.92-0.97; P<.001 • Use of sedatives: RR 1.08, 95% CI 1.04-1.23; P=.003	Severe depression (higher scores on CSDD) significantly predicted ≥1 falls in a bivariate Cox regression. Age; higher scores on the NPI, CDR, and PADL; and use of sedatives were all independent predictors in a multivariate regression analysis.
Kron et al [56], 2003	Minimum Data Set of the Resident Assessment Instrument, version 2.0: n=225 (47.7%)	• Fallers: n=247 (52.3%), • 645 fallers/1000 resident-years, • 2.558 falls/1000 resident-years • Frequent fallers: n=115 (24.4%)	• Depression and >2 falls: OR 1.6, 95% CI 1.0-2.6; P=.049	• Total transfer assistance: OR 0.4, 95% CI 0.2-0.7; P=.002 • Urinary incontinence: OR 2.1, 95% CI 1.2-3.6; P=.007 • Fall in last 180 days: OR 5.2, 95% CI 3.2-8.5; P<.001	Depression, transfer assistance, urinary incontinence, and a positive fall history were important risk indicators associated with the risk of ≥2 falls.

[g]PADL: Personal Activity of Daily Living.

Characteristics of the Included Studies

Most of the studies were published between 2012 and 2018 [50-55], with one published in 2003 [56]. The papers were written by 7 different first authors and examined 7 countries (Malaysia, Spain, Egypt, Taiwan, China, Norway, and Germany), with 43% (3/7) of the studies carried out in Europe [51,55,56], 43% (3/7) in Asia [50,53,54], and 1 (14%) in Africa [52]. Of the 7 studies, 6 (86%) were cross-sectional [50,51,53-56], and 1 (14%) was a prospective cohort study [52].

Population

The studies included a total of 4016 participants, with a mean of 574 (SD 380) older adult participants and a significant

variance in numbers from 84 [52] to 1147 participants [55]. The total sample contained 48.2% (1935/4016) men and 51.8% (2081/4016) women. The median age of the overall sample was 83 (IQR 79.4-84.9) years, with minimum and maximum ages of 71.9 and 85.5, respectively.

Long-Term-Care Facility Definitions

The review considered studies focusing on NH residents with at least a mean or median age of 65 years and living in a geriatric or psychiatric NH, although different terms were used. Ku et al [53] examined 4 long-term stay settings for male veterans only. Of the 7 studies, 3 (43%) [50,52,55] specifically mentioned NHs as their setting, 2 (29%) referred to long-term care institutions [54,56], 1 (14%) described its location as a long-term stay setting [52], and 1 (14%) described them as older people living institutions [51].

Aims of the Studies

The 7 studies retained examined relationships between depression or depressive symptoms and falls in different ways. One cross-sectional study [54] focused directly on the directional relationship between depression status and falls. Another cross-sectional study [55] examined the effects of the severity of dementia, behavioral and psychological symptoms, and depression on falls. The studies retained frequently aimed to describe the risk factors for and factors associated with falls, including 4 cross-sectional studies [50,51,53,56] and 1 cohort study [49].

Depression

Detection and Diagnosis of Depression

Several different depressive symptom measurement tools were used. The 15-item and 10-item Geriatric Depression Scales (GDS) were most commonly used, with 57% (4/7) of the studies [50,52-54] using the GDS-15 and 14% (1/7) of the studies using the GDS-10 [51]. Of these 4 studies, 2 (50%) [53,54] defined depression as a GDS score≥5, but 1 (25%) study [50] categorized participants with a score of 0 to 5 as normal. The study using the GDS-10 [51] scored 0 to 3 as normal and scores of 4 to 7 and 8 to 10 as moderate and severe depressive symptoms, respectively. One study using the GDS-15 [52] did not describe its categorization of depressive symptoms. One study used the Cornell Scale for Depression in Dementia to measure depressive symptoms [55], and the final study used indicators of the Minimum Data Set of the Resident Assessment Instrument, version 2.0 [56]. Neither of the studies mentioned how they categorized depressive symptoms. Two studies specified having based their depression assessments on interviews with residents about their status over the previous 7 days [51] and self-related depressive symptoms [54]. One study [55] was based on information from NH staff members. The other 4 studies [51-53,56] did not specify this information. Only one of the studies revealed a medical diagnosis of depression [51]. Multimedia Appendix 2 [50-56] presents the depression measurement strategies used by the studies retained.

Prevalence of Depression

Of the 7 studies, 6 (86%) included [50-54,56] showed a prevalence of depression above 20%. The mean prevalence of

depressive symptoms in Asian studies was 26.9%, with a significant variation observed between countries [50,53,54]. Ku et al [53] and Wang et al [54] used the GDS-15 scale, with identical cutoff scores, resulting in an overall mean prevalence of depression of 32.8% (402 participants with depressive symptoms/1226 participants). The lowest prevalence of depression was 21.5% (76 participants with depressive symptoms/354 participants) as reported by Kioh and Rashid [50]. In the European studies, Kron et al [56] reported the highest prevalence of depression, at 47.7%, using data from the MDS-RAI 2.0 assessments. Damian et al [51] reported a 33% prevalence of depressive symptoms using the GDS-10 scale. The study by Sylliaas et al [55] reported unclear data on the prevalence and limited the data collected to reporting the odds ratio (OR) of the relationship between depression and falls. No additional data was available. The study by Khater and Mousa [52], performed in Egypt, revealed a notably high prevalence of depression, at 46.4%.

Falls

Descriptions of Falls

The studies included described falls heterogeneously. Khater and Mousa [52] and Wang et al [54] referred to the studies by Delbaere et al [57,58] to define a fall as an unexpected event in which the person comes to rest on the ground, the floor, or a lower level. Kioh and Rashid [50] and Kron et al [56] described falls as unintentionally coming to rest on the ground, the floor or another lower level, whether accidentally or nonaccidentally, other than as a consequence of the sudden onset of paralysis, an epileptic seizure or an overwhelming external force. Damian et al [51] did not define falls. Ku et al [53] based their definition on Tinetti's, which defines a fall as an event that results in a person coming to rest unintentionally on the ground or another lower level, not due to any intentional movement, a major intrinsic event (eg, stroke) or an extrinsic force (eg, being forcefully pushed down, knocked down by a car) [59]. Finally, Sylliaas et al [55] referred to Lord [60], who defined a fall as an unexpected event in which the participant rests on the ground, the floor or at a lower level.

Frequency of Falls or Fall Risks

Different methods were used to collect fall frequency. Two studies [50,54] collected data on the history of falls in the past 12 months through a resident questionnaire and face-to-face interviews. Kioh and Rashid [50] also used the Fall Risk Assessment Tool to determine fall risk. Damian et al [51] used physician and nurse interviews and annotations to determine the number of falls in the preceding 30 days and used the Timed Up and Go test to assess fall risk. Ku et al [53], Sylliaas et al [55], Khater and Mousa [52], and Kron et al [56] explored data collected on events recorded during the study period. Wang et al [54] considered participants who had had a single fall or no falls as "nonfallers," and all other participants with ≥2 falls or with at least 1 injurious fall as "fallers." Kron et al [56] distinguished "fallers" (participants with 1 or 2 falls) from "recurrent fallers" (participants with >2 falls). Multimedia Appendix 3 [50-56] presents the retained studies' definitions and measurement strategies for falls.

Prevalence of Falls

All the studies reported the number of residents who had at least one fall during the study period. Of the total combined sample of 4016 participants, based on each study's definition or description of a fall, 1206 (30%) fell at least once. The highest prevalence of fallers was 63%, with 53 of a sample of 84 participants falling during the 1-year follow-up period in the study by Khater and Mousa [52] in Egypt. The mean prevalence of falls in the studies conducted in European countries was 34.8% (SD 16.86%). The lowest prevalence was 12%, with 88 of 733 participants having at least one fall in the preceding 30 days in the study by Damian et al [51]. Fallers made up 52.3% (247 fallers/472 participants) in the study by Kron et al [56] and 40% (459 fallers/11,147 NH participants) in the study by Sylliaas et al [55]. The prevalence of fallers in Asian studies showed a mean of 26.1% (SD 5.6%). During the year of their study, 162 (17.2%) of 940 participants fell in the study by Ku et al [53], 81 (28.3%) of 286 participants fell in the study by Wang et al [54], and 116 (32.8%) of 354 participants fell in the study by Kioh and Rashid [50]. Ku et al [53] reported a single-fall prevalence of 10.3% (97 fell once/940 male veteran participants) and a recurrent-falls prevalence of 6.9% (65 with a history of falls fell/940 participants). Three studies [51-53,56] reported fall incidence rates. In the study by Khater and Mousa [52], 163 falls occurred among 53 fallers, equivalent to 1940 falls/1000 resident-years (5.3 falls/1000 resident-days). Kron et al [56] recorded 980 falls (2.558 falls/1000 resident-years) among 247 fallers (645 fallers/1000 resident-years). With a total number of 146, Damian et al [51] reported an incidence of 2.4 falls (95% CI 2.04-2.82) per resident-year. On the basis of the FRAT scores, Kioh and Rashid [50] identified 307 (86.7%) participants at a low risk of falls and 47 (13.3%) participants at a moderate or high risk of falls.

The Relationship Between Depression and Falls

The main retrieved publications in our integrative review used the OR to examine the relationship between depression and falls among NHs residents [50,52-54,56]. The OR was used to quantify the association between exposure to depressive symptoms and the occurrence of falls. Consequently, the findings of these studies reflected the odds of falls occurring in the presence of depressive symptoms.

The remaining studies used the risk ratio (RR) to study the mentioned relationship [51,55]. The RR allowed for a comparison of the probability of falls occurring in NH residents with depressive symptoms versus those without depressive symptoms.

Four studies [50,53,54,56] identified a significant association between depression and falls among NH residents. Kioh and Rashid [50] revealed that having depression (OR 1.80, 95% CI 1.07-3.04) was a significant factor associated with falls. After performing a binary logistics regression to take account of possible confounders, depression was also associated with the prevalence of falls among participants (OR 1.71, 95% CI 1.00-2.91) [50]. Ku et al [53] showed that fallers tended to have more severe depression than nonfallers (44.4% vs 33.7%, respectively; P=.01). Using multivariate logistic regression analyses, they revealed that depression status (OR 1.05, 95%

CI 1.01-1.10; P=.01) was an independent variable for predicting falls [53]. On the basis of the univariate analysis, Wang et al [54] found depression to be significantly associated (OR 2.00, 95% CI 1.13-3.55; P<.05) with the risk of falling. In addition, they reported that depression also had a significant association in a multivariate logistic regression analysis (OR 1.92, 95% CI 1.00-3.64; P<.01). Kron et al [56] revealed that depressive symptoms were a significant risk indicator (OR 1.6, 95% CI 1.0-2.6; P=.049) for predicting recurrent falls among their participants. Damian et al [51] reported an association between depression and falls (RR 2.49, 95% CI 1.38-4.50); however, they found a mediating effect of antidepressant and anxiolytic medication (RR 1.55, 95% CI 0.95-2.51). Khater and Mousa [52] showed that levels of depression were not significantly different between fallers and nonfallers. Sylliaas et al [55] found that severe depression was 1 of the 4 strongest predictors of falls (RR 1.38, 95% CI 1.13-1.65; P=.001), but it was no long a significant independent variable after multivariate regression analysis (RR 0.99, 95% CI 0.96-1.02; P=.55).

A total of 19 potential risk factors, other than depression, were associated with falls among NH participants. Kioh and Rashid [50] showed a significant association between respiratory illnesses and falls (OR 3.38, 95% CI 1.11-10.30; P<.05) as well as between a history of >1 fall in the past 12 months and risk of falls (OR 3.90, 95% CI 1.72-8.8; P<.05). A history of falls in the last 180 days was also identified as an important fall risk indicator (OR 5.2, 95% CI 3.2-8.5; P<.001) in the study by Kron et al [56]. Kron et al [56] documented that urinary incontinence was one of the most relevant factors for falls (OR 2.1, 95% CI 1.2-3.6; P=.007), and in the study by Damian et al [51], it was an important risk indicator associated with ≥2 falls (RR 2.89, 95% CI 1.48-5.65). Wang et al [54] found that polypharmacy was significantly associated with the risk of falls (OR 3.23, 95% CI 1.44-7.26; P<.01). Damian et al [51] found that antidepressants were a relevant factor for falls (RR 3.40, 95% CI 1.65-7.04), and Sylliaas et al [55] reported sedatives as an independent predictor of an increased risk of falling (RR 1.08, 95% CI 1.04-1.23; P=.003). In addition, Damian et al [51] found that multimorbidity (RR 1.40, 95% CI 1.27-1.54) and arrhythmias (RR 3.36, 95% CI 1.80-6.30) were relevant risk factors for falls. Stroke (OR 2.16, 95% CI 1.18-3.96; P=.01), gout (OR 1.96, 95% CI 1.36-2.81; P<.001), cataracts (OR 1.48, 95% CI 1.03-2.15; P=.04), and advanced age (OR 1.04, 95% CI 1.01-1.07; P=.02) were independent variables for predicting falls in the study by Ku et al [53]. Age was also identified as an independent predictor of a risk of falls in the study by Sylliaas et al [55].

Frailty (OR 2.340, 95% CI 1.542-16.746; P=.01) and poorer results in Timed Up and Go tests (OR 3.271, 95% CI 1.287-19.539; P<.001) were the only independent risk factors for falls in one study [52]. Wang et al [54] found that ancillary device use increased the risk of falls (OR 2.70, 95% CI 1.50-4.86; P<.01) and that the risk of falling was enhanced by the interacting factors of depression, ancillary devices (OR 6.52, 95% CI 2.62-16.3; P<.01), nervous system diseases (OR 11.3, 95% CI 1.96-65.2; P<.01), and >4 medications (OR 5.28, 95% CI 1.46-19.1; P<.05). Finally, in one study, higher scores on the Neuropsychiatric Inventory, Clinical Dementia Rating scale,

and Personal Activity of Daily Living were all independent of other predictors of an increased risk of falling [55].

Assessment of the Risks of Bias in the Studies Retained

The quality and risks of bias of the studies retained were assessed using the NOS [47] and AXIS [48]. One cohort study [52] was classified as being of good quality, scoring 8 stars, with 3 in the selection domain, 2 in the comparability domain, and 2 in the outcome domain. Of the 6 cross-sectional studies [50,51,53-56], 4 (67%) [50,51,53,54] were considered of good quality and 2 (33%) of moderate quality [55,56] but sufficient to be integrated into our integrative review and undergo data extraction. Multimedia Appendix [52] 4 and 5 [50-56] summarize the quality evaluation results of the cross-sectional studies and the quality and risk of bias assessments of the cohort study.

Discussion

Principal Findings

This integrative review rigorously searched for publications on the relationship between depression or depressive symptoms and falls among NH residents. A total of 7 studies were selected, with 6 (86%) published in the last 10 years and 1 (14%) published in 2003. The studies included 4016 participants with an overall median age of 83 years. Of the 7 studies, 6 (86%) reported a prevalence of depression >20%, and approximately 30% of the total sample had experienced at least one fall. Despite the methodological differences between the studies, their results predominantly showed a significant relationship between depressive symptoms and depression and falls and the risk of falls [50,51,53-56]. To the best of our knowledge, this was the first review to synthesize relevant publications on how depression is related to falls among NH residents. The results highlight the significance of falls and depressive symptoms among NH residents.

Most of the studies had small sample sizes (Table 1), but most of them had a sufficient sample size individually, and they gave the total sample the necessary statistical power [50-54]. The studies did not all use the same precise definition of an NH or an NH resident. A fall was defined in different ways: some studies used the variable of risk of falls or near falls, and one study considered a resident who had only had one fall to be a nonfaller, making a detailed comparison between fall prevalence between studies somewhat of a conundrum. These differences can be explained by the studies' designs and geographical contexts and the use of heterogeneous fall assessment tools. To increase comparability and improve the meta-analysis of existing data, it is advisable that future studies adopt a universal description of a fall, for example, the WHO's definition [61]. Nonetheless, as previously mentioned, the heterogeneous clinical practices of different countries make comparison difficult. In addition, because some of the studies retained only received a moderate quality assessment, any interpretations should be made with care. The review revealed that the relationship between depression and falls is complex and multifactorial, and that the mechanisms of this relationship were not always completely understood [62]. All the studies considered other risk factors. The studies retained were unclear about the methods used to

diagnose depression, and although these were primarily based on validated tools, they failed to mention whether physicians had confirmed the diagnoses. The average occurrences of depression reported in the studies retrieved were similar to other studies conducted in NHs [63,64]. Our studies used 4 different validated tools for depression, and there was not always consistency in the cutoff scores used with the same diagnostic tools. In the study by Kioh and Rashid [50], participants with GDS-15 scores of 0 to 5 were categorized as normal, which may explain its lowest prevalence of depression (76 depressed residents/354 participants). This corroborated the findings from similar studies conducted among community-dwelling older adults [65,66]. The literature suggests that many NH residents could have unidentified and thus untreated depression [67]. This could be explained by the potential stigma surrounding mental illness or the idea that depression is a normal state among NH residents and thus has no additional consequences on their health or social life.

Our integrative review did not include publications that took into account NH residents receiving antidepressant medication without a diagnosis of depression or without reported depressive symptoms. Although it was difficult to discriminate whether it was low mood or medication use that predisposed older adults to falls. Kvelde et al [68] found that depressive symptoms remained a risk factor for falls in a large subgroup of older adults not taking antidepressant medications.

Our results seem to support the hypothesis of an interdependent association between the presence of depression and falls or a risk of falls, despite the high percentage of cross-sectional studies preventing any inference of the association's direction [50,51,53-56]. This is consistent with the clinical review by Iaboni et al [35], which stated that depression and falls had a significant bidirectional relationship. An excessive fear of falling, which is frequently associated with depression, also increases the risk of falls. Both depression and the fear of falling are associated with impaired gait and balance, an association that is mediated through cognitive, sensory, and motor pathways, and which consequently allows us to concur on the bidirectional relationship between depression and falls [35].

In addition, NH residents form a huge population of older adults with a significant number of comorbidities that can contribute to falls. Using different strategies to assess the risk of falls [65] makes causality and relationships extremely difficult to demonstrate. In the studies addressing NH residents that we retained, the prevalence of falls was 30% (1206 fallers/4016 participants), varying over the years. The risk factors of fall history, impaired performance in the ADLs, and insomnia all had strong associations with all falls. Risk factors with low to moderate ORs were vertigo; walking aids; poor balance; use of antidepressants, benzodiazepine, antipsychotics, and anxiolytics; polypharmacy; dementia; unsteady gait; hearing problems; and being male. Having bed rails was identified as a protective environmental factor.

Considering the limitations of this integrative review, current knowledge and the call to action laid out by Matos Queiros et al [44], the bidirectional relationship between depression and falls among NH residents has been inadequately studied. There

is an urgent need to clarify their complex interplay [35], and this will require robust, high-quality research. Our literature search strategy found many references (Figure 1 [46]); however, surprisingly, few studies considered the relationship between depression and falls among NH residents as one of their principal variables of interest—depression was regarded more as a contributing factor [16,29]. Most studies focused on the relationships between neurodegenerative diseases, functional impairment, and falls, as well as the associations between these factors and medication prescriptions for NH residents [69,70]. Another concern was that most of the studies were intervention studies to prevent or reduce falls and fall risks among NH residents [71,72]. Another avenue of research involved falls among community-dwelling older adults in assisted living facilities or their own homes [73-76].

Depression may lead to an increased risk of falls through behavioral, neuromuscular, or pathological pathways, and coherent with the fact that depressed NH residents are mostly less active than those without depression [77]. Moreover, the lower sense of self-efficacy and negative expectations about the future found among repeated fallers with depression can lead to decreased social participation [78].

Furthermore, our integrative review's findings may draw attention to the need to enhance comprehensive geriatric assessment practices as a suitable, more multidimensional, multidisciplinary approach to addressing NH residents' complex needs [79]. Specifically, health care professionals should implement regular screening for depressive symptoms as part of comprehensive fall risk assessments [79]. This proactive approach could lead to the early introduction of targeted therapeutic strategies to address depressive symptoms among NH residents, and it could also yield the positive outcome of reducing fall incidents [68]. In addition, fostering interdisciplinary collaboration among health care professionals, including old-age psychiatrists, nurses, and physiotherapists, should be encouraged to create a holistic, person-centered care approach [80,81].

Study Limitations

This integrative review had some limitations. Despite a thorough literature search using recognized methodological guidelines and recommendations, the review may have missed some studies meeting all the selection criteria due to search errors or investigators' mistakes. The studies retrieved evaluated NH residents' clinical state of depression using self-reported data, which could have created a risk of bias. In addition, studies did not clearly specify if there was a physician diagnosis of depression. The studies selected mainly used depression as an independent variable of interest, which may have led to this variable's overrepresentation compared to other factors affecting falls. Substantial heterogeneity in the classification and measurement of falls and depressive symptoms resulted in studies using different constructs, making comparisons difficult. Finally, any generalization of the present findings should be made cautiously, as the NHs and residents studied were always from a particular region or country.

Conclusions

By synthesizing existing research and drawing conclusions from diverse studies, this integrative review provides a more holistic understanding of the relationship between depression and depressive symptoms and falls. Our findings suggested that depression was a potential and independent risk factor for falls among NH residents. Moreover, depression and depressive symptoms should be addressed and systematically evaluated so that nursing professionals can implement preventive measures. Our results underscore the importance of policies that invest in and support the implementation of depression and fall risk assessment guidelines within NHs. These are essential for developing personalized care plans, thereby reducing fall risks and enhancing NH residents' overall quality of care and life. Although the precise associations of depression and depressive symptoms have yet to be clarified, it seems certain that they are risk factors for falls. The small number of studies published on our phenomenon of interest emphasizes the need for further research. Further longitudinal studies are urgently needed to elucidate the complex relationship between depression and falls in NHs. Considering their serious consequences, depression and falls among NH residents are a significant public health problem and require urgent attention from frontline health care professionals, researchers, and policy makers. Addressing these gaps through rigorous research will be critical to informing effective interventions and enhancing outcomes for NH residents.

Abstract

Background: People with chronic diseases can benefit from wearable devices in managing their health and encouraging healthy lifestyle habits. Wearables such as activity trackers or blood glucose monitoring devices can lead to positive health impacts, including improved physical activity adherence or better management of type 2 diabetes. Few literature reviews have focused on the intersection of various chronic diseases, the wearable devices used, and the outcomes evaluated in intervention studies, particularly in the context of primary health care.

Objective: This study aims to identify and describe (1) the chronic diseases represented in intervention studies, (2) the types or combinations of wearables used, and (3) the health or health care outcomes assessed and measured.

Methods: We conducted a scoping review following the Joanna Briggs Institute guidelines, searching the MEDLINE and Web of Science databases for studies published between 2012 and 2022. Pairs of reviewers independently screened titles and abstracts, applied the selection criteria, and performed full-text screening. We included interventions using wearables that automatically collected and transmitted data to adult populations with at least one chronic disease. We excluded studies with participants with only a predisposition to develop a chronic disease, hospitalized patients, patients with acute diseases, patients with active cancer, and cancer survivors. We included randomized controlled trials and cohort, pretest-posttest, observational, mixed methods, and qualitative studies.

Results: After the removal of 1987 duplicates, we screened 4540 titles and abstracts. Of the remaining 304 articles after exclusions, we excluded 215 (70.7%) full texts and included 89 (29.3%). Of these 89 texts, 10 (11%) were related to the same interventions as those in the included studies, resulting in 79 studies being included. We structured the results according to chronic disease clusters: (1) diabetes, (2) heart failure, (3) other cardiovascular conditions, (4) hypertension, (5) multimorbidity and other combinations of chronic conditions, (6) chronic obstructive pulmonary disease, (7) chronic pain, (8) musculoskeletal conditions, and (9) asthma. Diabetes was the most frequent health condition (18/79, 23% of the studies), and wearable activity trackers were the most used (42/79, 53% of the studies). In the 79 included studies, 74 clinical, 73 behavioral, 36 patient technology experience, 28 health care system, and 25 holistic or biopsychosocial outcomes were reported.

Conclusions: This scoping review provides an overview of the wearable devices used in chronic disease self-management intervention studies, revealing disparities in both the range of chronic diseases studied and the variety of wearable devices used.

RenderX

These findings offer researchers valuable insights to further explore health care outcomes, validate the impact of concomitant device use, and expand their use to other chronic diseases.

Introduction

Background

Noncommunicable diseases, commonly referred to as chronic diseases, are the leading cause of death worldwide, responsible for 41 million deaths annually and accounting for 74% of global mortality [1]. Aging populations, combined with unhealthy lifestyles such as poor diet and sedentary habits, contribute to a significant rise in chronic disease risk factors, including hypertension, hyperglycemia, and hyperlipidemia [1]. These diseases are characterized by their long-term nature, slow progression, and need for continuous care and self-management [2]. Most patients with a chronic disease in primary care have at least one additional chronic condition, making multimorbidity (defined as 2 concomitant chronic diseases) a common challenge that requires integrated, patient-centered care approaches to reduce the treatment burden [3].

Self-management is a key element of the care plan, and capturing meaningful information to empower individuals with chronic diseases is essential. Technological advancements have paved the way for wearable electronic devices and sensors that empower individuals to manage their health conditions more independently [4,5]. These innovations support the adherence to disease-related recommendations, such as medication regimens and symptom monitoring, by facilitating real-time monitoring and data collection. Wearable devices operate as data collection tools, transmitting information to software applications for analysis and delivering actionable health updates or notifications [6]. Key features of these devices include (1) automatic data collection (eg, blood glucose [BG], blood pressure [BP], physical activity, and heart rate); (2) direct transmission of data to the patient and, in some cases, their primary health care providers; and (3) availability of data across multiple platforms (eg, smartwatches, smartphones, and monitors). These systems offer real-time feedback either automatically or via clinician intervention, promoting sustained patient engagement with recommended health behaviors [4-6].

This potential for patient empowerment using wearables is observed in several reviews that report positive effects on clinical outcomes, such as glycemic control, and behavioral outcomes, such as symptom self-management [7-15]. Systematic reviews have explored the efficacy of wearables in managing diabetes, especially in relation to glycemic control [8-15]. BG monitoring devices, a common wearable for diabetes management, exemplify the utility of these technologies in facilitating behavior change and adherence to treatment protocols [8-15]. Numerous literature reviews have explored the use of wearable technologies in chronic disease management focusing on specific devices and health outcomes. Existing literature reviews are focused on specific wearable technologies, such as activity trackers [16-20] or BG monitors [8,9,11], or on self-management within particular chronic disease populations, including patients with diabetes [8-15,21], cardiovascular diseases [22,23], and cancer [7] and cancer survivors [17], as well as populations at risk of chronic diseases [19,24].

Several reviews have emphasized the impact of wearables on specific health outcomes, such as increased physical activity [16,17,19,20]. While these focused reviews offer valuable insights, they often do not capture the broader implications of wearable technology across multiple chronic conditions and diverse health outcomes. Despite the growing body of research, few comprehensive reviews have examined the intersection of various chronic diseases, wearable devices, and the range of health outcomes assessed in intervention studies. A systematic review identified a gap in understanding how wearables influence health outcomes in chronic diseases despite their potential for enhancing self-management [25]. To address this gap, Mattison et al [25] conducted a comprehensive review across multiple chronic diseases and outcome measures, highlighting the importance of such an analysis particularly in the context of primary health care.

Building on this work, our review adopted broad objectives aiming to provide an overview of the role of wearables in chronic disease management considering the clinical realities of the variety of devices used and the high prevalence of multimorbidity. A comprehensive analysis of wearable devices across various chronic diseases and health outcomes is essential for future research and patient-centered interventions in primary care settings that will reduce the treatment burden.

Objectives

The objectives of this scoping review were to identify and describe (1) the chronic diseases represented in intervention studies, (2) the types or combination of wearables used, and (3) the health or health care outcomes assessed and measured. This scoping review uniquely presents a comprehensive overview of the populations of patients with chronic diseases involved, the wearable devices used, and the specific outcomes targeted in intervention studies.

Methods

Overview

We conducted a scoping review informed by the Joanna Briggs Institute guidelines [26] and reported our results based on the

XSL•FO

RenderX

PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist [27]. We registered the review protocol in the Open Science Framework Registries [28]. We followed the population, intervention, comparator, and outcome framework [29] in establishing the study selection criteria (Textbox 1).

Textbox 1. Population, intervention, comparator, outcome, time frame, and study design framework elements [29].

Inclusion criteria

- Population: adult populations (aged ≥18 years) with chronic diseases (diseases characterized by their long-term nature, slow progression, and need for continuous care [2]).

- Intervention: interventions using wearable devices or smart health devices, such as connected weighing scales, that automatically collect and transmit biological or behavioral data to patients

- Comparator: usual care (without a wearable device)

- Outcomes: clinical, behavioral, patient experience with technology, holistic or biopsychosocial, and health care system outcomes

- Time frame and study design: between 2012 and 2022; randomized controlled trials, quasi-randomized controlled trials, prospective cohort studies, pretest-posttest studies, observational studies, mixed methods studies, and qualitative studies; published in English or French

Exclusion criteria

- Population: participants aged <18 years; patients with acute diseases; hospitalized patients; patients with active cancer and cancer survivors; participants with only a predisposition to develop a chronic disease, such as obesity, prediabetes, and prehypertension (without a diagnosis of dyslipidemia or another chronic disease)

- Intervention: hospital inpatient setting; no automatic data collection or transmission by the device, manual device, or survey instrument; data transmission only to caregivers or researchers (not to patients); studies only involving glucose monitoring devices and only measuring glucose levels as an outcome; automated insulin delivery system, also known as "closed loop" control system

- Comparator: not applicable

- Outcomes: Outcomes not related to chronic diseases; studies only addressing development or validation outcomes

- Time frame and study design: reviews, surveys, quantitative descriptive studies, metrology or diagnostic studies, protocols or ongoing studies, and conference papers

---

We included interventions involving at least one wearable device that automatically collected and transmitted data to adult populations with at least one chronic disease in a primary health care setting. The term "wearables" refers to all devices that collect patient data by directly capturing physiological signals, including connected weighing scales, electronic medication pillboxes, and ingestible sensors. Chronic diseases are defined as health conditions that are likely permanent and can be managed in primary health care settings. We excluded studies involving participants who only had a predisposition to develop chronic diseases, hospitalized patients, individuals with acute diseases, patients with active cancer, and cancer survivors.

Our review included randomized controlled trials (RCTs), cohort studies, pretest-posttest studies, observational studies, mixed methods studies, and qualitative studies published between 2012 and 2022. We excluded reviews, surveys, quantitative descriptive studies, metrology or diagnostic studies, protocols or ongoing studies, and conference papers. Moreover, we modified our published protocol [28] to exclude studies focused solely on the efficacy of connected glucometers that only measure glucose levels as there is already a strong evidence base on this topic [8-15].

Search Strategy

We (MPG and MS) developed search strategies in the MEDLINE (Ovid) and Web of Science (Science Citation Index Expanded, Social Sciences Citation Index, Arts and Humanities Citation Index, and Emerging Sources Citation Index) databases with an experienced librarian (MCL) to identify sources published between January 1, 2012, and June 30, 2022. The search strategies can be found in Multimedia Appendix 1.

Data Collection

We imported all references on June 30, 2022, to the web-based collaborative tool Covidence (Veritas Health Innovation) [30] and removed duplicates manually and using the automated function in Covidence before screening. We conducted a calibration exercise with the reviewers (Victoria Bureau Lagarde, EA, WS, SO, Rouwayda Elouni, and SA) and 2 senior researchers (MPG and MS) using a sample of 10 sources to ensure consistency in the application of the inclusion and exclusion criteria before the full screening process. At the first *title and abstract* screening phase, 8 reviewers (Victoria Bureau Lagarde, EA, WS, SO, MPG, MS, Rouwayda Elouni, and SA) independently assessed the titles and abstracts of the sources by applying the inclusion and exclusion criteria. All titles and abstracts underwent dual screening. Discrepancies in decisions were resolved through team consensus. At the *full-text review* stage, we searched and obtained all missing full texts of the selected references and imported them into Covidence. We conducted another calibration exercise with 10 full texts; 7 reviewers (SO, WS, MS, MPG, Victoria Bureau Lagarde, SA, and EA) independently applied the same selection criteria, and all exclusion motives were recorded in Covidence. All full texts underwent dual screening, and any discrepancies were also resolved through team consensus. From the included texts to extract, we tagged those related to the same studies and combined them for extraction. We also performed backward

hand searching [31] for relevant articles in the bibliographies of the included studies and added them to Covidence for screening and extraction.

Data Extraction

Following the Joanna Briggs Institute recommendations [32], we developed a grid to extract relevant data from the included studies. We tested this grid in a meeting with reviewers (SO, WS, and EA) and 2 senior researchers (MPG and MS). The data extraction of each included study was performed once by 3 different reviewers (SO, WS, and EA) and validated by at least one senior researcher (MPG or MS). In Covidence, we extracted general information (eg, title of the paper, year of publication, lead author, country, and potential author conflicts of interest), methods (eg, RCT, nonrandomized experimental study, cohort study, pretest-posttest study, mixed methods study, qualitative research, or economic evaluation), intervention data (duration of the intervention and follow-up), setting data (where patients were sourced from), participant data (eg, target population, chronic disease or chronic diseases, inclusion and exclusion criteria, sampling methods, recruitment methods, and methods of allocation to the intervention group), total number of participants included in the analysis sampling (at the end of the study), participant baseline characteristics, process of the intervention (eg, wearable devices, intervention administration, type of blinding, comparator administration, and control group description), all outcomes measured and how they were measured, and intervention effects or results.

Quality Assessment

We imported the assessment questions from the Mixed Methods Appraisal Tool (MMAT) [33] into Covidence. According to the MMAT, each study is assigned a score that ranges from 0 to 5 stars, with 5 stars signifying the highest quality and reflecting the rigor of the study's methodology. The quality of each included study was assessed once by 3 different reviewers (SO, WS, and EA), with each study's score validated by at least one senior researcher (MPG or MS). Discrepancies were resolved through consensus among the reviewers and a senior researcher.

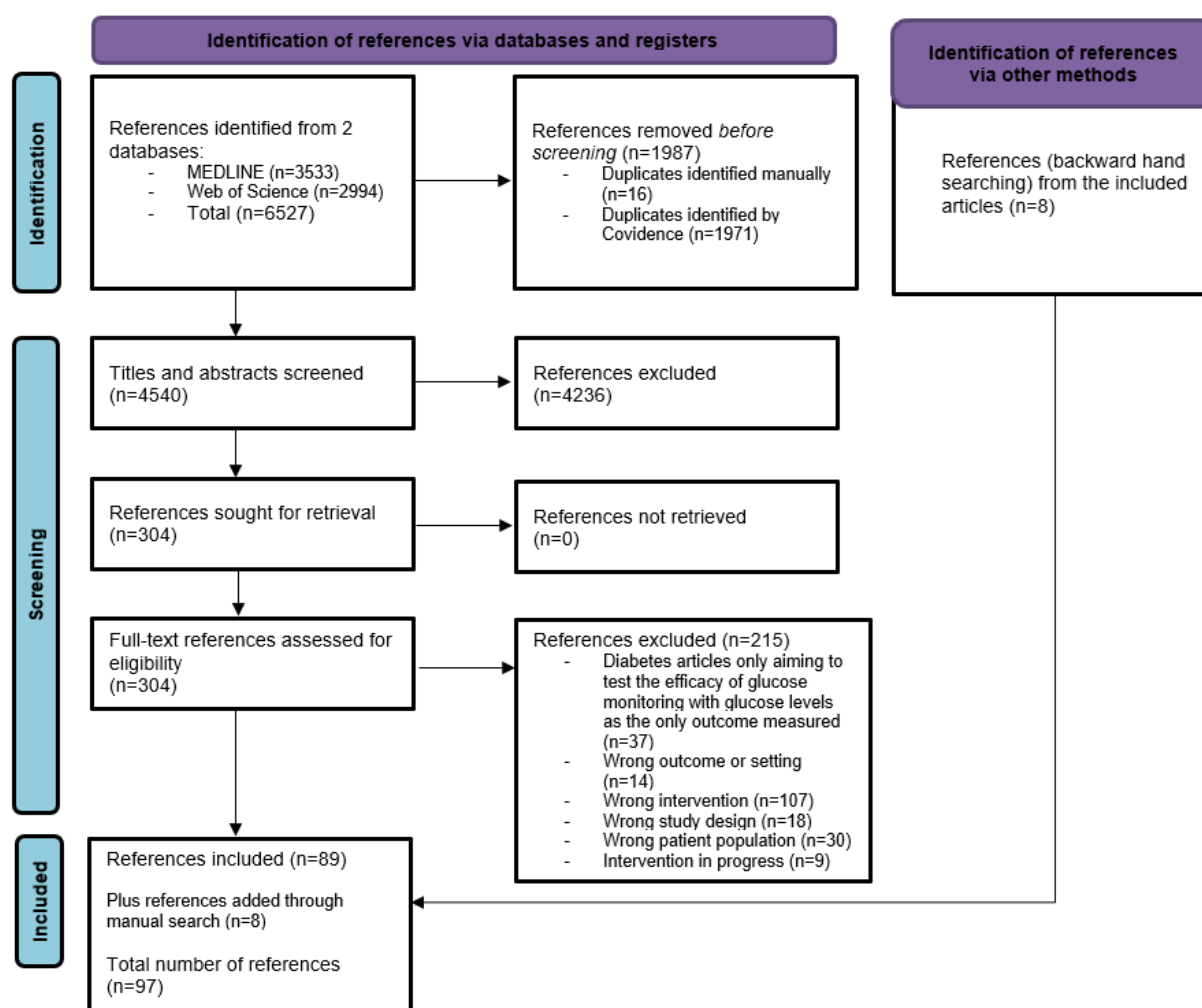
Data Synthesis

We structured our analysis according to chronic disease clusters; types and combination of wearable devices used; categories of health and health care system outcomes; and reported effects in terms of positive (reported in the studies as statistically significant), neutral, or negative. We synthesized data using tables explained through a narrative approach. We classified the outcomes reported in the intervention studies into 5 categories. The first category involves clinical outcomes, including indicators measured, such as glucose levels (glycated hemoglobin [HbA_{1c}]), BP, heart rate, weight, BMI, sleep time and quality, and pain intensity. The second category includes behavioral outcomes, such as physical activity levels, activation, motivation, self-efficacy, and disease-related knowledge. The third category involves patient technology experience, such as satisfaction, use, adherence, and engagement. The fourth category includes holistic and biopsychosocial outcomes, such as health status, health-related quality of life (QoL), physical well-being, anxiety, and depression. The fifth category involves the health care system, such as effectiveness, cost-effectiveness, admission or readmission to hospital, and emergency department visits.

Results

Overview

After the removal of 1987 duplicates (n=1971, 99.19% through Covidence and n=16, 0.81% manually), we screened 4540 titles and abstracts. Of the remaining 304 references after exclusion, we excluded 215 (70.7%) full texts and included 89 (29.3%). Of these 89 texts, we tagged 10 (11%) [34-43] related to same intervention studies and combined them for extraction, resulting in 79 included studies. We also hand searched and found 8 relevant articles [44-51] related to the included studies, totaling 97 references: 10 (10%) combined articles [34-43], 8 (8%) hand searched articles [44-51], and 79 (81%) main articles of the included studies [52-130]. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram [131] of the study inclusion process can be consulted in Figure 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.


Characteristics of the Included Studies

Of the 79 studies included, some were published in 2 or even 3 scientific articles. As a result, the number of references (n=97) is higher than the number of studies (n=79). The 97 references [34-130] of the 79 included studies [52-130] can be found in Multimedia Appendix 2. Most studies (45/79, 57%) were conducted in North America (39/45, 87% in the United States and 6/45, 13% in Canada), followed by 9% (7/79) conducted only in the United Kingdom, 5% (4/79) only in the Republic of Korea, 5% (4/79) only in China (one of them was conducted in Hong Kong), 4% (3/79) only in the Netherlands (3/79, and 4% (3/79) only in Spain. 5% (4/79) of the studies were conducted in 2 or more countries, and 11% (9/79) were conducted in other single countries.

We used the MMAT [33] to assess the methodological quality of the included studies. No studies were excluded based on MMAT scores accordingly with the aim of our scoping review to identify and describe existing knowledge [26]. The MMAT scores of the 79 studies [52-130] can be consulted in Multimedia Appendix 3 [34-130]. A total of 58% (46/79) of the studies used an RCT design. Most RCTs (20/46, 43%) obtained a score of 4 stars, 26% (12/46) obtained a score of 3 stars, 24% (11/46) obtained a score of 2 stars, and 7% (3/46) obtained a score of

1 star. Per the study context, an RCT could not have 5 stars due to unfeasible patient blinding.

In Table 1, we structure our results according to 9 chronic disease clusters: diabetes (18/79, 23% of the studies), heart failure (13/79, 16% of the studies), other cardiovascular conditions (10/79, 13% of the studies), hypertension (8/79, 10% of the studies), multimorbidity and other combinations of chronic conditions (8/79, 10% of the studies), chronic obstructive pulmonary disease (COPD; 8/79, 10% of the studies), chronic pain (6/79, 8% of the studies), musculoskeletal conditions (6/79, 8% of the studies), and asthma (2/79, 3% of the studies).

We also structured our results according to the technologies used. The most frequent were wearable activity trackers (WATs; eg, a smartwatch or a device worn at the chest, waist built-in accelerometers, or connected pedometers). We found WATs in 53% (42/79) of the studies, BP monitors in 35% (28/79) of the studies, weighing scales in 25% (20/79) of the studies, BG monitors in 20% (16/79) of the studies, and electrocardiogram (ECG) monitors/devices in 10% (8/79) of the included studies. A total of 61% (48/79) of the intervention studies used a single wearable (or smart health) device, whereas 39% (31/79) of the studies used ≥2 devices.

In Table 2, we structure our results based on the types or combinations of wearables used. Table 2 provides an overview of the outcomes measured for each wearable or combination of wearables along with the reported effects. There are 2 points that require clarification. First, the study designs and sample sizes are not presented, but this information is available in Multimedia Appendix 3 [52-130]. Second, confounding factors such as multicomponent behavioral interventions are not considered. Full details of the sources used for Table 2 can also be found in Multimedia Appendix 3.

Table 1. Wearable devices per chronic disease category (N=79).

Table 2. Summary of wearables used, outcomes, and reported effects[a].

Wearables	Clinical outcomes (eg, HbA_{1c}[b] or glucose levels, BP[c], HR[d], weight, BMI, sleep time or quality, and pain)	Behavioral outcomes (eg, PA[e] levels, activation, motivation, self-efficacy, and knowledge)	Patient technology experience outcomes (eg, use or adherence, satisfaction, and engagement)	Holistic or biopsychosocial outcomes (eg, HRQoL[f] and physical well-being)	Health care system outcomes (eg, use, effectiveness, and cost-effectiveness)
WATs[g] only [52-82]	• 19 outcomes[h] (BP [56], sleep time and quality [56], disability and pain [58]; BP [62], weight [62], waist circumference [62], BMI [62], BP [63], frailty [65], weight [65], BMI [65], disability at 6 months [67], pain [70], cardiorespiratory endurance [71], BMI [71], functional status [78], weight [79], insomnia severity [82], and acceptance of sleep difficulties [82]) • 3 outcomes[i] (Pain [55], disability at 12 months [67], and KOOS[j] pain and symptoms [69]) • 11 outcomes[k] (severe COPD[l] exacerbations [53], glucose level [62,66,71,80], weight [66], BMI [66], waist circumference [66], muscle strength [71,80], and cholesterol level [71])	• 13 outcomes[h] (self-reported walking and PA goals [52], decreased depressive symptoms [56], PA [66], perceived walking habits [70], MVPA[m] [70], daily step count [72,75,76], work productivity at 3 months [74], fatigue [76], heart failure knowledge [78], motivation to engage in behaviors [78], and minutes of daily PA [81]) • 9 outcomes[i] (PA levels [53], engagement levels [55], work productivity [55], PA [58], adherence to exercise guidelines [61], session attendance of a behavioral lifestyle intervention [65], mean MVPA time [69], mean daily steps and sedentary time [69], and KOOS, activities, sport, and recreation function [69]) • 8 outcomes[k] (self-management [52], functional activity capacity [53], self-efficacy [57], improvement in functioning and walking [64], work productivity at 6 and 12 months [74], self-efficacy to maintain PA [75], PA [79], and general self-efficacy [81]) • 1 outcome[n] (step count [57])	• 13 outcomes[i] (patient experience or satisfaction with WATs [54,55,64-66,68,78,81], satisfaction with wearable motion sensors with straps [55], acceptability and usability [60], and acceptance of forms of recommendations [55,64,77]) • 2 outcomes[n] (some technical or dexterity-related difficulties [64], acceptability, and responses to [waist-worn] wearable vibration prompts [73])	• 5 outcomes[h] (intervention group pretest-posttest health status [59,60], QoL[o] [78], HRQoL [79], QoL and mental health score [81]) • 1 outcome[i] (KOOS and HRQoL [69]) • 5 outcomes[k] (HRQoL [53,72], health status changes between intervention and control groups [59,60], and QoL [65])	• 2 outcomes[h] [60,78] (unplanned hospital visits [60] and heart failure–related hospitalization [78]) • 6 outcomes[i] (unplanned hospital visits and admissions during a 6-month follow-up period [59], hospital admissions during follow-up [60], continuity of care [60], incremental cost-effectiveness ratio [59,60], and person-centeredness [60])
Only BG[p] monitoring devices (but with more outcomes measured than only glycemic control) [83-86]	• 4 outcomes[h] (glucose level [83,84,86] and cholesterol control [84]) • 2 outcomes[i] (weight [83] and glucose level [85]) • 5 outcomes[k] (weight [84,86], BP [83,84], and cardiovascular risk [84])	• 2 outcomes[h] (medication management [84] and knowledge about diabetes and BG testing [84]) • 2 outcomes[k] (skill and technique acquisition [85], depressive symptoms and lifestyle changes [85])	• 2 outcomes[h] [84] (overall treatment satisfaction [84], willingness to recommend treatment to others [84])	• 1 outcome[k] (HRQoL [85])	• 2 outcomes[h] (initiating web messages to providers, mostly nurse care managers [84], health service navigation self-management [85]) • 1 outcome[k] (health care use [84])
WATs and BG monitoring devices [87,88]	• 1 outcome[h] (glucose level [88])	• 1 outcome[h] (self-care activity scores [88]) • 1 outcome[i] (self-regulation behaviors [87])	—[q]	—	—

Wearables	Clinical outcomes (eg, HbA_{1c}[b] or glucose levels, BP[c], HR[d], weight, BMI, sleep time or quality, and pain)	Behavioral outcomes (eg, PA[e] levels, activation, motivation, self-efficacy, and knowledge)	Patient technology experience outcomes (eg, use or adherence, satisfaction, and engagement)	Holistic or biopsychosocial outcomes (eg, $HRQoL$[f] and physical well-being)	Health care system outcomes (eg, use, effectiveness, and cost-effectiveness)
WATs, BG monitoring devices, and connected WSs[r] [89,90]	• 1 outcome[i] (weight [90])	• 1 outcome[i] (reduction of dose of oral hypoglycemic agents or insulin [90]) • 2 outcomes[n] (changes in caloric intake over time [90], mean daily step count [90])	• 1 outcome[i] (patient experience and satisfaction [89])	—	—
BP monitoring devices only [91-94]	—	• 1 outcome[h] (self-efficacy [93]) • 1 outcome[i] (self-efficacy [92]) • 1 outcome[k] (hypertension knowledge and participants' perspectives on an mHealth[s]-based care model [91])	—	—	• 1 outcome[i] (all-cause 30-day readmissions [93]) • 1 outcome[k] (ED[t] visits [93])
WATs and BG and BP monitoring devices [95]	• 1 outcome[h] (VO_2max[u] [95]) • 2 outcomes[i] (weight [95], waist circumference [95])	• 2 outcomes[i] (PA [95] and adherence rates for self-monitoring [95])	• 1 outcome[i] (patient experience and satisfaction [95])	—	—
BG and BP monitoring devices and medication tray or pillbox devices [96]; BP monitoring devices and medication pillbox or tray devices [97-99]	• 4 outcomes[h] (glucose level [96], BP control [97,99], and resting BP [99]) • 1 outcome[i] (ambulatory BP [99])	• 2 outcomes[i] (medication adherence [97,99])	• 1 outcome[i] (patient experience and satisfaction [96])	—	—
BG and BP monitoring devices [100,101], WSs [102,103], and ECG[v] devices [104]	• 1 outcome[h] (BG and BP control [101]) • 2 outcomes[i] (weight, BP, BG, and symptoms reported by patients [102], BG, BP, and weight [103]) • 1 outcome[k] (body fat, BP, and BG [100])	• 1 outcome[h] (changes in medication adherence, general adherence to treatment, adherence to disease-specific activities, and diabetes and hypertension knowledge [101]) • 1 outcome[i] (health self-management [104])	• 1 outcome[i] (patient experience and satisfaction [102]) • 1 outcome[k] (patient experience and satisfaction [100])	—	• 1 outcome[k] (health care resource use [104])
Connected WSs only [105]	• 2 outcomes[i] (weight change [105], waist circumference, BP, and BG [105])	—	—	—	—

Wearables	Clinical outcomes (eg, HbA_{1c}[b] or glucose levels, BP[c], HR[d], weight, BMI, sleep time or quality, and pain)	Behavioral outcomes (eg, PA[e] levels, activation, motivation, self-efficacy, and knowledge)	Patient technology experience outcomes (eg, use or adherence, satisfaction, and engagement)	Holistic or biopsychosocial outcomes (eg, HRQoL[f] and physical well-being)	Health care system outcomes (eg, use, effectiveness, and cost-effectiveness)
BP monitoring devices and WSs [106-113]	• 1 outcome[i] (BNP[w] values [112])	• 1 outcome[h] (self-efficacy and self-care management [112]) • 4 outcomes[i] (self-efficacy and self-care management [107,108,113], daily monitoring after the intervention [108]) • 1 outcome[k] (the use of guideline-recommended medical therapy [110])	• 5 outcomes[i] (usability and adherence to devices [106,108,111], end-user experience [107], contribution to a sense of safety and security after hospital discharge [107]) • 1 outcome[m] (use of the devices [109])	• 1 outcome[h] (QoL [112]) • 2 outcomes[i] (QoL [107,113]) • 1 outcome[k] (physical well-being of participants [110])	• 2 outcomes[h] (30-day all-cause readmission after discharge [109], health service use [112]) • 3 outcomes[i] (unscheduled ED revisits, readmission to hospital, and overall length of hospitalization [107], health system cost-effectiveness, including cost reduction and hospital bed capacity [107], proximity and communication with health care team or physicians [113]) • 1 outcome[k] (hospital resource use [113]) • 1 outcome[n] (traditional communication and engagement with providers prevailed, delaying access to care [108])
ECG devices only [114,115]	• 2 outcomes[h] (detection of AF[x], flutter recurrence [114], and detection of AF or other atrial arrhythmias [115])	• 1 outcome[h] (two scales of the PCS[y]: Physical Functioning and Role Physical, and two scales of the MCS[z]: Vitality and Social Functioning [115])	• 1 outcome[i] [114] (monitor usage among patients with AF [114])	• 1 outcome[h] (two scales of the MCS: Role-Emotional and Mental Health [115]) • 1 outcome[k] (HRQoL in patients with AF [114])	—
WATs and ECG devices (a chest strap) [116]; WATs, ECG devices, and sleep trackers [117]	• 1 outcome[h] (the eGFR[aa] [117]) • 1 outcome[k] (body weight and BMI [117])	• 2 outcomes[h] (self-care management and confidence [116], self-efficacy and self-management [117]) • 2 outcomes[i] (medication adherence [116], number of steps [117])	—	• 1 outcome[i] [117] (QoL [117]) • 1 outcome[n] [116] (QoL [116])	—

Wearables	Clinical outcomes (eg, HbA_{1c}[b] or glucose levels, BP[c], HR[d], weight, BMI, sleep time or quality, and pain)	Behavioral outcomes (eg, PA[e] levels, activation, motivation, self-efficacy, and knowledge)	Patient technology experience outcomes (eg, use or adherence, satisfaction, and engagement)	Holistic or biopsychosocial outcomes (eg, HRQoL[f] and physical well-being)	Health care system outcomes (eg, use, effectiveness, and cost-effectiveness)
ECG devices, BP monitoring devices, and WSs (a small sensor worn on the patient's chest wall) [118]; ECG devices, BP monitoring devices, and WSs with [119,120] or without [121] WATs and sleep trackers	—	• 1 outcome[h] (lifestyle behavior [120]) • 1 outcome[i] (self-care management and confidence [118])	• 2 outcomes[i] (patient experience and satisfaction [118], adherence to mHealth program [121]) • 1 outcome[k] (patient experience and satisfaction [119])	• 1 outcome[k] (QoL [120])	• 1 outcome[i] (rehospitalization rates [118])
An ingestible sensor and a wearable patch that incorporates an accelerometer [122]	• 1 outcome[i] (BP [122])	—	• 1 outcome[i] (experiences with a digital health feedback system [122])	—	• 1 outcome[i] (patients' experiences with pharmacists [122])
COPD multicomponent systems (monitoring of SpO_2[ab]) [123-126]; SpO_2 device only [123]; inhaler adherence monitoring device+BG monitoring device [124]; SpO_2 device+BP device+WS [125]; SpO_2 device+WAT [126]	• 1 outcome[k] (symptom scores [125])	• 3 outcomes[h] (awareness level [123], self-efficacy [123], behavioral intention [123]) • 1 outcome[i] (self-management skills [125])	• 1 outcome[i] (continuous wearing of a vest may be stressful [124])	• 1 outcome[h] (between-group generic health status differences [126])	• 1 outcome[h] (median number of visits to practice nurses [126]) • 1 outcome[i] (median number of visits to general practitioners [126]) • 2 outcomes[k] (hospitalizations, ED visits, or clinic visits [125,126])
Asthma devices (an inhaler adapter, an indoor air quality monitor, a portable spirometer, and a fraction exhaled nitric oxide device [127]; a small electronic medication monitor attached to inhalers [128])	• 2 outcomes[h] (asthma control [127], exacerbations [127])	• 1 outcome[h] (inhaler use [ICS[ac] and SABAs[ad]] [128])	• 1 outcome[h] (technology acceptance [127])	• 1 outcome[h] (QoL [127])	—
Photoplethysmography signal devices [129,130]	• 3 outcomes[h] (difference in the AS-DAS[ae] [130], total pain [130], VO_2max [130]) • 3 outcomes[i] (glucose level [129], weight [129], and BP [129])	• 1 outcome[h] (between-group frequency of difficulty feeling high motivation [130])	• 1 outcome[i] [129] (patient experience and satisfaction [129])	—	—

[a]The results presented in this table can be interpreted as follows. Can we significantly improve clinical, behavioral, technology experience, psychosocial, and health care system effects or results by using a specific wearable or a combination of wearables? Taking the first row as an example, we identified 31 intervention studies in which only wearable activity trackers were used. In these 31 interventions, we identified 19 clinical, 13 behavioral, 5 holistic or biopsychosocial, and 2 health system outcomes showing positive effects or results (reported as statistically significant in the studies).

[b]HbA$_{1c}$: glycated hemoglobin.

[c]BP: blood pressure.

[d]HR: heart rate.

[e]PA: physical activity.

[f]HRQoL: health-related quality of life.

[g]WAT: wearable activity tracker.

[h]Positive effect (identified as statistically significant).

[i]Neutral effect (positive effect but not identified as statistically significant).

[j]KOOS: Knee injury and Osteoarthritis Outcome Score.

[k]Neutral effect.

[l]COPD: chronic obstructive pulmonary disease.

[m]MVPA: moderate to vigorous PA.

[n]Negative effect.

[o]QoL: quality of life.

[p]BG: blood glucose.

[q]Not applicable.

[r]WS: weighing scale.

[s]mHealth: mobile health.

[t]ED: emergency department.

[u]VO$_2$max: volume of oxygen maximum.

[v]ECG: electrocardiogram.

[w]BNP: B-type natriuretic peptide.

[x]AF: atrial fibrillation.

[y]PCS: physical component summary.

[z]MCS: mental component summary.

[aa]eGFR: estimated glomerular filtration rate.

[ab]SpO$_2$: peripheral capillary oxygen saturation.

[ac]ICS: inhaled corticosteroids.

[ad]SABA: short-acting beta-agonist.

[ae]ASDAS: Ankylosing Spondylitis Disease Activity Score.

The most frequently reported clinical outcomes were BP control-related, in 23% (18/79) of studies [56,62,63,83,92, 93,95,97-101,103-105,112,122,129]. The other clinical outcomes most reported were weight or BMI changes in 13% (10/79) of studies. The most frequently reported behavioral outcomes were PA or lifestyle changes, including the number of steps and self-reported walking, in 27% (21/79) of studies [52,53,57,58,61,63-66,69,70,72,75, 76,78-81,90,95,117]. Other behavioral outcomes, such as self-efficacy (9/79, 11%) [53,57,75,81,92,93,107,117,123], and self-care management (6/79, 8%) [88,107,112,113,116,118], also appeared in a substantial number of studies. Adherence to treatment or recommendations (12/79, 15%) [61,65,78,94,95,97,99,101,106, 111,116,121] and engagement (6/79, 8%) [55,78,89, 108,113,115] are also frequently reported. Other commonly reported outcomes include satisfaction with technology (12/79, 15%) [55,64,66,68,75,78,81,84,96,100,102,118], and technology usability (6/79, 8%) [60,78,96,106,108,111]. QoL or health-related QoL are assessed in 19% (15/79) of studies [53,65,72,79,81,85,94,102,107,114-117,120,127], reflecting a broad focus on clinical, behavioral, technological experience, holistic, and biopsychosocial aspects.

In terms of positive results, BP control-related outcomes were reported as statistically significant in 8% (6/79) of studies [56,62,63, 93,97,98], and PA or lifestyle behavior changes in 10% (8/79) of studies [52,66,70,72,75,76,81,120]. Other behavioral outcomes, such as self-efficacy and self-care management enhancement, were reported as statistically significant in 5% (4/79) [112,116,117,123] of studies. Positive changes in weight or BMI were reported as statistically significant in 4% (3/79,) of studies [62,65,79] but demonstrated neutral or non-significant results in 9% (7/79) of studies [83,86,88,103,105,117,129]. Other outcomes, such as QoL or health-related QoL (8/79, 10%) [65,72,102,107,113,114, 117,120], technology usability (5/79, 6%) [60,96,106,108,111], and adherence to devices (4/79, 5%) [65,95,101,111], also demonstrated non-significant or neutral findings in those studies.

As shown in Table 3, we then counted the number of outcomes measured for each chronic disease cluster according to our 5 outcome categories. The results showed that clinical and behavioral outcomes were the most assessed and measured. Full details of the sources used for Table 3 are available in Multimedia Appendix 4 [52-130].

Table 3. Effects of outcomes measured for each chronic disease cluster across 5 outcome categories (N=79)[a].

Effect	Diabetes (n=18), n	Heart failure (n=13), n	Other cardio-vascular conditions (n=10), n	Hypertension (n=8), n	Multimorbidity and other combinations of chronic conditions (n=8), n	COPD[b] (n=8), n	Chronic pain (n=6), n	Musculoskeletal conditions (n=6), n	Asthma (n=2), n	Total, n

[a]The results presented in this table can be interpreted as follows. Can we significantly improve clinical, behavioral, technology experience, psychosocial, and health care system effects or results by using one or more wearables? Taking the diabetes column as an example, 16 clinical, 4 behavioral, 2 patient experience, and 2 health care system outcomes showed positive results (reported as statistically significant in the included studies). There are 2 points that need to be clarified. First, the number of participants and the duration of the studies were not considered. Second, confounding factors such as multicomponent behavioral interventions were not considered either.

[b]COPD: chronic obstructive pulmonary disease.

[c]HbA$_{1c}$: glycated hemoglobin.

[d]BP: blood pressure.

[e]HR: heart rate.

[f]Not applicable.

The following sections present the outcomes assessed and measured, as well as the effects reported for each wearable or combination of wearables within each chronic disease cluster.

Diabetes

We identified 23% (18/79) of the studies in which participants with diabetes were recruited [54,62,65,66,68,71,80,83-90,95,96,129]. The complete table with details is available in Multimedia Appendix 4.

Participants with diabetes used a WAT in 67% (12/18) of the studies. We identified 22% (4/18) of the studies that included only a connected glucometer but measuring more outcomes than only glycemic or HbA$_{1c}$ levels [83-86]. A total of 75% (3/4) of these studies reported statistically significant positive effects between groups on HbA$_{1c}$ or glycemic control at 6 [83,86] and 12 months [84]. In the remaining study, HbA$_{1c}$ levels decreased in all groups but did not differ between groups [85]. WATs were used in 67% (12/18) of all diabetes studies

and in 86% (12/14) of diabetes studies that did not use a connected glucometer. With only using WAT without BG monitoring, no effects were found on glucose or HbA$_{1c}$ levels [62,66,71,80].

Across all 23% (18/79) of the diabetes studies included, positive effects reported as statistically significant were found for 16 clinical (glucose or HbA$_{1c}$ levels [83,84,86], cholesterol control [84], maximal oxygen consumption [95], frailty [65], weight [62,65], BMI [62,65,71], cardiorespiratory endurance [71], waist-to-hip ratio circumference [71], and BP [62]), 4 behavioral (physical activity [66], self-care activity scores [88], medication management [84], and knowledge about diabetes [84]), 2 patient technology experience (overall treatment satisfaction [84] and willingness to recommend to others [84]), and 2 health care system (initiating web-based messages to providers [84] and health service navigation self-management [85]) outcomes. No holistic or biopsychosocial outcomes showed effects. In total, 2 weak negative behavioral effects were found on a small

single-group study of 9 participants in which changes in caloric intake and mean daily step count declined over the 12-week intervention [90].

Heart Failure

We identified 16% (13/79) of the studies in which participants with heart failure were recruited [61,78,102,106-113,116,118]. The complete table with details is available in Multimedia Appendix 4.

Most heart failure studies used connected weighing scales (12/13, 92%) and BP monitoring devices (11/13, 85%). WATs were used in 23% (3/13) of the studies [61,78,116]. Clinical outcomes were measured in 15% (2/13) of the studies [102,112], and both studies showed no effects. Positive effects reported as statistically significant were found for 4 behavioral (self-efficacy or self-care management [112,116], heart failure knowledge [78], and motivation to engage in behaviors [78]), 2 holistic or biopsychosocial (QoL [78,112]), and 3 health system (30-day all-cause readmission after discharge [109], health service use [112], and heart failure–related hospitalization [78]) outcomes. A total of 3 outcomes showed weak negative effects related to technology experience (ie, use of the devices [109]), holistic or biopsychosocial (ie, QoL related to wearing a chest strap [116]), and health care system (ie, delaying accessibility to care as traditional communication with providers prevailed [108]) outcomes.

Other Cardiovascular Conditions

We grouped 13% (10/79) of the studies in which participants with cardiovascular diseases such as chronic heart disease, coronary artery disease, atrial fibrillation or atrial flutter, poststroke control or cardiac rehabilitation, acute myocardial infarction, and any combination of heart failure and hypertension were recruited [75,76,92,93,114,115,117,119-121]. The complete table with details is available in Multimedia Appendix 4.

ECG devices were used in 60% (6/10) of the studies, WATs and BP monitors were used in 50% (5/10) of the studies, and connected weighing scales were used in 30% (3/10) of the studies. Positive effects reported as statistically significant were found for 3 clinical (detection of atrial fibrillation or atrial flutter recurrence [114], detection of other atrial arrhythmias [115], and slower decline in the estimated glomerular filtration rate [117]) outcomes in which ECG devices were involved. Positive effects reported as statistically significant were found for 6 behavioral (daily step count or walking time [75,76], fatigue [76], self-efficacy or self-management [93,117], physical functioning [115], and lifestyle behavior [120]) outcomes. Positive effects were found for 1 holistic or biopsychosocial outcome (mental health domain scores [115]). All other outcomes had weak positive or neutral effects.

Hypertension

We identified 10% (8/79) of the studies in which participants with hypertension were recruited [56,63,91,94,97-99,122]. The complete table with details is available in Multimedia Appendix 4.

A total of 62% (5/8) of the hypertension studies used BP monitors, 38% (3/8) used a connected medication tray or pillbox, and 25% (2/8) used WATs. Positive effects reported as statistically significant were found for 5 clinical (BP measures or control [56,63,97,99] and sleep time or quality [5]) and 1 behavioral (decreased depressive symptoms [56]) outcomes. No other patient technology experience, holistic and biopsychosocial, or health care system outcomes showed positive effects.

Multimorbidity and Other Combinations of Chronic Conditions

We identified 10% (8/79) of the studies that recruited participants with ≥2 chronic conditions [60,79,81,100,101,103-105]. The complete table with details is available in Multimedia Appendix 4.

A total of 50% (4/8) of the studies used BG and BP monitoring devices [100,101,103,104], 38% (3/8) used only WATs [60,79,81], 25% (2/8) used connected weighing scales [103,105], and 12% (1/8) used ECG devices [104]. Positive effects reported as statistically significant in the studies were found for 2 clinical (weight [79] and BG and BP [101]), 2 behavioral (minutes of daily physical activity [81] and hypertension knowledge [101]), 3 holistic or biopsychosocial (health status [60], health-related QoL [79], and QoL and mental health score [81]), and 1 health care system (unplanned hospital visits [60]) outcomes. The wearable devices used had only weak positive or neutral effects on patient technology experience outcomes.

Studies on COPD

We identified 10% (8/79) of the studies in which participants with COPD were recruited [53,57,72,73,123-126]. The complete table with details is available in Multimedia Appendix 4.

We identified a first group of 50% (4/8) of the studies comprising multicomponent systems in which oxygen saturation or inhaler adherence was monitored [123-126] and a second group of 50% (4/8) of the studies that used only WATs [53,57,72,73].

In the first group of 50% (4/8) of the studies, 1 clinical effect was measured and found out to be neutral (symptom scores [125]). However, positive effects reported as statistically significant were found for 3 behavioral (awareness level, self-efficacy, and behavioral intention [123]), 1 holistic or psychosocial (generic health status [126]), and 1 health care system (reduction of median number of visits to practice nurses [126]) outcomes. Negative effects were found for 1 patient technology experience outcome (stress related to continuously wearing a monitoring vest [126]).

In the second group of 50% (4/8) of the studies, which used only WATs, 1 clinical effect was measured and found out to be neutral (severe COPD exacerbations [53]). Positive effects reported as statistically significant were found for 1 behavioral outcome (daily step count [72]), whereas step count decreased over time in another study [57]. Another negative effect was reported for 1 patient technology experience outcome (low acceptability and responses to the waist-worn wearable vibration prompts [73]).

Chronic Pain

We identified 8% (6/79) of the studies in which participants with chronic pain were recruited [52,55,58,64,67,77]. The complete table with details is available in Multimedia Appendix 4.

Only WATs were used in the identified studies on chronic pain. Positive effects reported as statistically significant were found for 4 clinical outcomes (symptom score [58], disability [58], pain [58], and chronic back pain–related disability at 6 months [67]). Another positive effect was found for 1 behavioral outcome (self-reported walking and physical activity goals [52]). All other outcomes had neutral or weak and nonsignificant positive effects, and negative effects were found on 1 patient technology experience outcome (technical or dexterity-related difficulties [64]).

Musculoskeletal Conditions

We identified 8% (6/79) of the studies in which participants with osteoporosis, rheumatoid arthritis, systemic lupus erythematosus, or ankylosing spondylitis were recruited [59,69,70,74,82,130]. The complete table with details is available in Multimedia Appendix 4.

We identified 83% (5/6) of the studies on osteoporosis, rheumatoid arthritis, or systemic lupus erythematosus that all used WATs [59,69,70,74,82]. The remaining study recruited participants with ankylosing spondylitis, and their intervention used photoplethysmography signal technology [130]. Positive effects reported as statistically significant in this study were found for 3 clinical (Ankylosing Spondylitis Disease Activity Score [130]; total pain, fatigue, spinal pain, and morning stiffness intensity [130]; and maximal oxygen consumption back extensor endurance test and range of motion of cervical lateral flexion [130]) and 1 behavioral (frequency of difficulty with high motivation [130]) outcomes. Concerning the other 83% (5/6) of the studies, positive effects reported as statistically significant were found for 2 clinical (pain reduction [70] and Insomnia Severity Index score and acceptance of sleep difficulties [82]) and 3 behavioral (perceived walking habits [70], moderate to vigorous physical activity for participants with rheumatoid arthritis [70], and work productivity at the 3-month follow-up [74]) outcomes. Regarding the latter work productivity behavioral outcome, we noticed that the effects were no longer significant at the 6- and 12-month follow-ups [74].

Asthma

We identified 3% (2/79) of the studies in which participants with asthma were recruited [127,128]. The complete table with details is available in Multimedia Appendix 4. Positive effects reported as statistically significant were found for 2 clinical (asthma control [127] and asthma exacerbations [127]), 1 behavioral (inhaler use [128]), 1 patient technology experience (technology acceptance [127]), and 1 holistic or biopsychosocial (QoL [127]) outcomes. Health care system outcomes were not investigated.

Discussion

Principal Findings

This scoping review aimed to achieve 3 main objectives related to health intervention studies involving wearable devices. The primary strength of this review lies in our broad portrayal of interventions across multiple chronic diseases, various wearable devices, and distinct categories of health and health care outcomes, along with their reported effects (positive, neutral, or negative). We selected these broad objectives because, as other reviews have highlighted [24,25], providing a comprehensive overview of this topic is relevant for informing and shaping future research directions.

First, we identified and described clusters of chronic diseases that have been studied. We observed significant disparities—diabetes and heart failure have been extensively researched, whereas musculoskeletal conditions and asthma have been studied much less frequently despite showing promising results. We intentionally excluded studies that solely involved BG monitoring devices measuring BG levels as the only outcome given the existing evidence [8-15]. Nevertheless, diabetes emerged as the most represented chronic disease, appearing in 23% (18/79) of the studies, whereas only 3% (2/79) of the studies included participants with asthma.

Second, we identified and described the technologies used. WATs were commonly used either alone or in conjunction with other devices tailored to specific chronic conditions, such as BG monitors, BP devices, ECG devices, and connected weighing scales. There was notable variation in technology use—while WATs were widely used, other devices such as oxygen saturation monitors, photoplethysmography sensors, inhaler adapters, indoor air quality monitors, portable spirometers, small devices attached to inhalers, ingestible sensors, and wearable patches with accelerometers were less common.

Third, we identified and described the outcomes measured in 5 distinct categories. Clinical and behavioral outcomes were the most frequently assessed, whereas patient technology experience, health care system (such as use or efficiency), and holistic or biopsychosocial (such as QoL) outcomes were reported less frequently.

Limitations

This scoping review has several limitations. We did not integrate the individual interventions into our analysis. Although we report the measured outcomes, these results must be interpreted with caution as effect sizes were not considered. However, informed readers can consult the appended files that contain all the relevant information, including study design, sample size, intervention and participant characteristics, outcomes measured, and effects. We only conducted searches in the MEDLINE (Ovid) and Web of Science (Science Citation Index Expanded, Social Sciences Citation Index, Arts and Humanities Citation Index, and Emerging Sources Citation Index) databases, which may have led to missing sources. Confounding factors such as multicomponent behavioral strategy interventions were also not considered. Nevertheless, these confounding factors were similarly not addressed in a previous systematic review and

meta-analysis on the effectiveness of WATs due to the heterogeneity of study designs and interventions [18]. In total, 3 reviewers extracted and assessed the quality of all the studies only once, although this was mitigated by data validation from an experienced researcher.

Comparison With Other Reviews

Our findings revealed significant disparities in the chronic diseases studied. Type 2 diabetes and heart failure were extensively researched, whereas conditions such as musculoskeletal disorders, chronic pain, and asthma were less represented. This both complements and contrasts with the findings of another review, which noted type 2 diabetes, Parkinson disease, and chronic lower back pain as among the most studied conditions [25]. Many other reviews have focused on diabetes [8-15,21] and cardiovascular diseases [22,23]. One reason for this emphasis on cardiovascular disease and type 2 diabetes may be the inherent capabilities of wearables to monitor and manage these conditions [4], along with their availability and affordability. For instance, regarding asthma, we found promising effects on health outcomes but identified only a limited number of studies [127,128].

In terms of the technologies used, we observed that the most common devices used were WATs. This aligns with the number of reviews focusing on the effects of WATs for different diseases [16-20], often in combination with disease-specific devices. This observation is also consistent with those of other reviews as wearable technologies have emerged as promising tools for managing chronic diseases, offering continuous monitoring of vital signs, physical activity, and disease-specific markers [132,133]. Similarly to our findings, these devices have shown potential across various conditions, including BP and ECG monitors for cardiovascular diseases [22,23] and BG monitoring devices for diabetes [8,9,11], by enabling early detection of complications and promoting patient engagement [25,132-134].

Regarding outcomes, we identified 5 distinct categories in our review, with clinical and behavioral outcomes being the most frequently reported. This aligns with the growing body of research highlighting the role of wearables in monitoring physiological parameters and behaviors [134]. Similarly to our findings, other reviews have reported clinical outcomes such as glycemic control [8-15] as well as behavioral outcomes, including physical activity levels [16-20], medication adherence, and self-management [5,18].

Future Directions

Despite the promising health outcomes reported, other reviews have highlighted that the quality of evidence varies considerably, with many studies limited by small sample sizes or short durations [25]. Researchers emphasize the need for more long-term studies and systematic reviews that incorporate RCTs with larger sample sizes to measure the effectiveness of wearables across a wider variety of chronic diseases [18,24,25]. There is a need for rigorous, long-term studies to establish the clinical effectiveness and cost-efficiency of wearables in chronic disease self-management [25,132].

Our findings indicate that patient technology experience, holistic and biopsychosocial, and health care system outcomes have been covered less and could benefit from more robust studies. As the integration of wearable technology into health research and clinical practice continues to expand, establishing comprehensive guidelines to ensure effective use across diverse chronic conditions and applications will be important, ranging from chronic disease management to real-time health monitoring for specific or underrepresented populations [134].

In line with our findings, which show that health care system outcomes are reported less frequently than clinical and behavioral outcomes and often have inconclusive effects, a significant challenge will be integrating wearable data into existing health care systems and clinical workflows [135].

Conclusions

This review provides a comprehensive overview of wearable devices used in chronic disease self-management intervention studies, revealing disparities in both the range of chronic diseases studied and the variety of wearable devices used. We described the clinical and behavioral benefits of wearable devices, particularly for activity trackers, BG and BP monitors, and ECG wearable devices. These findings lay a foundation for future research, offering researchers valuable insights to further explore health care system outcomes, validate the impact of concomitant device use, and expand their use to other chronic diseases.

Data Availability

The PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist [27] was included in the manuscript submission and can be consulted in Multimedia Appendix 5. The data sets generated and analyzed during this study are available from the corresponding author (MPG) on reasonable request.
