Abstract

Online labor platforms (OLPs) have the potential to change how the workforce is allocated and managed in health care. The contracting, coordination, and communication of bookings and work assignments happen on these platforms in near real-time with no delay and without any human interactions. This perspective paper describes the worldwide trend toward OLPs in health care, gives an overview of the functioning of these platforms, and discusses the prospects and challenges for health care management. As a real-world case, the platform logic, growth and traffic of a Swiss OLP designed for temporary nurse deployment are presented. OLPs facilitate managing different work arrangements (float pools and temporary work) through (1) offering health care staff flexible work options, which in turn lowers the dropout rates of health care professionals; and (2) effectively managing internal staffing allowing human resource sharing within and across health care organizations. For health care management research, OLPs yield data that can be used to analyze the characteristics, use, and dynamics of flexible work arrangements and temporary work in health care.

(Interact J Med Res 2025;14:e68546) doi:10.2196/68546

KEYWORDS

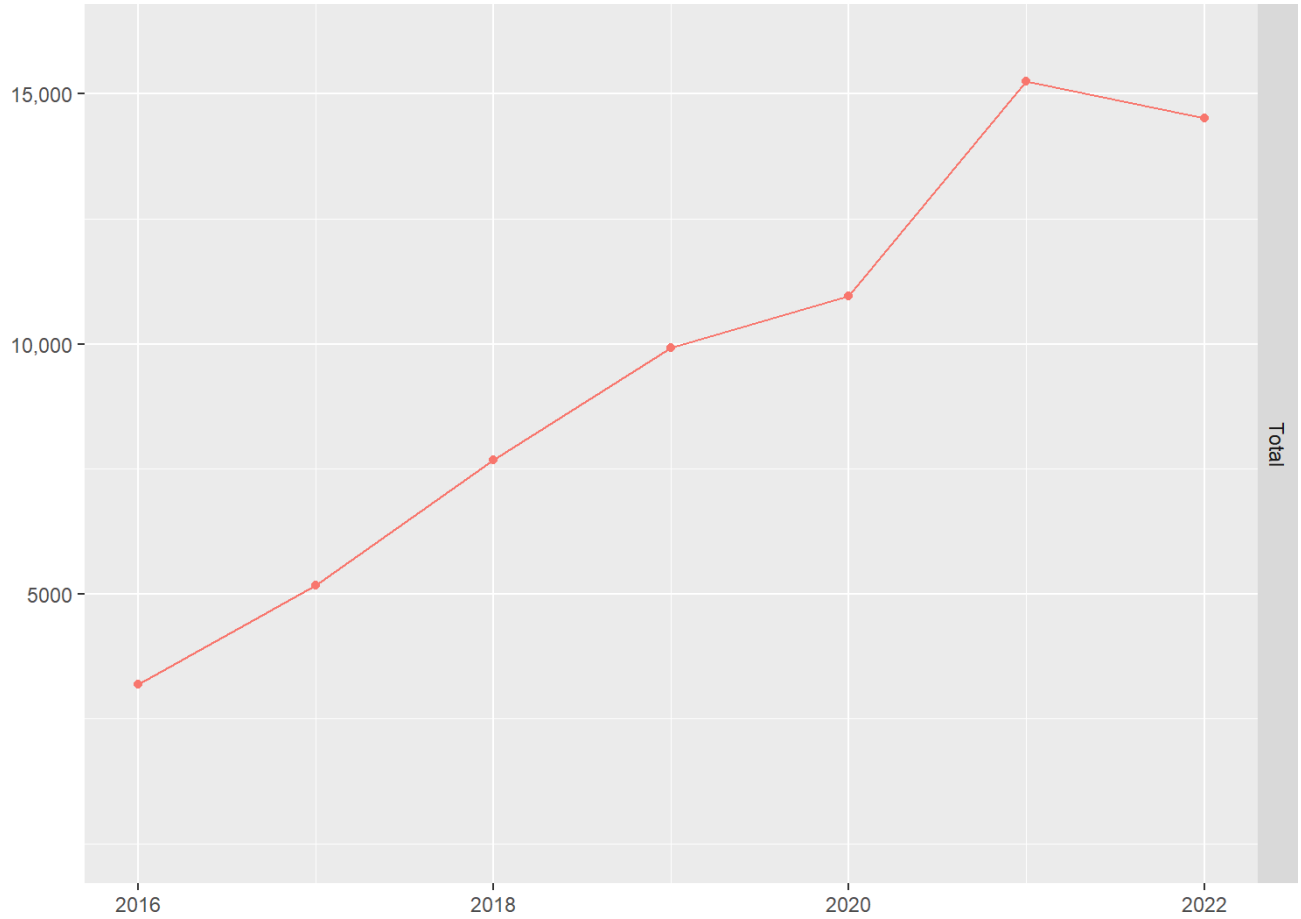
online labor platform; temporary work; workforce management; gig work; health care; personnel staffing and scheduling

Online Labor Platforms (OLPs): The Emerging Face of Temporary Employment in Health Care

For decades, health care organizations have relied on agencies to deploy temporary workers to fill their short-term vacancies and match workforce resources with care needs [1]. The use of temporary staff in hospitals is widespread globally. In the United States, about 75% of hospitals frequently employ temporary nurses [2]. Similarly, in the United Kingdom, the care hours provided by nonpermanent nurses increased more than doubled between 2012 and 2015 [3]. In Switzerland, though precise data are lacking, the use of temporary health care workers has risen since 2010. By 2022, temporary workers accounted for 3.5%-5.3% of health care staff, with agency nurses and care staff being the largest group [4]. With the emergence of OLPs, flexible work arrangements have undergone intense growth, and OLPs are increasingly replacing human match makers in temporary agencies for the intermediation between their temporary workers and their institutional clients.

In the United States, platforms such as Nomad, Medely, SnapCare, and CareRev have embraced the concept of temporary work by using web-based tools to connect hospitals with doctors and nurses for flexible, short-term assignments. Similarly, in Switzerland, web-based platforms like Careanesth, Coople, and Adecco serve as prominent avenues for the recruitment of temporary health care professionals.

Figure 1 shows the rising trend of annual shift bookings on Careanesth from 2016 to 2022. This trend has been largely neglected by health care managers as well as health services management research although OLPs could facilitate the efficient and effective use of temporary work and bring up new opportunities, challenges, and management issues for health care organizations with respect to processes and outcomes of recruitment, matching, administration, and evaluation of these arrangements.



OLPs leverage information and communication technology (ICT) to make a continuous, real-time matching of staff availability with the demands [5]. Individuals can accept or decline work contracts as they choose, without obligations. OLPs vary widely in functionality: some of them allow individuals to transact, while others match between organizations and individuals. Some of them support and facilitate web-based work and others coordinate onsite or offline tasks at client locations, including in health care settings [6]. In health care, OLPs may be implemented for internal health professional float pools in a single organization, float pools across organizations but also for the booking of external temporary staff.

XSL•FO
RenderX

While there are substantial literature exploring temporary work via OLPs in various sectors, there remains a notable limitation of evidence specific to health care. This gap is critical because the nature of platform work in health care diverges significantly from other industries as mentioned. The onsite provision of services introduces unique challenges and complexities that are not as common in other sectors. Moreover, in health care, platform workers are often highly qualified professionals like doctors and nurses, unlike the less specialized workforce found in other sectors. Managing this specialized workforce requires advanced strategies, including strategic shift planning, rapid response to fluctuating demands, and coordination of diverse teams comprising various health care professionals. These complexities underscore the need for robust and adaptive workforce management strategies tailored to the unique demands of the health care sector. The evidence around integrating ICTs into the recruitment of health care professionals shows advantages such as cost-effectiveness, wider reach, and time-saving compared to traditional methods of recruiting health care professionals [7]. Although ICTs could have positive effects, their implementation may also provoke concern. The growth of digital labor platforms presents regulatory challenges, particularly in cross-border contexts [8]. The systematic review by Gagnon et al [9] provides a broader perspective, emphasizing the impact of ICTs on workforce sustainability. They can support the recruitment and retention of health care professionals by improving job satisfaction, streamlining communication, and reducing administrative burdens. They have the potential to transform workforce management in health care, from operational scheduling to strategic workforce planning, addressing both immediate and long-term needs [9]. Despite its relevance, there is limited research on this topic and considering that this is a rising phenomenon, the existing evidence is relatively dated. Moreover, the existing studies primarily address the broader integration of ICTs into workforce management in health care, often overlooking the specific and unique application of OLPs for deploying temporary professionals. These studies predominantly focus on outcomes, leaving many aspects of the underlying dynamics of OLPs unexplored. Therefore, there is a critical need to understand the dynamics of OLPs and how the integration of them affects various aspects of workforce management. This includes evaluating the reliability of current data, identifying gaps, and understanding the potential benefits that can be derived from more comprehensive and accurate datasets.

Our perspectives in this paper describe the worldwide trend toward OLPs in health care, gives an overview of the functioning of these platforms, and provides an in-depth discussion on the impact of OLPs on health care workforce management, focusing on staffing practices, demand responsiveness, and team dynamics. By providing insights into these areas, we aim to help improve management practices and enhance the efficiency and effectiveness of health care delivery, ultimately leading to high-quality patient care.

Ethical Considerations

The empirical results provided in this paper have been the subject of an ethical consideration by the Cantonal Ethics Committee of the Canton of Zurich within the Crowis project. The study does not fall under the Human Research Act and an exemption of an ethical review was received (BASEC-Nr. Req-2022-00708). The use of the per-diem nurse data of the platform was based on informed consent with an opt-out system. All employees of the temporary agency were informed by a letter of information about the study and could dissent the use of their individual data. The employee IDs as identifiers of the entries in the platform data were replaced by an alphanumeric code by the temporary agency to guarantee confidentiality. Platform data were stored in a server protected by a password and accessible only to the members of the research team. No compensation was paid to the temporary nurses for data provision.

Operational Dynamics of OLPs and the Evolution of Workforce Management Practices

OLPs impact the whole process within the triangle of temporary agencies, temporary workers, and organizations booking services which can be divided into five steps: (1) enrollment in the platform; (2) offerings; (3) matching mechanisms; (4) administration; and (5) evaluation. The impact of OLPs on these steps is described in detail in the following.

Step 1: Enrollment

It typically refers to the process through which temporary workers register or sign up to become part of the platform's pool of available temporary workers. The registration requires a health care professional's basic personal information, professional credentials, and work experience. After the verification of the information and the certificate check by the platform, temporary workers may be required to review and sign agreements or contracts outlining the terms of their engagement with the platform, including payment terms, confidentiality agreements, and code of conduct. These profiles serve as a reference for health care facilities when they are looking to deploy temporary staff.

On the other side, organizations using OLPs need to provide key information to ensure smooth operations and compliance with platform standards. This includes clear details about shift offerings, payment terms such as hourly rates, payment methods, and timelines, along with guidance on administrative procedures. Additionally, organizations must share information about relevant labor laws and regulations that apply to health care workers, including their rights, protections, and available support mechanisms [6]. By transitioning from traditional agency-based enrollment methods to web-based platforms, temporary workers benefit from a more efficient, transparent, and accessible process for joining the health care workforce. It enhances communication and empowers health care professionals to manage and update their profiles effectively in real-time, reflecting changes in their professional status or preferences. Referring to the exemplary use case of the Swiss OLP, in 2022, 78 hospitals, 33 long-term facilities, 30 home-care organizations, and 11 other health care institutions were clients of the platform. On the platform, float pool as well as per-diem nurses who are employed by the platform provider can be booked for single shift assignments. A total of 283 per-diem nurses and 227 float-pool nurses were enrolled on the platform. Per-diem nurses can be booked from all institutions which are clients of the platform whereas float-pool nurses can be booked exclusively by each institution within their defined float pool, administered by the platform provider (Dettling M, Liberatore F. Unpublished data, April 2025).

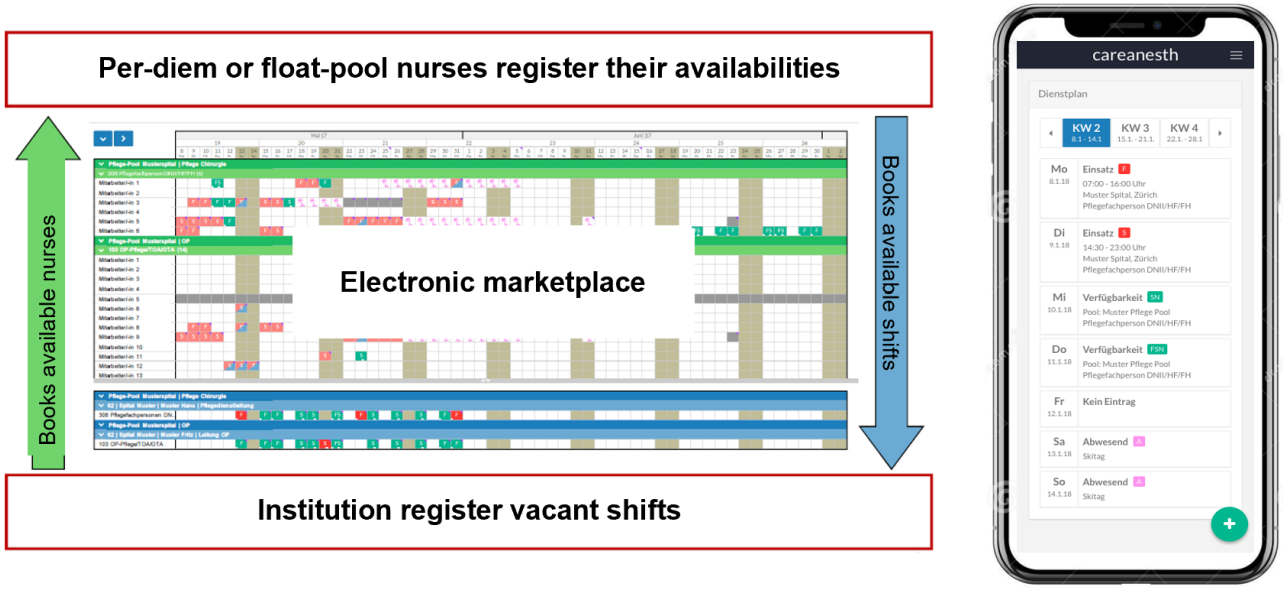
Step 2: Offerings

Temporary workers and organizations can use a web browser or smartphone app to manage shift availability and vacancies (Figure 2). Health care professionals post the days and specific shifts they are available to work (eg, Monday, morning shift), while organizations post vacant shifts, specifying the ward type, required qualifications, and shift details (Figure 3).

Transitioning from the agencies to web-based platforms, health care professionals and hiring organizations have greater accountability and autonomy in leading transactions. Furthermore, OLPs provide the flexibility for hiring organizations to collect a group of "preferred" workers to prioritize them for job offerings. This differs from temporary agencies, where hiring organizations depend on human intermediaries in the agency to request temporary workers. This new model empowers both parties by eliminating the need for agency middlemen and streamlining the hiring process.

XSL•FO
RenderX

Figure 2. Managing shift offerings via the web browser or smartphone app.



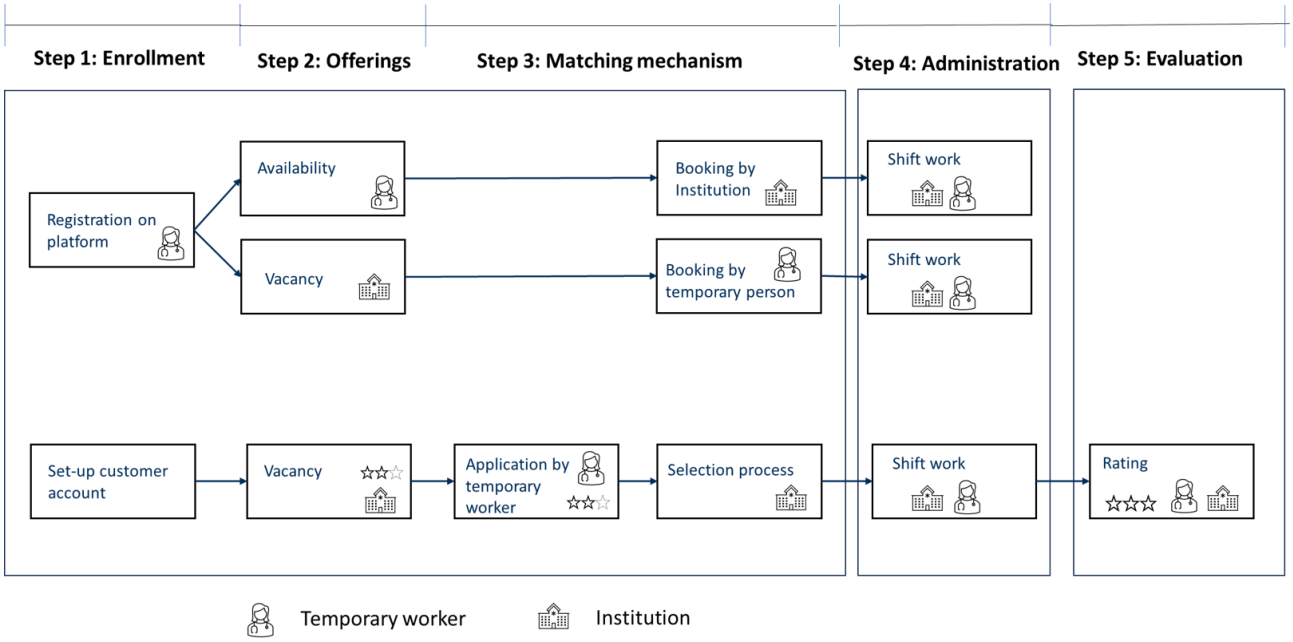


Figure 3. Overview about steps and general process on online labor platforms in health care settings.

Step 3: Matching Process

A match on a platform can either result from an organization booking a shift availability or from a temporary worker taking on a vacant shift offer. Both lead to a binding agreement regarding the shift assignment. However, in some OLPs, the initiation process stems solely from the organization's end, attracting a diverse pool of temporary job seekers. Here, applicants submit their applications, entering a selection process where the organization evaluates each individual against their criteria. This approach allows the organization to handpick the most suitable applicants. Matching mechanisms can follow the first come–first serve rule, which means that the first organization or temporary worker books the availability or vacant shift offer, and there is a binding agreement on the work. The exemplary case of the Swiss OLP uses this mechanism. In the booking process, the institutions see which type of nurse (registered nurse; vocational trained nurse assistant [Fachangestellte or Fachangestellter Gesundheit]; and intensive care nurse specialist [Intensivpflege]) is available for which shifts and have access to the individual curriculum vitae of the nurses to inform about qualifications and experience. Another possibility is that the organizations or temporary workers can apply for the offer and then after an evaluation by the contracting partner the contract is negotiated. (Figure 3). The web-based platform of Coople is an example that uses this mechanism. Alongside the bookings by hospitals and clients, some platforms use algorithms with and without artificial intelligence to analyze the data collected from both sides—organizations and professionals. These algorithms use various criteria and techniques to match the right health care worker with the right offer. Criteria may include skills, experience, location, availability, preferences, and historical performance data.

XSL•FO
RenderX

Platforms as managed service providers streamline the process of booking by allowing hospitals to access multiple temporary agencies through a single platform. This centralized approach simplifies staffing management and enhances efficiency for health care organizations. Hospitals can easily compare available temporary staff from various agencies, view their credentials, and make bookings according to their specific needs.

On OLPs, prebooking and prioritization rules are typically established to optimize the matching process between health care workers and organizations while ensuring efficient allocation of resources. These regulations may vary depending on the specific platform. These rules consider factors such as urgency of need (prioritize matches for immediate or time-sensitive vacant positions), availability (prioritize matches for only available workers), specialization, ratings, geographical proximity, repeated bookings in the past, premium services, and dynamic pricing (pricing algorithms may take into account factors such as demand, supply, and worker ratings to determine pricing for prebooked assignments, incentivizing workers to accept priority assignments) [7].

While OLPs primarily rely on ICT for matchmaking, traditional temporary agencies use "human matchmakers," such as agency representatives, to connect workers with short-term job opportunities. However, this does not mean temporary agencies avoid using technology. They use ICT to collect and manage data on their contingent workforce, including qualifications, work experience, and current assignments. Human match makers then use this information to assign workers to clients. In contrast, OLPs function without human intermediaries, offering a web-based marketplace where labor supply and demand directly meet [5].

Step 4: Administration

The contracting, coordination and communication of a work assignment happens in near real-time with no delay. The platform usually requests a fee for the service from the platform provider like fees for a personnel agency for the placement service or licensing fees for the use of the platform as health care organizations.

When comparing the contracting processes between traditional temporary agencies and OLPs, distinctions emerge, especially in how they engage with temporary workers. There exist 2 primary models within OLPs: co-employment platforms and freelance platforms, each with their distinct characteristics. Co-employment platforms establish an employment relationship with their workers, subjecting them to collective labor agreements either within the platform firm or with client organizations. Consequently, these platforms typically offer a fixed hourly pay rate to their temporary workforce, with potential surcharges during periods of labor scarcity. Conversely, freelance platforms engage solo self-employed workers who operate as independent contractors, allowing them to set their own hourly rates. The negotiation of pay rates can vary, with either the freelance worker or the client organization proposing rates depending on the platform's technical setup. At the same time, to avoid "races to the bottom," some of the freelance platforms' digital interfaces do not allow workers and hiring organizations to set hourly pay rates below a minimum level [5].

Additionally, automatic contracting as a key feature of OLPs facilitates the automatic generation and execution of contracts between the parties involved in a booking or transaction. This process is seamless and transparent, with the platform creating a standardized contract template based on the agreed-upon terms and relevant policies. These contracts typically outline key details such as service expectations, payment terms, duration, and other conditions. Once created, the contract is automatically sent to both parties for review and acceptance. This automated approach simplifies transactions, reduces administrative workload, and ensures clear communication and accountability for both parties.

In the use case of the Swiss OLP, the booking of a shift availability by an institution or the acceptance of a vacant shift by a float-pool nurse leads to a binding agreement between the institution and the temporary nurse. The matching (an assignment being offered and accepted) may occur as late as 24 hours before the start of the shift in question. The contracting, coordination and communication of a work assignment happens over the platform in near real-time with no delay.

Step 5: Evaluation

Some OLPs feature advanced ratings and reputation systems that foster trust and transparency between users. The Quality Rating 360 empowers both parties to provide comprehensive feedback on performance, behavior, and competencies, ensuring a fair and reliable marketplace. Temporary workers can rate organizations on factors like work environment, communication, and overall satisfaction, helping guide fellow professionals in making informed choices. Conversely, organizations can rate temporary workers based on professionalism, performance, and reliability, contributing to a dynamic feedback loop that enhances platform quality and accountability. Unlike traditional agencies, this feature grants the users valuable insights into the reputation and performance of various entities, enhancing transparency and informed decision-making. In the use case of the Swiss OLP, no rating system has been established to date but is planned.

The Prospects and Challenges of OLPs for Health Care Management

Impact of Using OLPs

The use of OLPs for temporary deployments has a significant impact on organizational management endeavors related to shift planning, the availability of new work arrangements, patient flow management, and the opportunities to share resources within and across organizations. However, the impact is associated not only with prospects but also with new challenges for health care managers.

Managing Flexible Workforce in Shift Planning

In terms of workforce management, there are both benefits and challenges for hospitals whose workforce includes temporary staff. On the one hand, the web-based booking mechanisms, facilitate the staffing of shifts according to demand and make

XSL•FO
RenderX

the covering of short-term absences more efficient (eg, by requiring fewer phone calls and emails) [8]. On the other hand, the operations on these platforms bring new administrative burdens for managers. They must draft and publish vacant shifts, and select temporary health care workers according to their shift demands, and availabilities of temporary staff [5]. Competencies and work experiences of temporary health care workers must be assessed based on the provided nurse-related information on the platform without personal contact or assessment [9]. Further, on OLPs, availabilities for unpopular shifts (eg, night shifts or shifts on public holidays) may be much less. Because OLPs act as a labor market, shift managers must adopt selective booking behaviors. This means that they do not book temporary workers for popular shifts and instead post vacancies for unpopular shifts, and temporary workers are forced to adapt their operational availability to the demands of the hospital in order to work there. Moreover, the monitoring of compliance with maximum working hours regulations and rest periods is challenging for health care institutions because the temporary health care workers may work in various institutions based on multiple work contracts with agencies and health care institutions in parallel.

Offering New Work Arrangements for Health Care Professionals Using OLPs

The digital platform economy provides opportunities for new and diverse work arrangements. It potentially enables mixed contracts where individuals can engage in part-time, freelance, or fixed work simultaneously, reflecting the evolving nature of work in this digital era. The web-based booking systems save temporary workers from being permanently on call. Either they offer their shift availabilities which are most suitable to their individual preferences and obligations [10] or they consider overtaking vacant shifts offered by organizations that pop up on the platform. The decisions can be made without any obligations. This feature of self-scheduling in new work arrangements has been associated with higher job satisfaction and retention. However, nurse managers must cope with greater complexity due to the mixture of various temporary work arrangements in the shift planning. The lack of organizational boundaries in the work arrangements poses the challenge of assessing the competencies and experiences of temporary nurses without personal contact or assessment [9]. Health care managers must find solutions to overcome the resistance to change and install working contexts in which ad hoc teams with a mixture of permanent and temporary staff can work together in an efficient and effective way.

While for some health care professionals, these working models offer new opportunities, others may prefer traditional working and staffing models. Platform work increases the potential for worker exploitation and the workers have to deal with challenges caused by platform-based vulnerabilities such as inequality and precarity; which refers to the short-term contingent nature of the work and lack of clear training and career promotion [11,12]. As platform workers are most likely to be considered self-employed, rules on data protection and privacy become challenging. There is very little information on how platforms protect data and the privacy of workers as well as organizations. Concerns have also been raised that platforms possess an inequitable advantage over conventional agencies, as platforms have fewer responsibilities for working conditions such as issues related to the data privacy and intellectual property rights of temporary workers [6], making it challenging for health care institutions to comply with these regulations using temporary health care workers from these platforms. Furthermore, issues such as wage discrimination can occur on OLPs during the matching process due to varying wage structures. Some platforms let organizations set hourly rates, potentially leading to inconsistencies. Others offer fixed rates, possibly undervaluing experienced temporary workers. Platforms with flexible rates based on factors like experience may unintentionally perpetuate disparities. Additionally, fluctuating rates based on demand-supply dynamics could result in unequal pay.

Sharing Resources Within and Across Organizations Using OLPs

OLPs are instrumental in promoting resource sharing within and across health care organizations. They facilitate sharing health care professionals across different organizations or units using 1 single tool and without the need for human matchmaking in each organization or unit. This approach aligns with the contemporary trend of using technology to bridge gaps and streamline interactions within and across organizations. Regarding sharing the workforce within and across organizations through OLPs, several challenges arise. Appropriate rules and mechanisms for prioritization, booking or prebooking, cost allocation, and activity tracking need to be defined to optimize resource use and enhance user experiences in the sharing economy paradigm. Prioritization in workforce management is essential for efficiently allocating resources and ensuring that the right people are in the appropriate roles at the correct time. Further, yield management and dynamic pricing approaches may be applied within the booking mechanisms of OLPs to foster the market mechanisms on these platforms resulting in a better allocation of the shared resources. Yield management as a dynamic pricing approach can be used to control capacities by adjusting prices based on real-time demand, supply, and market conditions. The sharing of health care professionals across organizations may be challenging because of obligatory minimum staffing regulations and its verification by nurse-patient ratios depending on the health care system setting.

Effects of OLP Application on Patient Flow Management

Another significant advantage offered by OLPs is their facilitation of patient flow management and staff rescheduling within health care organizations. These platforms provide real-time access to data regarding the availability of health care professionals. This enables facilities to promptly address staffing gaps and adjust patient flow plans and staffing levels, accordingly, ensuring appropriate staffing levels in unexpected surges in demand [5]. Furthermore, the retrospective data capabilities of OLPs facilitate proactive workforce planning for both fixed and temporary staffing level requirements. By examining the trends and patterns, health care facilities can potentially forecast future demands and make strategic decisions about resource allocation to effectively address patient needs.

XSL•FO
RenderX

This data-driven information enables organizations to align their staffing schedules more precisely with anticipated demand, thereby maximizing resource utilization and boosting the overall efficiency of patient flow management.

Propositions for Future Research on Online Health Care Labor Platforms

OLPs and their application for the recruiting and management of temporary health care workers offer several propositions for future research.

First, studies should calculate and compare changes in administrative costs (cost savings vs new administrative burdens) using OLPs for the application of temporary work arrangements in health care organizations. Second, future research should address the impact of different offering and matchmaking rules on OLPs on matching rates and labor costs to understand better how OLPs allow health care organizations to apply and rely on dynamic shift planning systems with a mix of permanent and flexible staff. Third, the consequences of the increasing use of short-term single-shift assignments arranged via OLPs on treatment processes, costs, and outcomes require more research. Fourth, the market dynamics on OLPs and the leverage of health care organizations altering the supply side on these platforms is an important area informing health care managers how to behave optimally on these OLPs. Fifth, OLPs yield data that can be used to analyze the characteristics and dynamics of temporary work contributing to a greater understanding of their behavior as well as the use of temporary nurses in organizations. Compared to findings from surveys of temporary agency managers and temporary health care workers yielding motivations and behavioral intentions for temporary work, data from platforms represent actual behavior and therefore offer a sound basis for discussion on the extent and patterns of temporary work in a health care system. More specifically, platform data includes the following information.

- Data about the organizations and temporary health care workers operating on the platform inform about the sociodemographics of the temporary health care workers and organizational characteristics.
- Shift availabilities show how many and which shifts temporary health care workers offer thereby revealing their work preferences. Shift offers by the organizations on the platforms inform about the volume and characteristics of unstaffed shifts.
- Matching data displays how often temporary health care workers are booked, in how many different organizations they work, and in which types of shifts they are deployed. Further, matching rates provide information about the effectiveness of the platforms matching temporary health care workers' availabilities and shift demands.

Overall, it can be concluded from the perspective paper, that health services management research should increase research activities in the field of OLPs in health care. The potential of allocating health care workers to their needs, but also according to the demands of the health care organization is a key topic for health care systems worldwide.

Abstract

Sarcopenia is defined by age-related reductions in muscle mass, strength, and physiological function, and it is especially prevalent among individuals with autoimmune diseases. Autoimmune disorders, characterized by immune dysregulation, cause systemic inflammation and damage to multiple tissues through unregulated immune activity. Research indicates that autoimmune diseases negatively impact skeletal muscle functions and may worsen the progression of sarcopenia. This viewpoint comprehensively discusses the pathogenesis and potential mechanism of sarcopenia in 3 autoimmune diseases: inflammatory bowel disease, rheumatoid arthritis, and type 1 diabetes mellitus. Mechanistically, chronic immune microenvironment alterations induce compartment-specific redistribution of leukocyte subsets and cytokine networks. These perturbations disrupt critical signaling pathways governing muscle protein synthesis, satellite cell activation, and mitochondrial bioenergetics, leading to impaired regeneration and accelerated sarcopenia progression. By delineating shared and distinct pathomechanisms across these models, this analysis reframes our understanding of immune-mediated muscle wasting. Beyond mechanistic insights, it establishes a translational framework for targeted therapies and highlights emerging research directions bridging immunology and age-related musculoskeletal decline.

KEYWORDS

sarcopenia; immune diseases; type 1 diabetes mellitus; rheumatoid arthritis; inflammatory bowel disease

Introduction

Sarcopenia is an age-related syndrome characterized by progressive and systemic loss of skeletal muscle mass and strength [1]. The decline of skeletal muscle function caused by sarcopenia has aroused widespread concern [2]. Maintaining skeletal muscle mass and integrity is essential for the proper functioning of the musculoskeletal system and for the effective absorption and storage of nutrients [3]. Sarcopenia has a significant impact on general health, with numerous important effects. It is closely related to the development of exercise-related diseases, such as falls, fractures, and disabilities [4]. Additionally, it is also associated with adverse outcomes such as cardiovascular diseases [5], metabolic diseases, and even death [6]. However, the exact cause of primary sarcopenia is not fully understood yet. Recent studies suggested that cellular aging [7], mitochondrial disorder [8], decreased physical activity [9], and excessive caloric intake could accelerate the progression of sarcopenia. Moreover, an imbalance of oxygen in the body may contribute to the development of sarcopenia as well [10].

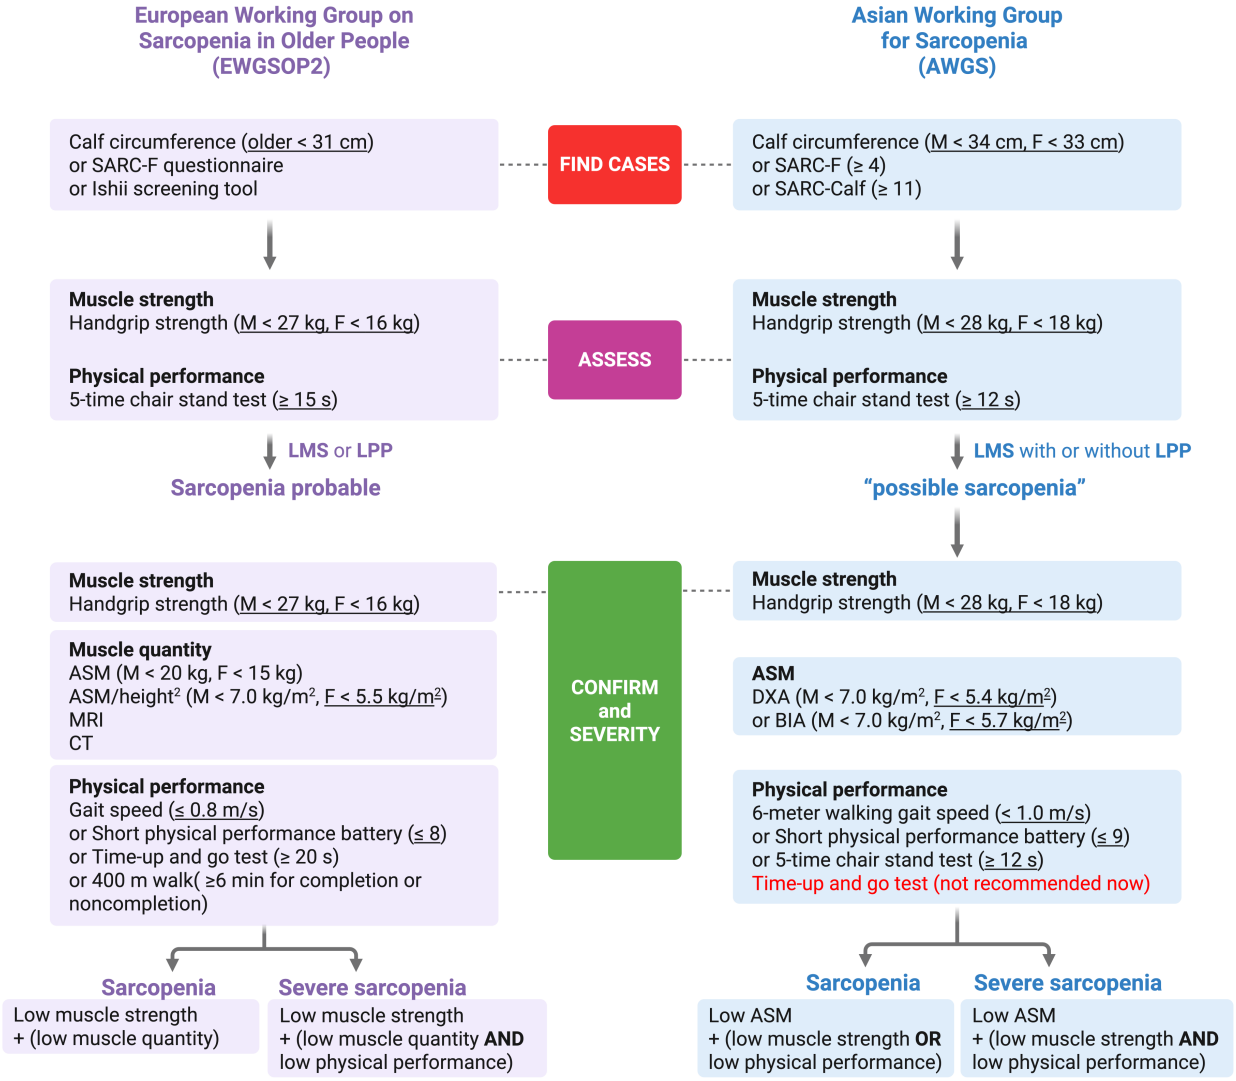
Sarcopenia afflicts not only the older people but also the patients with immune diseases. Studies have shown that immune diseases such as type 1 diabetes mellitus (T1DM), rheumatoid arthritis (RA), inflammatory bowel disease (IBD), spinal arthritis, and systemic sclerosis are often associated with sarcopenia [11]. Autoimmune diseases combined with sarcopenia are closely related to adverse clinical outcomes, poor effects of treatment and prognosis, and low quality of life [12]. Current research efforts have concentrated on the high prevalence of sarcopenia among autoimmune disease patients and its associated adverse

XSL•FO
RenderX

prognosis. Studying the relationship between sarcopenia and autoimmune diseases is crucial, as is clarifying the incidence and pathogenesis of sarcopenia linked to immune disorders. Immune disorders regulate key cascades like JAK/STAT (Janus kinase/signal transducers and activators of transcription) by influencing immune cells, profoundly impacting muscle protein synthesis and metabolism. This is a crucial factor in the pathogenesis of autoimmune diseases accompanied by muscular atrophy. Previous studies have focused on the differences in performance between healthy and sick individuals through case-control analysis. However, our comprehensive and in-depth analysis shows that focusing on immune cells and the related factors released and exploring the pathogenesis of diseases based on this, to find effective targeted therapies, will become a new and promising direction for the study of autoimmune diseases and sarcopenia. The elucidation of these underlying mechanisms may pave the way for novel research avenues in understanding the pathophysiology of sarcopenia associated with autoimmune disorders, while simultaneously offering crucial mechanistic insights to inform the development of targeted therapeutic interventions with enhanced precision. This study aims to provide a theoretical foundation and new avenues for future research.

Sarcopenia

In 1989, Irwin Rosenberg first described sarcopenia as the loss of muscle mass that occurs with aging [13]. With the deepening of research, sarcopenia is generally recognized as a progressive and systemic skeletal muscle disease manifested by accelerated loss of muscle mass and function [14]. The European Working Group on Sarcopenia in Older People 2 updated the definition of sarcopenia to account for muscle mass, muscle strength, and motor function performance for the first time [13]. The European Working Group on Sarcopenia in Older People 2 suggests that sarcopenia may be present when muscle strength is insufficient, and can be diagnosed when low muscle quantity or quality exist simultaneously [13]. Moreover, when the patient has low muscle mass, low muscle strength, and weak motor function at the same time, severe sarcopenia can be diagnosed [15]. Applying Western diagnosis criteria to Asian people may not be adequate. For special considerations such as different body sizes, fat distribution, and physical activity from the Asians, the Asia Working Group for Sarcopenia proposed and revised an algorithm for diagnosing sarcopenia based on the Asian data [1,16] (Figure 1).



The prevalence of sarcopenia in older individuals within community health care settings has been reported to reach up to 29% [16]. Aging changes the homeostasis of skeletal muscle and disturbs the balance between anabolic and catabolic processes on the protein production pathway [16]. Sarcopenia is characterized by a decrease in the size and number of satellite cells and the atrophy of type 2 muscle fibers. Sarcopenia is distinct from malnutrition and cachexia, although each exhibits interrelated pathophysiology leading to different magnitudes of “wasting” and susceptibility to cardiovascular events (Table 1) [2].

Diagnosing sarcopenia requires a combined measurement of muscle mass, strength, and physical performance [17] (Figure 1). At present, imaging methods, such as computed tomography, dual-energy x-ray absorptiometry (DXA), and magnetic resonance imaging are used for muscle mass detection [18]. However, those instruments are expensive, time-consuming, and laborious. Besides, computed tomography detection has a certain level of radioactivity, which limits its application in clinical practice and population research [19]. DXA can distinguish adipose tissue from other soft tissues and measure the volume of tissues and organs accurately, so it is suitable for different populations and is considered the “gold standard” for measuring muscle mass [20]. Owing to the characteristics of fast, convenient, and low radioactivity, DXA is also frequently used for body composition detection. However, DXA has the limitations of not assessing muscle quality (ie, muscle fat infiltration), and DXA measurements may be influenced by the patient’s hydration status [21]. The machine requires a large space and is inconvenient to move away, making DXA not an ideal measurement for large-scale clinical trials of sarcopenia, bedside assessments, or community health screening work [18]. Bioelectrical impedance analysis (BIA) is another measurement for muscle mass detection. The principle underlying BIA is that different body compositions at the tissue-organ level exhibit varying electrical conductivity, with skeletal muscle demonstrating good conductivity and adipose tissue showing poor conductivity. This enables BIA to estimate the quantity of body fat and skeletal muscle mass [22]. Comparatively speaking, except inexpensive, BIA is a portable device that can easily perform bedside diagnostics as well. Therefore, BIA is frequently used in many types of studies. As BIA equations and cut-off values are population and device-specific, results can vary between devices and different populations [23]. Moreover, studies showed that the mass of hospitalized older patients was overestimated [24]. Nevertheless, the results of BIA would also be affected by the placement of electrodes, so it is necessary to combine grip strength and walking speed detection to evaluate the occurrence of sarcopenia [25].

Sarcopenia increases the risk of falls, fractures, and death. When combined with other diseases, it can hinder recovery after hospitalization, prolong prognosis recovery time, and increase the economic burden on patients [26]. Previous studies suggested that sarcopenia and osteoporosis interacted with each other. Compared with healthy people, individuals with sarcopenia have a heightened susceptibility to developing osteoporosis. Conversely, individuals experiencing severe osteoporosis often undergo substantial loss of skeletal muscle mass, thereby increasing their vulnerability to falls and fractures [27]. Sarcopenia is known to adversely affect the outcomes of patients with various forms of cancer. Apart from what is mentioned above, there exists an interaction between sarcopenia and immune diseases. The complication of sarcopenia greatly increases the incidence; mortality; and prognosis of diabetes, arthritis, and IBD.

Table . Differences between sarcopenia, cachexia, and malnutrition.

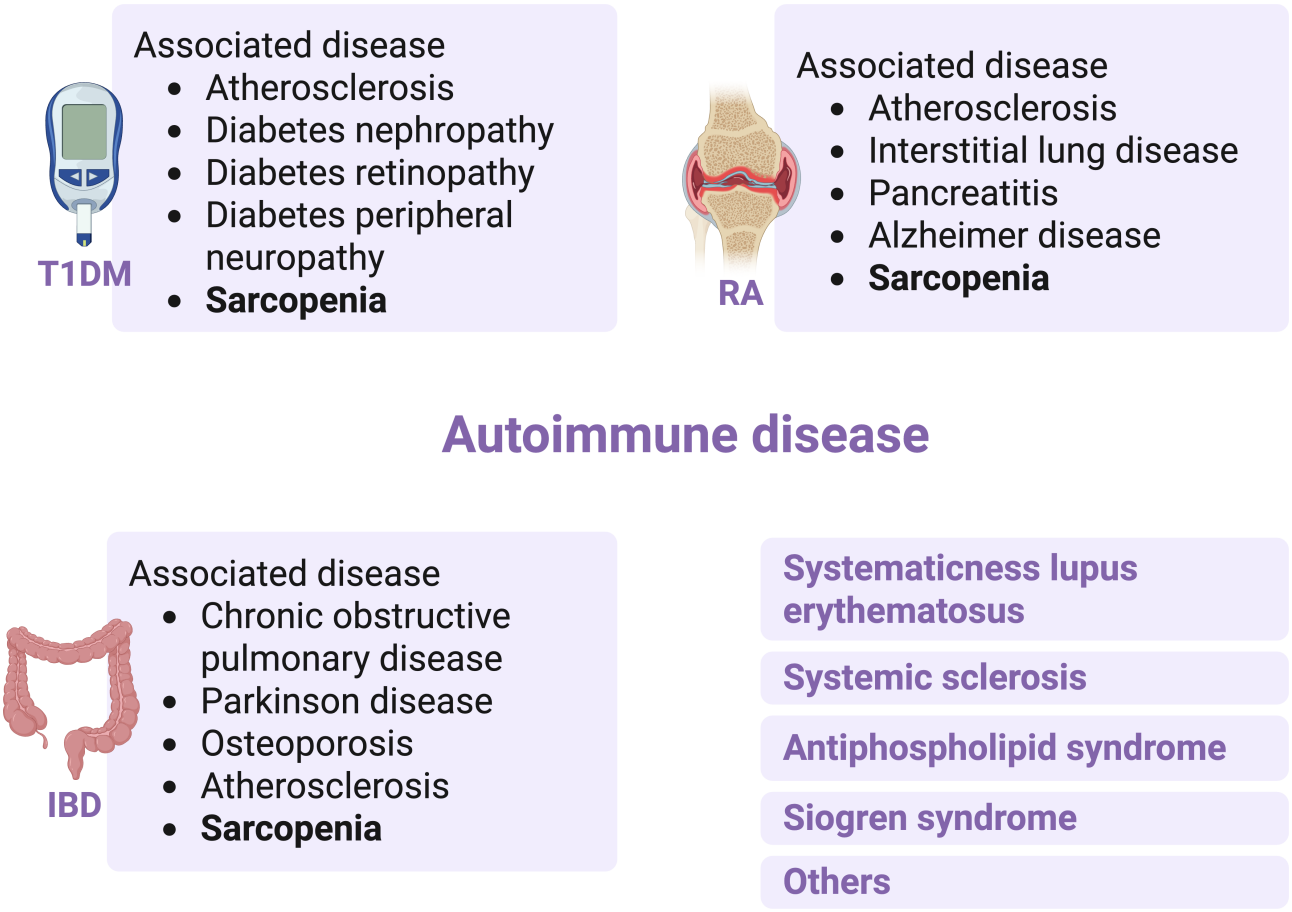
	Sarcopenia	Cachexia	Malnutrition
Clinical features	Loss of muscle strength and muscle mass	Weight loss with loss of muscle mass	Weight loss
Functional impairment	Indicate severity	+++[a]	–[b]
Mechanism	Age-related, pathologic	Pathologic	Inadequate caloric intake, malabsorption
Inflammation	+/–[c]	+++	–
Anorexia	+/–	++[d]	+/–
Fat mass	+/–	Decreased	Decreased
Protein degradation	+/–	+++	+[e]

[a]+++: high, a higher degree or intensity of a feature or symptom in the disease.

[b]–: absence of the characteristic/symptom indicates the absence or absence of a characteristic, symptom, or mechanism.

[c]+/–: variable presence or inconsistency across conditions.

[d]++: moderate, the presence or intensity of a characteristic or symptom in the disease.



[e]+: low, a feature or symptom that is less present or intense in the disease.

Autoimmune Diseases

Autoimmune diseases are a series of related diseases characterized by dysregulation of the immune system, in which immune cells cannot distinguish self-antigens from non–self-antigens and give rise to activation of immune cells to attack autoantigens, leading to inflammation and multi-tissue damage [28]. T1DM, RA, and IBD are autoimmune diseases [29]. Moreover, some of the autoimmune diseases are organ-specific, such as primary biliary cirrhosis, and some reflect a variety of immunological dysfunctions involving multiple organ immune dysfunction such as systemic lupus erythematosus [30]. T1DM is dramatically increasing in many parts of the world [31], they affect millions of people and are prone to serious complications such as heart and kidney disease, stroke, and blindness [32] (Figure 2). RA is an autoimmune disease that damages joints and other tissues and organs such as the heart, kidneys, lungs, digestive system, eyes, skin, and nervous system [33]. IBD is a chronic, progressive immune-mediated inflammatory condition of the gastrointestinal tract [34]. The incidence of IBD has rapidly increased worldwide. Patients with IBD may suffer from malnutrition, characterized by an energy or nutrient imbalance, leading to sarcopenia, micronutrient deficiencies, overweight, obesity, and sarcopenic obesity [35]. Sarcopenia is a common complication of autoimmune diseases, and the primary cause is the loss and damage of skeletal muscle induced by immune dysfunction [36-38].

Figure 2. The associated disease of autoimmune diseases. IBD: inflammatory bowel disease; RA: rheumatoid arthritis; T1DM: type 1 diabetes mellitus.

Type 1 Diabetes Mellitus and Sarcopenia

T1DM results from the autoimmune dysfunction and death of β-cells, requiring lifelong insulin therapy [39]. This condition arises from a complex interaction between invading or resident macrophages and T cells. These immune cells release various substances, such as chemokines and cytokines, in the islet microenvironment that promote the apoptosis of beta cells. Simultaneously, β-cells can attract and activate immune cells to the islet area through their signaling, especially in response to stress, damage, or cell death [40]. The primary consequence of T1DM is hyperglycemia. Research indicates that the insulin-like growth factor (IGF) and IGF-binding protein (IGFBP) axis are crucial in maintaining normal glucose levels. Patients with T1DM showed a significant reduction in serum IGF-I levels. Additionally, mitophagy plays a crucial role in regulating the autoimmune response during the development of T1DM by preventing the accumulation of defective or dysfunctional mitochondria in pancreatic cells [41]. Muscle fibers can be damaged and undergo adverse remodeling due to the hyperglycemic and inflammatory microenvironment caused by T1DM, ultimately leading to sarcopenia [42]. A cross-sectional study showed that the prevalence of sarcopenia in participants aged 65 years or older with T1DM is 42.9%, which is significantly higher than that in people of the same age without sarcopenia [43]. Moreover, musculoskeletal system health would be affected if T1DM was poorly controlled in childhood and adolescence, and then sarcopenia would become the late complication of T1DM in adults [42].

Skeletal muscle is a primary driver organ that maintains whole-body glycemic balance [44]. Poor blood glucose control is the main risk factor for T1DM, which is complicated by sarcopenia [45]. IGFs, especially IGF1 and IGF2, can promote glucose metabolism, with their availability regulated by IGFBPs. In sum, IGFs are dysregulated both before and after the clinical diagnosis of T1DM and may serve as novel biomarkers to improve disease prediction [46]. Subsequently, Hata et al [47] discovered that a low serum IGF-1 level is associated with sarcopenia and low skeletal muscle mass in subjects with T1DM. Moreover, growth hormone could regulate cell survival and the musculoskeletal system function through growth hormone/IGF1 signaling pathway [48]. Other researchers found that IGF1 activates the AKT/PKB pathway and protein synthesis pathway by binding to the IGF1 receptor, thereby increasing muscle synthesis [49]. In addition, previous reports have pointed out that mitochondrial dysfunction is the common cause of regulating muscle degeneration induced by aging and T1DM [50]. However, increased oxidative stress, decreased respiration and oxidative capacity, and increased permeability pore opening in mitochondria could promote the process of apoptosis.

Rheumatoid Arthritis and Sarcopenia

RA is an autoimmune disease characterized by the presence of symmetrical polyarthritis, which tends to lead to severe cartilage and bone destruction, thereby resulting in joint pain and arthritis [51]. Persistent joint inflammation can lead to cartilage and bone damage, joint damage, and even disability if the patients

XSL•FO
RenderX

receive treatment not in time [52]. The pathogenesis of RA is complex and has not been fully elucidated [53]. Genetic susceptibility contributes to the increased prevalence of RA pathogenesis [54]. Epigenetic factors, such as DNA methylation and histone acetylation play a key role in RA [55]. The production of autoantibodies and the presence of autoreactive T cells in blood and synovial structures are distinguishing features of RA [56].

Studies have shown that RA is a potentially pathogenic effect of low appendicular lean mass and low grip strength [49]. The injury of RA to skeletal muscle can accelerate the occurrence of sarcopenia and seriously affect the life quality of patients [57,58]. Li et al [59] pointed out that the prevalence of sarcopenia in patients with RA was 31%, which is much higher than that in people without RA. Another cross-sectional study of 388 patients with RA showed that 37.1% of the participants had sarcopenia (14.7% severe sarcopenia, 22.4% sarcopenia) and 49.0% had low muscle mass [60]. Even more importantly, the incidence of sarcopenia increases with the lastingness of RA progression [59,61]. It is worth noting that RA patients with a higher percentage of body fat are more likely to develop sarcopenia [62].

Chronic inflammation is closely related to muscle damage in RA [63]. RA primarily affects the joints, but the risk and susceptibility factors can also cause inflammation in mucosal sites such as the mouth, lungs, and intestines. These sites can be recognized by the adaptive immune system, which triggers an immune response with the help of antigen-presenting cells. This response occurs in secondary lymphoid tissues, resulting in the production of autoantibodies. Subsequently, activated stromal cells like fibroblast-like synovial cells, antigen-presenting cells, and macrophages (MΦ) produce various inflammatory cytokines, including interleukin (IL)-1, IL-2, IL-6, IL-8, IL-17, tumor necrosis factor-α (TNF-α), IFNγ (interferon gamma), and others, which can cause local inflammation and damage [64]. Researchers indicated that skeletal muscle metabolic disorders might be the leading cause of RA combined with sarcopenia [10]. However, skeletal muscle metabolism disorders can lead to loss of skeletal muscle due to impaired muscle anabolism, excessive muscle catabolism, or a combination of both [65]. The ubiquitin-proteasome pathway is a key pathway to increase muscle proteolysis [62,63]. Excessive production of proinflammatory factors makes a significant contribution to the breakdown of muscle protein. Higher levels of TNF-α and IL-1β induced by RA condition could elevate the expression level of IGFBP-5, IGFBP-3, scroggin-1, and muscle ring finger protein-1 (MuRF-1) through regulating the ubiquitin-proteasome system, thereby leading to increased hydrolysis of myofibrillar and soluble proteins [65].

Additionally, it was found that the amount of body fat and the density of muscle were closely linked to disability and physical performance in patients with RA. Specifically, individuals with a higher percentage of body fat showed a stronger correlation with the development of sarcopenia in RA. Therefore, it is recommended that the focus be on reducing fat and improving muscle quality as effective approaches to alleviating the disability of patients with impaired physical functioning [62]. Exercise could increase muscle mass in patients with RA effectively, so physical inactivity might be another risk factor for the high prevalence of RA combined with sarcopenia [66].

Inflammatory Bowel Disease and Sarcopenia

IBD, which includes ulcerative colitis and Crohn disease, is a progressive immune-mediated bowel disease for which there is no effective therapy treatment currently [57,67]. The intestinal microecology of patients with IBD is disturbed, which triggers changes in host immune response and metabolism that subsequently promote inflammation. The inflammatory response to IBD is characterized by a sustained increase in the production of inflammatory cytokines by T cells (TNF-α, IL-6, IL-1b, etc) [68]. Increased IL-12/23 and IFN-c levels, mediated by T helper cell 1, are supposed to be major factors in the maintenance of inflammation in patients with Crohn disease [69]. But T helper cell 2-mediated IL-5 and IL-13 levels elevation is an important factor for inflammation in ulcerative colitis patients [70].

Chronic inflammation and malnutrition resulting from IBD contribute to the development of sarcopenia [71,72]. Sarcopenia is a common condition in IBD patients and it increases fatigue and decreased quality of life. According to a recent study, sarcopenia occurs in 52% of people with Crohn disease and 37% of people with ulcerative colitis [71]. Although the underlying mechanism of sarcopenia in IBD patients remains unclear, studies indicated that the gut-skeletal muscle axis sheds light on the pathophysiology of IBD-associated sarcopenia. This axis comprises specific mediators from the gut that activate signaling pathways for amyotrophic and antimuscular atrophy in skeletal muscle cells [73]. The up-regulation of TNF-α, NF-κB (nuclear factor kappa-B), and JAK/STAT signaling pathways is an important factor in the pathogenesis of sarcopenia [74]. Studies have shown increased levels of proinflammatory factors such as TNF-α, IL-6, circulating lipopolysaccharide, antimyogenic mediators, and promyogenic mediators (myostatin and insulin-like growth factor-1) in IBD patients [75,76]. Both TNF-α and IL-6 can activate NF-κB, which induces transcription of components of the ubiquitin-proteasome proteolytic pathway, such as atrophic protein-1 and MuRF-1, triggering protein degradation [77]. In addition, NF-κB further enhances IL-6 expression, creating a vicious cycle of inflammation and muscle protein degradation [78]. Inhibiting myostatin and muscular dystrophy factors such as atrophin-1 and MuRF-1 and enhancing myogenic factors including MyoG (myogenin) and MyoD (myoblast determination) can improve muscle atrophy [79]. Notably, the JAK/STAT signaling pathway is highly involved in the pathogenesis of IBD [80], mediating the function of several inflammatory cytokines involved in intestinal inflammation, such as IL-2, IL-4, IL-6, IL-7, IL-9, IL-12, IL-15, IL-21, IL-23, and IFN-γ [81].

Malnutrition often occurs in patients with intestinal insufficiency and intestinal failure. Malabsorption of micronutrients and macronutrients resulting from malnutrition can cause changes in body composition and increase the risk of sarcopenia [82]. In general, dietary patterns would have a great influence on the gut microbiota structure and function of patients with inflammatory diseases. For instance, the Mediterranean diet is

XSL•FO
RenderX

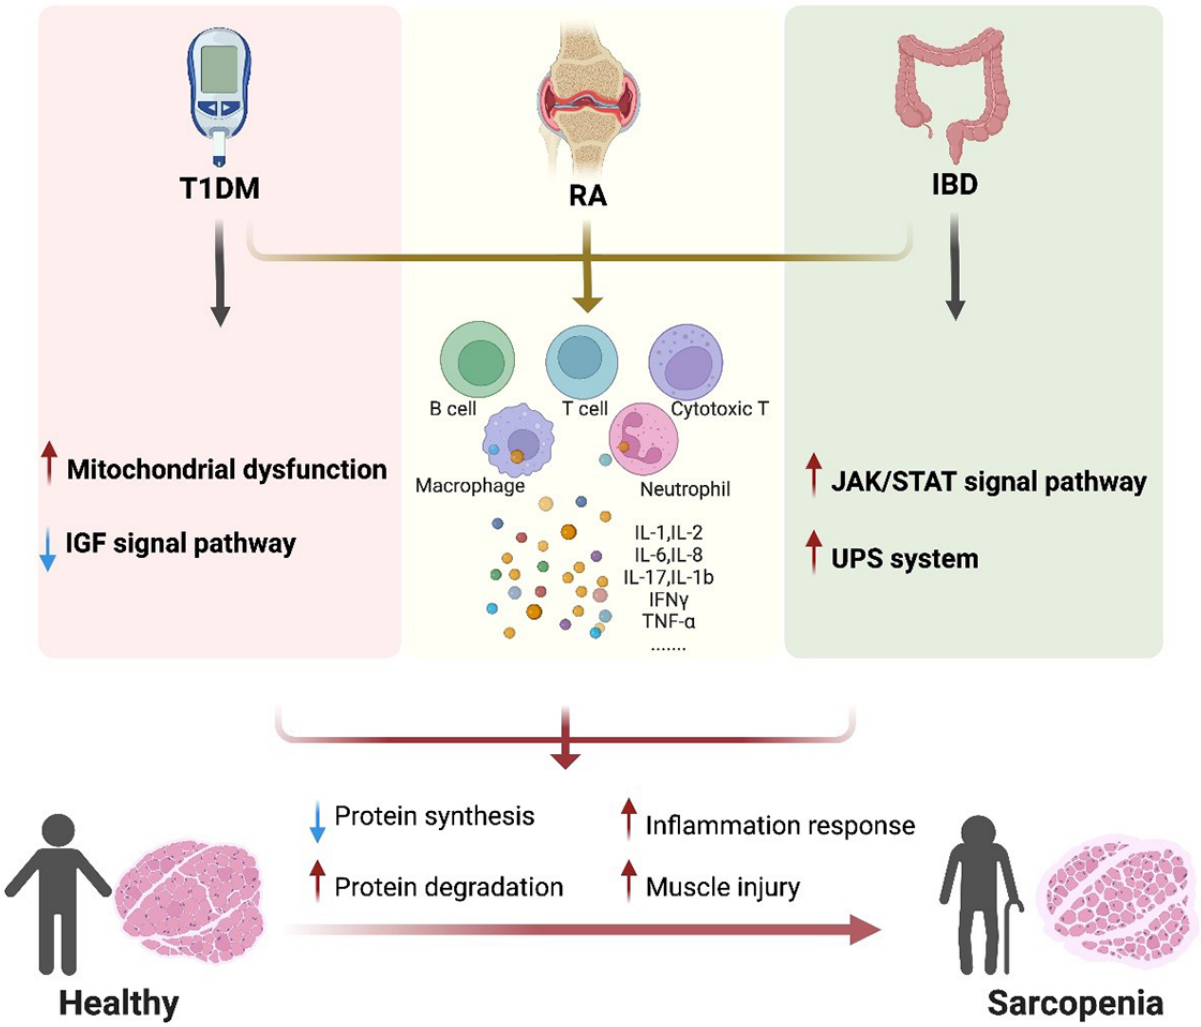
beneficial for IBD patients with reduced inflammation and improved immune function, but the Western diet has the opposite effect [83]. In addition, vitamin D is involved in regulating muscle cell proliferation, differentiation, and regeneration. Consistent with this, research has shown that vitamin D supplementation is expected to reduce the occurrence of sarcopenia in IBD patients [84]. The inability to maintain protein balance after meals can lead to a decrease in muscle mass in patients with Crohn disease, exacerbating the occurrence of sarcopenia [85].

Ethical Considerations

This study used exclusively publicly accessible deidentified datasets, ensuring the absence of personal identifiers or sensitive information. Therefore, no ethical approval or declaration was required per the journal's policy and institutional guidelines. Given the absence of secondary analysis involving pre-existing nonidentifiable data, the research maintained full alignment with the Declaration of Helsinki principles. Methodological rigor was further reinforced through strict adherence to ethical protocols outlined in the JMIR Editorial Policies for data governance, as well as compliance with internationally validated open-science frameworks for responsible data use.

Discussion

Sarcopenia is common in the 3 autoimmune diseases commented on in this manuscript, T1DM, RA, and IBD. The combination of autoimmune diseases and sarcopenia can result in a diminished life quality, long-term disease prognosis management, and impose a substantial financial burden. Thus, it is important to investigate the relationship between sarcopenia and autoimmune diseases. Essentially, perturbations within the immune microenvironment of patients with autoimmune disorders elicit fluctuations in the populations of immune cells and alterations in the expression patterns of relevant factors. These modifications subsequently disrupt the functional coherence of muscle regeneration signaling cascades, ultimately underlying the pathogenesis of sarcopenia (Figure 3).



Autoimmune diseases are closely associated with alterations in the immune microenvironment. Pathological interactions between T-cells and B-cells serve as the foundation for numerous autoimmune diseases [86]. For T1DM [87] and RA [88], disruption of T-cell and B-cell tolerance, along with the production of autoantibodies, typically precede the diagnosis of autoimmune diseases. T1DM is characterized as the pancreatic beta cells destroyed by the immune system, resulting in life-long use of exogenous insulin, which places a great burden on patients and medical resources [89]. Pancreatic β cell injury is primarily attributed to T cells while antigen-presenting B cells exacerbate this damage by presenting antigens to T cells [90]. Multiple pieces of evidence indicate that T cells play a pivotal role in driving autoimmune responses in RA, with an abundance of these cells observed within inflamed synovial membranes [91]. The intestinal environment is highly complex, and the immune system maintains the entire intestine's health [92]. Among various factors contributing to the balance of intestinal microbiota, B cells undergo activation and maturation to generate the largest population of plasma cells secreting immunoglobulin A within the human body, thereby promoting immune system homeostasis [93]. Additionally, Follicular helper T cells are enriched in several inflammatory conditions, particularly within the intestine where they exhibit higher levels compared with other tissues [94].

Muscle atrophy represents a significant contributor to sarcopenia development wherein immune cells play a vital role in muscle regeneration. Immune cells release key inflammatory mediators that regulate the muscle fiber microenvironment [95]. Early recruitment of neutrophils leads to robust nonspecific responses that further exacerbate muscle fiber and extracellular matrix injuries [96-98]. Neutrophils exacerbate cellular injury by releasing reactive oxygen species, which induce muscle fiber damage and increase extravasated vascular permeability [99]. Furthermore, neutrophils secrete proinflammatory cytokines IL-6, IL-1β, and TNF-α, promoting satellite cell proliferation while inhibiting differentiation [100]. Both IL-6 and reactive oxygen species have been demonstrated to cause mitochondrial dysfunction/damage and alterations in protein stability within muscle fibers [99,100].

Cytotoxic T lymphocytes exhibit similar functions to neutrophils during the early stages of injury response [101]. Additionally, neutrophils and cytotoxic T lymphocytes recruit inflammatory macrophages to aid in the phagocytosis of damaged tissue for clearance while releasing proinflammatory mediators that stimulate satellite cell and fibroblast proliferation and enhance vascular permeability [102]. However, the investigation of their roles in patients with autoimmune diseases complicated by sarcopenia remains limited. It can be speculated that these disruptions within the skeletal muscle microenvironment may lead to increased loss of muscle mass and fibrosis, resulting in reduced muscle plasticity, weakness, and fatigue.

Figure 3. The potential mechanism of autoimmune diseases combined with sarcopenia. IBD: inflammatory bowel disease; IFN: interferon; IGF: insulin-like growth factor; IL: interleukin; JAK/STAT: Janus kinase/signal transducer and activator of transcription; RA: rheumatoid arthritis; T1DM: type 1 diabetes mellitus; TNF: tumor necrosis factor; UPS: ubiquitin proteasome system.

Conclusions

Autoimmune diseases are closely associated with alterations in the immune microenvironment which plays a crucial role in skeletal muscle differentiation and remodeling [103]. The pathogenesis of autoimmune diseases combined with sarcopenia can be attributed to an imbalance of hormones, growth factors, and proinflammatory factors in the immune microenvironment. This leads to muscle metabolism disorders resulting in a decline in muscle mass due to blocked muscle synthesis and excessive muscle catabolism. To mitigate muscle loss, it is recommended to improve diet quality by consuming nutrients like vitamin D [104] and high-quality protein supplements [105]. Additionally, engaging in physical exercise may be an effective therapy to prevent autoimmune diseases combined with sarcopenia. However, there is still a lack of effective clinical treatment for these diseases, and the pathogenesis of autoimmune diseases combined with sarcopenia needs to be further elucidated [66,106,107]. Future research should focus on understanding the molecular mechanisms of various autoimmune diseases combined with sarcopenia and developing targeted therapies [108].

Acknowledgments

We thank the Gao lab members for the helpful discussion for this study. This study was supported by grants from the Medical and Health Research Project of Zhejiang Province (2025KY1038 and 2024KY182), the Hangzhou Agricultural and Social Development Research Program (20231203A07), the Construction Fund of Medical Key Disciplines of Hangzhou (OO20200055), the Zhejiang Province Science and Technology Plan Project (2022C03035), and the Project of Hangzhou Health Science and Technology Program (A20200210).

Abstract

Case report forms (CRFs) are the instruments used by research organizations worldwide to collect information about patients and study participants with the purpose of answering specific questions, assessing the efficacy and safety of medical products, and in general improving prevention and treatment in health care. To obtain significant research results out of the collected data, CRFs should be designed following the recommendations issued by regulatory authorities. However, we believe that semantic interoperability in CRFs has not yet been properly addressed. Within an international consortium comprising several COVID-19 cohorts, we scrutinized the questions included in the different CRFs with the purpose of establishing semantic interoperability across the different study data elements so that data could be merged and jointly analyzed. We realized that similar concepts were structured very differently across the different CRFs, making it hard to find and match the information. Based on the experience acquired, we developed 5 guiding principles on how to design CRFs to support semantic interoperability and increase data quality while also facilitating the sharing of data. Our aim in this viewpoint is to provide general suggestions that, in our opinion, should support researchers in designing CRFs. We conclude by urging authorities to establish an international coordination board for standards and interoperable clinical study data with competence in clinical data, interoperability standards, and data protection as part of a preparedness plan for future pandemics or other health threats.

KEYWORDS

case report form; CRF; interoperability; standard data model; data format; metadata; core data elements; data quality

Introduction

Since the onset of the COVID-19 pandemic, we have witnessed the emergence of numerous studies worldwide aimed at deepening our understanding of SARS-CoV-2 infection and enhancing treatment strategies [1]. The urgency to produce meaningful research results in a relatively short timeframe has underscored the importance of efficiently merging data from diverse studies. However, differences in languages, formats, and terminologies often complicate the sharing and integration of data.

The European project ORCHESTRA [2], which sought to build a pan-European cohort of COVID-19 patients, confronted the significant challenge of harmonizing data from various cross-country studies [3]. Achieving interoperability among disparate datasets is critical not only for supporting ongoing research but also for bolstering preparedness against future global health crises. This aligns with the European Commission's objectives under the European Health Data Space regulation [4], which emphasizes improving data accessibility and integration across member states.

Case report forms (CRFs) are essential tools employed by research organizations worldwide to gather detailed information from patients and study participants. These forms are designed to address specific research questions, evaluate the efficacy and safety of medical interventions, and ultimately advance prevention and treatment in health care.

A clinical study is designed to answer one or several research questions based on the analysis of data collected from patients that have been enrolled and are being observed or are partaking in specific interventions following the study protocol. CRFs, either in paper form or electronic format, are the instruments used to collect study data and form the basis of any subsequent statistical analysis. Electronic CRFs (eCRFs) are preferred over paper CRFs because data can automatically be stored in a digital format and immediately used, removing inaccuracies derived from the interpretation and transcription of handwriting. Additionally, if properly structured, the digital format intrinsically offers great potential for data objects to be more findable, accessible, interoperable, and reusable, in other words, more FAIR [5], than paper. The design of eCRFs is crucial for the outcome of a study [6]. Therefore, it should be optimized to enhance data quality and data interoperability.

XSL•FO
RenderX

Ideally, a standard operating procedure is established initially for designing eCRFs. Common recommendations for eCRF design include suggestions to reduce data entry errors and ambiguity in the interpretation of variables such as maximizing the use of coded questions and answer lists and minimizing the use of free text answers; using built-in consistency checks for admissible ranges and plausible date checks; facilitating data entry using branching logic strategies; specifying units of measurement (particularly for laboratory parameters, but also for vital signs, etc); adopting standard data formats; using (and reusing) published Common Data Elements, if available, and unambiguous temporal reference (eg, before or during infection).

Regulatory authorities and international expert organizations, such as the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use and the Society for Clinical Data Management, have published detailed guidance on how to design CRFs, placing their focus on ensuring accuracy, utility, and poignancy of layout and content[7],[8] , [9]. However, the idea of designing CRF variables to facilitate standardization and reusability in the context of data interoperability has remained unaddressed by these expert institutions.

In the simplest setup, a study will be limited to 1 cohort, enrolling patients within one country, across several participating medical offices or hospitals. In more complex cases, patients are enrolled across several cohorts located in multiple countries. Regardless of the complexity of the study, interoperability and quality of data should always be considered high-priority objectives when designing the collection forms. By so doing, study results are more reliable, and collected data are ready for potential secondary use.

The COVID-19 pandemic, along with disease outbreaks caused by other viruses such as human monkeypox, Zika, and Ebola, has highlighted the need for international collaboration in terms of research. They have led to large-scale clinical studies conducted in the private sector and by public research consortia [10]. Multi-country and multi-cohort retrospective studies come with more challenges, as they generally need to combine data that were collected in different formats and, at times, different languages. This means that even when variables cover similar information, extensive transformation or translation activities are required before merging data can take place. This highlights the need for coherent study protocols across research groups and across countries, based on common formats and terminologies. Here is where data standardization and harmonization are the key to enabling quality data that can be merged easily without resource-heavy transformation activities, thus expediting analysis and gaining timely insights [11,12].

Aim

Our aim in this viewpoint is to provide researchers with general suggestions in designing CRFs that, in our opinion, should support interoperability, reduce ambiguity, improve data quality, and facilitate data exchange across different systems.

The ORCHESTRA Project

ORCHESTRA was funded by the European Commission during the COVID-19 pandemic and ran until the end of 2024. It aimed at creating a pan-European cohort of COVID-19 patients to study the disease, the efficacy of the treatment, and the long-term effects on general and fragile population as well as on health care workers. We were responsible for establishing interoperability within the European ORCHESTRA project. Partners in ORCHESTRA followed the goal to merge data from different clinical studies to generate new knowledge about multiple aspects of COVID-19 [3]. We examined over 3700 variables (comprised of questions and answers) with the objective of identifying similar information across studies that could be matched and analyzed jointly. This way, we compared the variety of approaches used across 7 different COVID-19 studies to investigate similar health care concepts. Within our project task, we associated international identifying codes from the most pertinent standard health terminologies to the questions and answers included in 7 clinical studies in ORCHESTRA. Ambiguous or complex wording found in the CRF variables needed to be evaluated as part of this mapping activity as well.

Based on our experience of being involved in large-scale national and international research projects, we believe that apart from ensuring accuracy and quality of collected data, CRF design should also maximize semantic interoperability. That way, time- and cost-efficient merging, analysis, and sharing of data can be facilitated. Our conviction is supported by the report published by the Joint Action Towards the European Health Data Space, which is a European initiative that developed principles for the secondary use of health data [13] and that places semantic interoperability as one of the operational objectives to achieve excellence of data quality.

To address the pressing need for streamlined data exchange and integration in clinical research, we have formulated 5 guiding principles that should be considered when designing CRFs. The principles address the need to harmonize data, unambiguously identify variables, associate clinical concepts with international identifiers, promote data quality, and enhance semantic coherence.

We believe that the application of the proposed principles would enhance semantic interoperability and support the exchange of information across different research groups.

Five Guiding Principles to Enhance Interoperability of CRFs

Following our aim statement, we propose 5 guiding concepts aimed at increasing semantic interoperability of CRF data and quality of collected information.

XSL•FO
RenderX

Harmonize Data

Concept 1: Creation or Reuse of Core Data Elements (CDEs)

Recurring information across clinical trials that are general in nature or specific to a specific disease should be identified and shared in a common format across the scientific community.

Data concerning demographics or clinical evaluation of patients, for example, is collected in many studies and should ideally be standardized to create a uniform format. Frequently collected disease progression and outcome information should also be identified and grouped into well-defined disease-specific core data elements (CDEs). CDEs can then be published for re-use by researchers worldwide.

Granted, the National Institutes of Health (NIH) have been focusing on developing CDEs for over 20 years. Yet, the adoption of CDEs is facing challenges. Reasons for low adoption by research projects, among others, are established data collection practices and ambiguous interpretations and implementations of health care concepts and CDEs.

The latter difficulty can, however be overcome by associating a common standard terminology to data elements to remove any ambiguity of meaning.

The increasing need to combine data in order to address global threats to life will eventually have to gain greater weight than maintaining localized, established practices.

National and international harmonization efforts such as the International Patient Summary (IPS) [14], the European Electronic Health Record Exchange Format [15], or the United States Core Data for Interoperability (USCDI) [16] should be considered to maximize reusability of data.

Unambiguously Identify Variables

Concept 2: Use of Standards in CRF Metadata

Following the FAIR principles, metadata is of foremost importance for the quality re-use of information. Metadata should ideally include references to international terminology codes that unambiguously represent each concept. Whenever possible, all CRF variables should be handled as close-ended questions. In case of measurement or observations, Logical Observation Identifiers Names and Codes (LOINC) should be used. LOINC offers the possibility of defining data elements without ambiguity by specifying with one code all the details relative to the observation to be performed.

When no LOINC codes are available, other international terminologies should be considered, such as the National Cancer Institute's Thesaurus for genomics data.

Qualitative answers should be restricted to defined (coded) value sets and identified with the appropriate terminology codes, such as those provided by Systematized Medical Nomenclature for Medicine–Clinical Terminology (SNOMED CT) [17]. The Anatomical Therapeutic Chemical Classification System can be used to describe drugs and chemicals, and the *International Classification of Diseases* to report diseases and disorders.

CRFs often include more complex questions that cover several informational components. That can include details about time, location, situation, etc. Hence, mapping several concepts to one semantic code can at times be difficult. This is a challenge that the postcoordination expression in SNOMED CT may help to solve in some contexts. However, integrating postcoordination into CRFs appears less feasible [18].

Terminology bindings proposed by national or international harmonization initiatives such as those mentioned in Concept 1 should be reflected in the metadata of the study data elements whenever possible. It should also be noted that the metadata could also include information on the format of the data. That can be achieved by mapping study elements to standards such as the Health Level Seven's (HL7) Fast Healthcare Interoperability Resources (FHIR) standard or to the Observational Medical Outcomes Partnership Common Data Model.

The combined use of semantic and syntactic standards would further support interoperability.

Associate Clinical Concepts With International Identifiers

Concept 3: One Concept at a Time (Unless It Is Part of a Questionnaire or Index)

The progressive adoption of FHIR by initiatives aiming to harmonize health data, such as IPS and USCDI, would suggest that information should follow the modular structure and be as precise as possible.

Hence, our second recommendation would be to only include one concept in a question. We have, for example, seen the following question in a COVID-19–related study CRF: asking enrolled patients whether they have had "Changes in or a loss of smell." In this case, we propose splitting the question into 2 variables: "Changes in smell" and "Loss of smell." With this approach, each variable could be represented by a specific semantic code. Additionally, splitting the question into 2 would also facilitate accurate analysis.

We acknowledge that this accuracy has to be balanced against the manageability of the length of a CRF. It should not lead to the creation of overly long CRFs, but rather to a focus on accuracy and key variables needed for analysis.

However, it is also important to note that at times some concepts which are included in questions could be removed without lowering accuracy of the question. For example, information like time points or target patients could be put as a header or as instructions within the CRF.

Of course, the ultimate decision on what constitutes the most relevant concepts to be included in the CRF questions always lies with the scientific group or the principal investigator or the sponsor.

Promote Data Quality

Concept 4: Accurate Wording

Initiatives such as IPS and the USCDI provide guidance on the use of patient-related core data elements. However, often CRFs

XSL•FO
RenderX

require the use of more study-specific variables. The wording of variables (questions and answers) should be carefully phrased to provide all and only the necessary information so that study nurses and respondents understand exactly what is asked. Precisely worded questions (and answer options) will increase the quality of data. This is to ensure that the data collected in response to these variables will be comparable and ready to be merged. In the case of laboratory examinations, the use of LOINC codes can be very useful because it automatically includes all the information necessary to remove ambiguity, that is, the methodology used, specimen type, or whether the expected result is qualitative or quantitative, unit information, etc.

If language translations of CRF variables are required, these should be meticulously performed. Additionally, a quality check on the wording and meaning of the translated variables is recommended and should be implemented, ideally by native speakers.

Enhance Semantic Coherence

Concept 5: Answer Options Should All Be Semantically Coherent, and Units of Measures Clearly Stated and Identified With the Unified Code for Units of Measure Units

Another aspect of standardization relates to the answer options that are the second component of a CRF variable, after the question. It is important to maintain coherent semantic coding of answers as well. We recommend that, during the design of CRFs, semantic codes be used for mapping answers instead of assigning generic numeric identifiers that lack specificity. This would provide an unambiguous and reusable representation of the answer concept. Furthermore, coding would help the precision of the information and the quality of data by highlighting inconsistencies such as value set options not being semantically aligned.

For example, the question “What kind of swab test was performed?” should not include “throat” and “PCR” as answers in the same value set. In this case, the use of a terminology system like SNOMED CT clearly shows that the codes of the 2 concepts belong to different semantic categories (“body structure” and “procedure” respectively). Therefore, the question might be equivocal and could lead to unclear results.

In addition, in case of variables that describe quantitative (laboratory) measurements, such as “Dose of immunosuppressive medication taken per day” “Body weight” or “Glucose concentration measured” units of measure should be clearly stated and identified with Unified Code for Units of Measure codes [19,20].

Summary and Considerations

Based on our experience in standardizing and harmonizing CRF variables from different protocols on COVID-19, we have presented five concepts aimed at improving CRF design and enhancing interoperability of clinical study data: (1) the creation of or (2) use of already existing standardized data objects can save time and help establish alignment and comparability with other research datasets, and (3) data quality can significantly be improved by paying attention to the fact that each CRF question and every answer option only contains 1 concept, (4) that variables are accurately phrased, and (5) that answer options are coherent, or in case of numerical results, that clearly defined units are included.

Probably, guidelines for reporting multiple concept codes in the metadata should be established, as this is a common occurrence in clinical research. In many cases, the possibility to code complex questions as coded questionnaires is very helpful. We believe it would be important to collaboratively address this difficulty of coding complex variables for the clinical study context.

The problem of not using interoperability standards is invisible to many researchers. That is because often, the advantages of such use become evident only when the need to merge data arises. Ideally, standards should be introduced already during the design phase of CRFs. Unfortunately, since the importance of data standards is still not adequately known, their implementation might be seen by some as a hassle that slows down or even limits the development of CRFs. In our opinion, a cultural change based on education and information in this field is needed.

It is necessary to abandon the idea of doing research in silos with data collected in incompatible formats by different research groups. Common data elements and their format should be identified, agreed on, and promoted by relevant national and international authorities. On the other hand, a scenario where clinicians are unwillingly responsible for standardization should be avoided, considering the already existing strain on their time and understandable gaps in expertise. New roles in health care are needed with expertise in digital medicine to enable interoperability of data and facilitate their integration within a wider eHealth ecosystem where data are being collected from different digital solutions and in a cross-country context.

The use of a common exchange format in combination with standard terminologies for study data elements in an eCRF would complete the interoperable data model of clinical research information. The innovative standard that is increasingly being adopted in the health care environment is HL7 FHIR. Thanks to FHIR’s innovative modular organization of information, a particularly efficient exchange of data is enabled. Its adoption in the clinical research environment is still low, but we expect this to change in the future. That is because the need to streamline activities and integrate information from electronic patient records or other medical devices into clinical research is progressively becoming more evident [21,22]. In fact, a dedicated HL7 working group is focusing on the design of FHIR resources to conduct clinical research more effectively [23].

In this context, as mentioned before, the European Commission has proposed a regulation for the European Health Data Space to support the interoperability of data in healthcare and in research. Forthcoming implementing acts will provide specifications for the exchange format of data to support cross-system and cross-border portability. In the United States, the Office of the National Coordinator for Health Information Technology promotes the USCDI [16], a set of health data

XSL•FO
RenderX

elements divided into thematic classes to support information exchange. In general, collaborations to improve interoperability are fortunately increasing, including, for example, the Observational Health Data Sciences and Informatics (OHDSI) and the NIH concerning the maternal health data [24] or the employment of the Observational Medical Outcomes Partnership Common Data Model by the NIH research program "All of Us" [25]. Very important is also the OHDSI and European Medicines Agency collaboration in the project DARWIN [26], and the HL7 Vulcan project bringing together OHDSI and HL7 FHIR [27].

In conclusion, the COVID-19 pandemic has revealed to the broad community how important it is to quickly analyze large amounts of data, develop vaccines, and assess their safety and efficacy. We therefore need to facilitate the exchange of information in the context of global health challenges (including cancer, infectious disease, and rare diseases) and implement standardization of clinical study data collection. Additionally, the establishment of an international coordination board for standards and interoperable clinical study data with competence in clinical data, interoperability standards, and data protection should be part of a preparedness plan to face future pandemics and other health threats. This proposed coordination board, in coordination with ongoing international initiatives, could be instituted at the regional level and associated with large funding bodies and policy makers (ie, European Commission within the European Union and NIH in the United States) or at the pan-regional level, for example, as part of the World Health Organization.

Acknowledgments

We would like to thank Prof Evelina Tacconelli for her invaluable support. The guiding principles were conceived based on the activities performed within the ORCHESTRA project, which has received funding from the European Union's Horizon 2020 research and innovation program (grant 101016167).

Data Availability

The metadata definitions on which we based our comment are publicly available on the standard-enabling platform ART-DECOR [28].

Authors' Contributions

ER and CS contributed equally conceiving and designing the guiding principles. ST has revised the paper critically and made important contributions.

Abstract

Although uroflowmetry and bladder diaries are widely used for noninvasive evaluation of lower urinary tract symptoms, they still have limitations in diagnostic capability and users' convenience. The aim of this paper is to discuss potential solutions by reviewing (1) the evolution and current clinical use of uroflowmetry and bladder diary, including clinical guidelines, daily practice applications, and their historical development; (2) a growing trend toward using home devices with various technologies; and (3) a comprehensive comparison of the strengths and weaknesses of these home devices. In our opinion, the following points can be highlighted: (1) the emerging trend of using home devices can enhance diagnostic capabilities through repeated measurements and the convenience of at-home testing and (2) home devices, which provide both frequency-volume and uroflowmetry information, have the potential to transform the management of lower urinary tract symptoms.

(Interact J Med Res 2025;14:e66694) doi:10.2196/66694

KEYWORDS

lower urinary tract symptoms; uroflowmetry; bladder diary; home devices; bladder; noninvasive; evaluations; viewpoint; diagnostic; mobile health

Introduction

As the population ages, there has been an increase in patients reporting lower urinary tract symptoms (LUTS) in recent years. To objectively assess the function of the lower urinary tract, uroflowmetry and bladder diaries (BD) are commonly used noninvasive examinations for those experiencing LUTS.

Uroflowmetry can measure various parameters during the voiding phase, including maximum flow rate (Qmax), and voided volume, which are essential metrics. Additional parameters, such as flow pattern, time to Qmax, flow time, and average flow rate, provide further insights [1]. This makes uroflowmetry a comprehensive and objective tool for evaluating the voiding phase. Consequently, uroflowmetry is recommended in the guidelines of both the American Urological Association and the European Association of Urology for assessing LUTS [2-4].

BD offers physicians valuable insights into urinary frequency, functional bladder capacity, most frequently observed bladder volume, urgency and urge urinary incontinence episodes, volume of water intake, nocturnal or daily urine output ratio, and associated bladder pain episodes [5]. They assess not only the storage phase but also some symptoms related to the voiding phase. For optimal adherence and reliability, a duration of 3-7 days is recommended for maintaining a BD [3,6]. Additionally,

XSL•FO
RenderX

BD is included in the guidelines of both the American Urological Association and the European Association of Urology for evaluating overactive bladder and LUTS [2-4].

Even though both of them can provide physicians with several parameters for evaluating the lower urinary tract, there are still some limitations of uroflowmetry and BD for depicting the whole picture of patients' LUTS, such as inconveniences, inadequate measurement frequency for uroflowmetry, lack of objective recording, and poor adherence for BD.

The aim of this paper is to discuss potential solutions for the earlier-mentioned limitations by reviewing (1) the evolution and current clinical use of uroflowmetry and BD, including clinical guidelines, daily practice applications, and their historical development; (2) a growing trend toward using home devices with various technologies; and (3) a comprehensive comparison of the strengths and weaknesses of these home devices.

Clinical Application and Limitation of Uroflowmetry and BD

Clinical Application and Limitation of Uroflowmetry

Uroflowmetry is typically performed in health care institutes, where patients may experience heightened emotional effects compared to when they are at home. Pre- and intratest anxiety (just like "white-coat hypertension") should be taken into consideration for its effect on lowering test reproducibility [7]. This practice also causes inadequate measurement frequency and a lack of voiding in different scenarios.

As to representativeness, some parameters are prone to within-subject variation [8-11], so it is recommended to repeat uroflowmetry measurements. The diagnostic accuracy of uroflowmetry is largely affected by threshold values [12,13], especially with physiological compensatory processes, detrusor underactivity, or an underfilled bladder [14]. Although uroflowmetry can be used to monitor treatment outcomes [15] and to correlate symptoms with these objective findings [12,16], its clinical value is still limited, as it is unable to differentiate between the possible underlying mechanisms. Again, specificity can be improved by repeated flow rate testing [6]. However, it is not feasible for a patient to receive multiple uroflowmetry in a clinical setting. Therefore, Caffarel et al [17] and Bray et al [18] even suggested the use of home uroflowmetry to achieve multiple measurements to improve the reliability of uroflowmetry.

In summary, uroflowmetry should be performed in a comfortable environment repeatedly to represent the whole picture of a patient's voiding pattern. This means that an at-home uroflowmetry is preferred.

Clinical Application and Limitation of BD

BD provides a method of quantifying symptoms, such as frequency of urge incontinence events and number of nocturia episodes [3], and reduces recall bias. However, it is not completely objective because the process relies on manual actions, such as recording the time and using measurement tools. These will affect BD's reliability.

Furthermore, the use of BD might induce a "bladder training" effect and influence the frequency of nocturnal voids [19]. Though it is important to guide patients to live an appropriate lifestyle [20], such modifications could potentially obscure the true micturition behavior of the patient. It is just like a clinical "uncertainty principle" (when you measure a system and change it at the same time), which should be taken into consideration when the goal of the test is to accurately depict the true picture of a patient's micturition. It is preferred to record a BD intuitively and insensibly.

The duration of BD has to be long enough to reduce sampling errors but short enough to avoid nonadherence [21]. It is recommended to conduct a BD including at least 3 days (continuous or separated) [22]. However, a longer BD is generally more reliable [23-26]. Because of the considerable effort required to complete each entry in a BD, there has been minimal achievement in comparing and validating BDs. Until now, the International Consultation on Incontinence Questionnaire BD is the only one that has undergone full validation [27]. The current protocol of BD necessitates that patients physically collect and measure each void, recording the volume along with associated symptoms. This practice requires patients' thorough intellectual understanding of the whole procedure and objectively recording BD. Among a survey of urogynecology or female pelvic medicine and reconstructive surgery specialists' fellowship-trained attendings, 25% had never or rarely (frequency of use <20%) used BD, and 97.5% reported difficulties associated with obtaining correctly completed and clinically applicable BD. The authors mentioned the best way is to teach patients with thorough instruction [20]. Therefore, a BD system capable of automation, objective recording, and repeated measurement appears to be the ideal solution.

Innovative and Possible Solutions for Avoiding Limitations

Evolution History of Uroflowmetry

As discussed in the "Clinical Application and Limitation of Uroflowmetry" section, it is important to provide patients with a comfortable environment and repeated measurements. In a clinical setting, urine weight–based, dipstick, and spinning-disk uroflowmetry are currently the most common conventional measurements of flow rate. Urine weight–based uroflowmetry detects the rate of changed weight or volume of voided urine. Dipstick uroflowmetry uses a dipstick immersed in voided urine sensing the change of fluid height and obtaining the flow rate. Spinning-disk uroflowmetry relates the power needed to counteract the slowing speed of the spinning disk hit by falling urine to the rate of urine flow [28]. In this paper, some trials of home uroflowmetry (relatively comfortable environment and feasible for repeated measurements) will be presented and discussed.

There have been several types of funnel-based uroflowmetry in the market or research fields [29-36]. The principle of funnel-based uroflowmetry is a combination of a funnel and some calibrating assembly for measuring Qmax. They all need

XSL•FO
RenderX

to be operated manually, and the results are then recorded on paper. One funnel-based home uroflowmetry has been developed for decades [37]. P-Flow (Tejnaksh Healthcare Ltd) is now a commercially available home uroflowmetry, which provides not only Qmax, average flow, voiding time of urine, flow curve, and total voided volume of urine but also simple urinalysis by an accompanied dipstick. However, users need to upload photos of the indicators on the device after finishing the test onto the health care company's server for interpreting the final results. There would be a time lag before obtaining the interpretation from the experts of this company. Additionally, it was found that Tejnaksh, the company behind this product, is a recognized teaching institute by the Ministry of Health and Family Welfare in India. To our knowledge, however, the product itself has not obtained certification from any other health authority.

There are at least 2 series of active research groups devoted to sound-based uroflowmetry, one from Singapore [38] and another from Korea [39]. Both systems use mobile phones to detect voiding sound and transfer it to the signal of voiding. Important urodynamic parameters, such as Qmax, voided volume, voiding time and average flow rate, and voiding flow patterns, can be presented through the embedded artificial intelligence (AI) algorithm. ProudP is currently commercially operated in the United States, which not only enhances the communication between patients and doctors but also improves the care quality for patients with LUTS. However, sound sensing uroflowmetry may be interfered in some noisy environments and even by the material of the testing urinal. There will be more discussion about the features of home devices in the "Comparison Between Home Devices of Different Technologies" section.

To provide a comfortable and intuitive environment for uroflowmetry, a toilet-shaped uroflowmetry (UM-100, Toto Ltd) was commercially developed in 2008 and was initially designed for clinical use [40]. A water-level measurement unit is installed with a connection to the toilet bowl. By balancing the hydraulic pressure between the measurement unit and the toilet bowl (communicating tubes in physics), urination-caused change in the water level can be measured and transformed to uroflowmetry parameters. The merit of this system is no necessity to do any cleaning work after each measurement. However, since the system detects the change in the total volume, it may have erroneous measurements when patients pass stool and urinate simultaneously [41].

A novel technology of vibration-based uroflowmetry was developed by a Taiwan-based interdisciplinary team [42]. This system simultaneously detects vibration signals during urination using an accelerometer alongside conventional uroflowmetry. Strong correlations were observed between this system and conventional uroflowmetry for parameters such as Qmax, voided volume, voiding time, and time to Qmax. Additionally, an AI model was used to analyze and predict 6 predefined patterns of uroflow curves, aiding in diagnosing voiding dysfunction with an accuracy of approximately 98%. This relatively low-cost system is suitable for automatic home urinary monitoring and enables repeated uroflow monitoring of patients outside health care institutions.

Evolution History of BD

With the reflection in the "Clinical Application and Limitation of BD" section, it is suggested to provide patients with automation, objective recording, and repeated measurements. It can be traced back to 1993 when the first computerized voiding diary "Compu-Void" was developed [43]. Compu-Void was a 64,000 RAM–capacity manual unit operated on the primitive operating system "DOS" of a personal computer. In the following decades, numerous trials have been conducted in pursuit of enhancing BD, aiming for automation, objective recording, and repeated measurement.

Quinn et al [44] ever developed a logical flow for asking users' symptoms on the portable electronic BD "MiniDoc." The advantage of an electronic data-inputting device lies in its accuracy and speed in retrieving data for further analysis [44]. Mangera et al [45] compared a paper-card reader and a hand-held input device with conventional written BD and found that an intuitive and user-friendly interface led to not only patients' preference but also the efficiency and accuracy of data management. With the onset of the digital era, application software (apps) on mobile phones and tablet computers began to play a crucial role in recording BD [46], and their numbers surged rapidly. Reports indicated that there were 55 apps available in languages such as Portuguese, Spanish, French, or English, with some offering functions for analyzing incontinence episodes and nocturia [47]. However, all of these apps require manual input.

For automated entry of data, Takai et al [48] ever introduced a body weight–based BD, which demonstrated a strong correlation between the voided urine weight recorded by the device and voided urine weight measured manually by the examinee [48]. This is the best practice of frequency or volume record and should be combined with entering episodes of LUTS to accomplish a comprehensive BD, though it cannot measure accurate urine weight during defecation.

With robust procedures of BD, the most common way to teach patients how to complete a BD is by providing detailed instructions along with any type of BD. In the current digital age, it should be expected that more clinicians like to use mobile apps or other digital resources. However, it was shown that very few clinicians actually used mobile apps (0.9%) or directed patients to use internet resources (1.2%) [20]. Furthermore, there is still no evidence to suggest that these digital apps can independently improve return rates or accuracy of the BD. In our opinion, the reason behind this is that there is only little difference between paper-based and electronic-based BDs. Electronic BDs simply record data through manual input or touch-screen processes, lacking automation. Moreover, the most cumbersome step of BD, collecting and measuring urine volume, remains unchanged. In this regard, a body weight–based BD offers certain advantages [48].

Since some important characteristics of a reliable BD, such as automation, objective recording, and repeated measurement, are fulfilled by the earlier-mentioned technologies (Table 1), we can envision a more advanced tool for accurately depicting a patient's voiding patterns. Additional suggestions for the development of a combined home uroflowmetry and BD system

XSL•FO
RenderX

are as follows: elimination of the need for cleaning after each use, incorporation of an intuitive and user-friendly interface, integration of wireless communication capability, accessibility of data for both users and doctors, and suitability for both storage and voiding phases. Therefore, such a comprehensive and intuitive "voiding recorder" will be a new standard for at-home voiding monitoring.

Table 1. Chronology of uroflowmetry and bladder diary (BD) advanced technologies in the recent century.

Year	Event	Remarks
1932	Ballenger suggested the maximum distance of a man's urine ejecting	[49]
1948	Drake recorded change in urine weight with time and manually calculated flow rate	[49,50]
1957	Kaufman improved Drake's system with electrical apparatus	[51]
1957	Von Garrelts electrically calculated flow rate	[41]
1965	Smith designed funnel-based uroflowmetry	[29]
1976	Drach used a dipstick to estimate the flow rate	[35]
1993	The first computerized voiding diary "Compu-Void" was developed	[43]
1999	International Continence Society defined uroflowmetry parameters	[52]
2003	Quinn drew a logical flow for asking users' symptoms	[44]
2008	Toto developed communicating tube uroflowmetry	[40]
2014	Mangera used paper-card reader	[45]
2014	Bright designed the first standardized and validated BD (ICIQ[a] BD)	[27]
2015	Krhut compared uroflowmetry and sonouroflowmetry	[53]
2016	Application of mobile phones and tablet computers in recording BD	[46]
2021	Takai introduced a body weight–based BD	[48]
2022	Pong linked vibration with uroflowmetry	[42]

[a]ICIQ: International Consultation on Incontinence Questionnaire.

The Emerging Trend of Using Home Devices

As we enter the era of AI, big data become crucial for training and applying AI models. This enhances the value of home devices, particularly for their ability to repeatedly measure home uroflowmetry and generate big data. Home devices facilitate mobile health or medicine by offering a comfortable environment, enabling repeated measurements, and providing big data for communication and application. It has been noted that extensive at-home data are often more reliable than single in-office tests [54]. Recently, there has been a surge in interest in home uroflowmetry at international scientific meetings and in literature [9,55-58]. Several commercial home uroflowmetry devices have also been introduced, offering repeated measurements of voiding parameters and uroflow curves. This method of repeated home measurement can provide a comprehensive picture of patients' daily-life voiding without the anxiety and stress associated with office uroflowmetry tests [9,55]. As mentioned in the "Introduction" section, uroflowmetry primarily describes the condition of the voiding phase, while BD addresses the storage phase and some symptoms related to voiding. Each can be applied to patients with different types of voiding dysfunction. Following advancements, home devices can now measure parameters in both the storage and voiding phases, making them suitable for almost all patients with voiding dysfunction.

Certainly, there is a need for home uroflowmetry to offer repeated measurements and convenience, addressing several clinical and practical challenges for practicing urologists [54]. With various home uroflowmetry technologies emerging in the market, it is important to understand their strengths and weaknesses. What are the comparative advantages and disadvantages of these different home uroflowmetry technologies?

Comparison Between Home Devices of Different Technologies

All types of home uroflowmetry technologies share common strengths, such as automatic recording, repeated measurements, and the generation of big data. However, each technology also has its own unique strengths and weaknesses when used for home uroflowmetry. Table 2 outlines various features of these technologies, including accuracy, susceptibility to environmental interferences, uroflow curve pattern recognition, AI algorithms, and contact-free operation.

XSL•FO
RenderX

Table 2. The comparison on different technologies for home uroflowmetry.

Features or technologies	Weighing (gravimetric)	Height sensor	Sound	Vibration
Accuracy	FDA[a] certified [57]	FDA certified [59]	Correlation with office uroflowmetry (R=0.91) [54]; prediction rate of 99% [60]	Uroflow curve pattern recognition accuracy>0.98 [42]
Vulnerability to the surrounding interferences	No	No	Yes [61]	No
Uroflow curve pattern recognition	No	No	Yes [60]	Yes
AI[b] algorithm or model	No	No	Yes [60,61]	Yes
Contact-free (no need for installation or cleaning)	No	No	Yes	Yes

[a]FDA: Food and Drug Administration.

[b]AI: artificial intelligence.

In terms of accuracy, all technologies yield results comparable to office uroflowmetry, with some even receiving Food and Drug Administration approval. However, sound-based technologies are sensitive to environmental interferences like noise or barriers due to their measuring mechanism. For accurate recording, the urine stream must be voided into a water-filled commode rather than a urinal [54]. Additionally, the sound of voiding varies between men and women, likely due to anatomical and postural differences during urination. Men, who typically urinate standing up, produce louder sounds, as there are no barriers to dampen the sound. In contrast, women, who usually urinate sitting down, produce quieter sounds, and the sitting position can block sound transmission. To address these issues, different models have been developed for both genders [61].

Vibration-based technology offers a potential solution by reducing the barriers to sound transmission. Vibration is transmitted more directly than sound, which travels through the air, while vibration is conveyed through the concrete toilet bowl or urinal to the sensor. Consequently, sound-based technologies are more vulnerable to surrounding noise compared to vibration-based ones [56].

After reviewing the literature, it is evident that only sound- and vibration-based technologies have used AI models or algorithms for uroflow curve pattern recognition [42,60,61]. These 2 technologies are advantageous for intuitive and contact-free measurements, as they do not require installation or cleaning for each use. The calibration of any device is crucial and must be verified during the approval process. It should be ensured that all home devices receive approval from health authorities before clinical application. Additionally, with repeated measurements using home devices, the current reference ranges for clinical urodynamic studies may be revised accordingly. However, such revisions should be undertaken only after sufficient evidence has been accumulated. These home devices not only enhance accessibility for patients and physicians in assessing voiding patterns, but they also improve the diagnosis and treatment process by collecting more comprehensive information. The use of home devices is anticipated to transform the management of LUTS.

Conclusions

Uroflowmetry and BD are key diagnostic tools for LUTS, despite facing limitations such as the absence of a comfortable environment and infrequent measurements for uroflowmetry as well as the lack of automation, objective recording, and repeated measurement for BD. Technological advancements have addressed some of these limitations.

In our opinion, the following points can be highlighted: (1) the emerging trend of using home devices can enhance diagnostic capabilities through repeated measurements and the convenience of at-home testing and (2) home devices, which provide both frequency-volume and uroflowmetry information, have the potential to transform the management of LUTS.

Acknowledgments

Microsoft Copilot was used for assisting wording and grammar polishing in the manuscript. The study received funding from Taipei Tzu-Chi Hospital, Buddhist Tzu-Chi Medical Foundation (TCRD-TPE-113-66).

Authors' Contributions

VFST, YHP, and YTT were responsible for the conceptualization of the study. YCT, SSDY, and YTT provided the necessary resources and supervised the project. VFST and YCT conducted the validation. VFST and MWL wrote the original draft. YCT, SSDY, YHP, YTT, and VFST reviewed and edited the manuscript.

Abstract

Large language models (LLMs) are artificial intelligence tools that have the prospect of profoundly changing how we practice all aspects of medicine. Considering the incredible potential of LLMs in medicine and the interest of many health care stakeholders for implementation into routine practice, it is therefore essential that clinicians be aware of the basic risks associated with the use of these models. Namely, a significant risk associated with the use of LLMs is their potential to create hallucinations. Hallucinations (false information) generated by LLMs arise from a multitude of causes, including both factors related to the training dataset as well as their auto-regressive nature. The implications for clinical practice range from the generation of inaccurate diagnostic and therapeutic information to the reinforcement of flawed diagnostic reasoning pathways, as well as a lack of reliability if not used properly. To reduce this risk, we developed a general technical framework for approaching LLMs in general clinical practice, as well as for implementation on a larger institutional scale.

KEYWORDS

medical informatics; large language model; clinical informatics; decision-making; computer assisted; decision support techniques; decision support; decision; AI; artificial intelligence; artificial intelligence tool; LLM; electronic data system; hallucinations; false information; technical framework

Introduction to Large Language Models

The development of artificial intelligence (AI) solutions and their recent democratization have allowed the public to access various innovative tools. Notably, several large language models (LLMs) have recently surged in popularity due to significant media attention and by offering free access for registered users (eg, ChatGPT, Gemini, and Meta LLaMA).

An LLM is a type of deep learning model that is pretrained on large text datasets. They are often based on the transformer architecture [1], an innovative form of neural network that uses an encoder-decoder structure to rapidly process large blocks of text, avoiding redundancies that hampered recurrent neural networks in the past. Several popular LLMs have integrated a chatbot interface to allow users to interact directly with the model, generating appropriate, context-aware responses to a user's input in a conversational manner. This allows the user to engage in dynamic conversations that appear natural, making the technology a powerful tool for various applications across a wide range of fields.

The use of LLMs has become widespread, and medicine is no exception. LLMs have the potential of becoming a disruptive tool in medicine [2] and will certainly have a major impact on clinical practice, medical education, and research. Within this field, LLM performance has already been evaluated to take specialist board exams [3], improve communication with patients [4,5], and write drafts for scientific papers. It can also be an interesting tool for creating a dynamic learning experience [6]. Although LLMs with chatbot interfaces represent an interesting tool for many tasks in clinical medicine and research, users should be aware of one of the most significant shortcomings of these models, called "hallucinations."

XSL•FO
RenderX

In this viewpoint, we review the underlying causes of hallucinations in LLMs and examine their implications within the field of clinical medicine. We also explore current and future strategies for mitigating these limitations and present a general framework to guide clinicians in critically assessing and integrating LLMs into clinical practice.

Overview of Hallucinations

In medicine, hallucinations refer to sensory experiences that occur in the absence of corresponding external stimuli. In the field of LLMs, hallucinations refer to the generation of false or fabricated information. This signifies that the LLM will create nonfactual content to answer a user's question without clarifying whether the answer contains fabricated information. Hallucinations stem from many root causes, which we will delve into below.

First, both the quality and volume of the dataset upon which the LLM has been trained are important variables and can explain the number of hallucinations the LLM produces to some degree [7,8]. How data are collected and how the model is trained can also influence hallucination frequency [8]. Furthermore, the method through which the editor fine-tunes the model can also influence the final output.

Another major cause of hallucinations stems from the very way certain LLMs are programmed. Indeed, most LLMs are auto-regressive; the term "auto-regressive" refers to the model's ability to predict future elements of a sequence based on its previous outputs. These elements, usually one or multiple words, are termed tokens. An auto-regressive LLM aims to produce an output based on token prediction; this signifies that the model will predict the most probable next token(s) given a specific input token. In practice, it predicts the following word(s) after the sequence of words it has already given. However, it generates each next token by considering the previous one, and not the whole sequence. This means words are generated in a word-after-word fashion, without necessarily using the whole of the previously generated sentence to predict the rest of the sentence [9]. This lays the groundwork for producing hallucinations since factual accuracy is not the end goal. Rather, accuracy is inferred from a high probability of adequate token prediction based on the data in the training dataset. Since the dataset is necessarily flawed or incomplete, hallucinations can arise.

The size of the training dataset can also influence hallucination type and degree. It has been demonstrated on multiple LLMs that the larger the training dataset size, the more likely the model will be capable of recognizing its limitations and acknowledging uncertainty [10]. Furthermore, choices made by the editor will also influence output quality (ie, fine-tuning decisions, output ranking, censorship, etc).

User input is also of great importance in determining the quality of the model output. Indeed, it has been shown that user input through contextualization and inclusion of source material can also modify the number of hallucinations an LLM produces [11].

Implications for Clinical Medicine

LLMs have many potential benefits in the health care system, for both providers and patients. For simple tasks, it is highly likely that part or all of the process will be carried out with LLM tools in the foreseeable future. Efficiency will likely be improved by reducing redundant and tedious tasks (most likely administrative before clinical) [12-14], and there may even be applications for reducing diagnostic delay for difficult diagnoses [15]. Nonetheless, despite these potential benefits, hallucinations represent a major risk if unaccounted for when using LLMs [16-18]. Below, we will review some situations that have appeared apparent to us when testing LLMs.

In practice, LLMs may erroneously attribute clinical, biological, or radiological characteristics to certain diseases or conditions, depending on the way the clinician inputs data as well as the probabilistic behavior of the model. This flaw, in combination with anchoring and confirmation bias, may unknowingly lead the clinician down an erroneous diagnostic or therapeutic pathway. This can have severe consequences for the patient's health.

LLMs may also make false claims about diagnostic accuracy for diagnostic procedures. This can lead the clinician to either overestimate or underestimate the diagnostic capacity of a procedure. The consequences could be either depriving a patient of a reliable diagnostic method or, on the contrary, relying on an inadequate diagnostic method to make a statement about the disease process. More specifically in the latter case, the absence of a disease process may be wrongly inferred based on an insensitive exam, and the presence of a disease process may be improperly inferred from a nonspecific exam.

Furthermore, the LLM may suggest inadequate workups and therapeutic procedures. It is important to remember that LLMs are trained on databases that may either not encompass the data necessary to provide adequate guidance (ie, absence of medical guidelines) or contain outdated medical recommendations. Further, given the crucial importance of input data supplied by the user, the omission of a simple characteristic may cause the LLM to produce an inadequate plan of care. Moreover, the LLM may not necessarily prompt the user for additional information regarding important characteristics that could influence the plan of care; most notably, social characteristics and cultural preferences may be inadequately accounted for. Specific diagnostic or therapeutic measures proposed by the LLM may be inadequate or inappropriate, based on important parameters such as pretest probability, as well as patient preferences and prognosis. In addition, given the diversity of health care system models in countries around the world, the inherent bias introduced by the LLM's dataset can lead to recommending inadequate plans of care for a different health care model than that which the dataset contains information on.

Consistency, and thus reliability, is another issue that can appear while using LLMs to make recommendations for plans of care. Indeed, even with a consistently identical user query, the information contained within the LLMs response may vary considerably when the user renews the query. This variability is an important consideration when the clinician is contemplating

XSL•FO
RenderX

the possibility of integrating LLMs into the patient care process. Indeed, it is well accepted in the health care quality community that reducing variability to a certain degree is an essential step in increasing quality [19]; this is even more so true when some parts of the information provided by the LLM are at risk of being inadequate.

In addition, the use of LLMs in clinical practice raises a significant number of ethical concerns, which we only slightly touch upon in this viewpoint. Questions regarding overreliance on LLMs and other AI tools, as well as the legal and ethical ramifications of decision-making based upon AI input, are crucial. In the era of evidence-based medicine, LLM source material and information traceability will be essential in order to reliably inform patient care decisions. The value of the clinician's experience in nuancing the LLM's outputs will also remain critical in delivering personalized patient care.

To build upon the legal and ethical concerns related to these LLMs, it is important to keep in mind that many LLMs are developed by private companies and are not open source. Data management, especially related to patient privacy rights, is an essential concern related to information input into the LLM. Implementation of LLM components in electronic medical record programs is being considered and poses the same risks. Notably, the question stands on the use of personal data to for-profit ends (targeted advertising or selling health care data to insurance companies). Local institutional governance and national regulations will be essential in managing and mitigating these potential risks.

Finally, LLM use also carries considerable potential to alter the patient-clinician relationship. Patients may increasingly discuss their symptoms and conditions with LLMs before seeing a medical professional, in a similar way that some patients use search engines before consulting a physician today. This poses the risk of fostering misguided self-diagnoses, with potentially harmful health consequences, especially in settings where access to health care can be financially challenging. Furthermore, patients might develop unrealistic expectations or demand unnecessary clinical resources, based on the information the LLM has provided. As a result, this could affect the dynamics of the patient-clinician relationship. On the other hand, LLMs possess the capacity to tailor medical information to the patient's level of comprehension, which may help enhance therapeutic education and adherence to medical advice.

Mitigating Hallucinations in Clinical Practice

Hallucinations can therefore represent a significant source of error if unaccounted for when using LLMs. A proactive and systematic approach is necessary to help interpret LLM output data and avoid succumbing to avoidable pitfalls that could cause harm to patients. This approach is summarized in Textbox 1.

Textbox 1. Important technical considerations before integrating large language models (LLMs) into clinical practice.

- What dataset was the LLM trained upon?
  - What specific considerations does this entail, with regard to bias?
  - Is the dataset up to date?
- What organization is behind the LLM and the dataset?
- Is the LLM specifically tailored for medical purposes?
- In testing rounds:
  - Is the information given by the LLM consistent with the existing knowledge on the subject?
  - Are the recommendations made by the LLM adequate compared to the accepted standard of care?
- How much variability exists within the LLM's responses? Can it be clinically significant for patient care?
- Enhanced capacity:
  - Does the model possess the capacity to integrate up-to-date information?
  - Does the model possess the capacity to search within reliable sources of information to better respond to the user's request? If the answer to one of the two above questions is yes, is this feature integrated within the LLM or is it operated by a third-party plug-in?
    - If a third-party plug-in is involved, what strengths and shortcomings does it entail?
  - Does the LLM possess the capacity to assess its answers' reliability?
  - Is the LLM capable of providing the links to its sources of information?
- Do best practice guidelines exist for the utilization of the LLM?
  - If so, are they specific to use in the health care sector?
  - If the guidelines are general use or specifically focused on another industry sector, what precautions must be applied before extrapolating their use to the health care sector?
- Has the model been tested in a rigorous fashion, and are the results of this evaluation subject to scientific publication?

XSL•FO
RenderX

First and foremost, understanding the model's origins, version, training database content, and strengths as well as drawbacks are essential prerequisites for an informed use of the LLM. With this information, the user should actively seek out what types of bias the model may contain and understand how it can affect the LLM's answers [2]. Furthermore, information on the training dataset should be sought out to understand how up-to-date the knowledge within it is, as well as if it is well equipped to answer medical inquiries. In this regard, a topic of emerging importance is the development of LLMs specifically trained for medical purposes. Although theoretically more performant than general LLMs, their relevance for clinical practice has not yet been evaluated.

Second, user input should be carefully crafted to create a high-quality request. The request should contain a detailed description of the clinical context; this requires carrying out a thorough history, clinical exam, and incorporating current as well as historical workup data. Clinical acumen thus remains essential in creating an adequate request. Therefore, although initially time-consuming, a higher-quality request can yield a more relevant answer.

Third, model accuracy and hallucination prevalence should be assessed before being put into practice, through iterative testing and evaluation. During testing rounds, LLM accuracy should be examined using standardized scenarios. Consistency, as well as variability in the answers, should be evaluated by regenerating the LLM's responses multiple times. Whether through formal, statistical evaluation or through getting a general sense of the model's characteristics, the clinician can evaluate the LLM's capabilities and shortcomings in this manner. Furthermore, the scientific adequacy of the LLM's responses should be assessed with regard to current standards of care and up-to-date guidelines. Even without knowing the database's knowledge cutoff, this method can help assess how up-to-date the data are, as well as understand how often hallucinations arise with regard to a specific subject.

Another useful tool that can help the clinician assess the reliability of the LLM's responses is plug-ins. These are usually third-party apps that can be programmed to serve a wide range of functions, including but not limited to, searching the internet, retrieving information from scientific databases, and substantiating responses with links to the sources of the presented information. LLMs may also possess certain of these capacities directly within the scope of their own functions. Although plug-ins may significantly enhance the reliability of the LLM's responses, by providing the ability for up-to-date referencing, they are not a guarantee that the response will be free from hallucinations. Therefore, plug-ins should be evaluated with the same amount of scrutiny as the LLM itself.

Finally, combining text, image, and video data in LLM training databases can lead to more accurate responses and may decrease the likelihood of hallucinations [20]. However, it is also important to remember that the multimodal model's performances still rely on the quality of their training dataset [21].

A crucial aspect in the deployment and judicious implementation of LLMs in a clinical setting lies in the establishment of a proactive error reporting program. In conjunction with the aforementioned recommendations, the implementation of such a program facilitates the identification and reporting of near-miss incidents. At the individual level, this allows the user to develop a personal appreciation of the model's shortcomings, as well as the topics subject to hallucinations. On an institutional level, it can help develop best practice guidelines by identifying frequent hallucination presentations and more general errors. If LLM solutions are delivered as an on-premises solution, it is conceivable that error reporting will help fine-tune local models.

Prospects

Research in AI will largely contribute to reducing hallucinations, be it through fine-tuning of the underlying model, prompt engineering techniques, development of specific medical LLMs, or other innovative approaches.

Given the increasing awareness of hallucinations, and understanding the risk they potentially pose to patient safety, ingenious mitigation strategies have recently developed. Measurement of semantic entropy [22], algorithmic approaches to address root causes of hallucinations [23], and more classical methods such as Retrieval-Augmented Generation [24] are some of the many techniques that have been proposed to identify and reduce hallucinations. Ideally, an automated combination of different strategies may help both accurately identify and reduce the occurrence of hallucinations. This would help ensure LLM response accuracy and reliability.

To remain up-to-date with these rapid and substantial developments in technology, many approaches will be required to ensure clinicians stay current and use these tools to the best of their capacity. Specific health care–related research will be required to evaluate the full extent of individual LLM capacities and performance. Furthermore, in the same way clinicians require continuing education in emerging and evolving health care topics, frequent training will be essential to use LLM-related tools adequately. Particular attention should be directed towards recognizing and mitigating the numerous pitfalls associated with their use. To this end, we have identified significant practical limitations of LLMs that may limit their rapid uptake into daily clinical practice (Textbox 2).

XSL•FO
RenderX

Textbox 2. Factors currently limiting the widespread implementation of large language models (LLMs) in clinical settings.

Model related

- Risk of bias related to:
  - The quality and quantity of the data used to train the model
  - How the model was trained and especially fine-tuned
  - How the LLM reacts to different methods of prompting
- Difficulty of complex models to explicit the reasoning behind their responses
  - Hallucination risk, without the capacity to inform the user on the final output's trustworthiness: information related to the source of the information not necessarily provided
  - No assessment of source reliability

Human related

- Risk of misuse related to:
  - Idealization of LLM capacities, and considering them to be completely foolproof, may lead to expert bias
  - Biased user input and uncritical approval of LLM output, aligning with the user's anticipated answer, can result in confirmation bias
  - Increased dependency on automated aids without critical thinking and reassessment, can lead to automation bias
- Absence of a strong legal framework defining the scope and regulatory environment of LLMs, as of date
- Lack of institutional governance defining the following:
  - Methods of informing patients and obtaining their consent for use of LLMs in their health care pathway
  - Integration of LLM use within a legal framework
  - Accountability in case of an error resulting from the use of the LLM
  - Methods of initial testing, implementation, and continuous improvement of the selected LLM
  - General operating conditions, namely:
    - Defining specific tasks for which the LLM should be used
    - Ensuring a human has the final word in the decision-making process, even though it is assisted by the LLM
  - Training procedures and certifications required for health care professionals to use the tool
  - Implementation format (on-premises vs outsourced)
  - Quality control processes
  - Traceability of feedback and changes in LLM implementation
  - Ethical framework

Economically related

- Cost of the initial investment
- Cost related to maintenance in an "on-premises" format, including:
  - Employee wages
  - Infrastructure costs
  - Energy costs
- Concerns regarding sustainability, given the high energy consumption of servers used to power and train current LLM models

As previously mentioned, future iterations of LLMs could also be specifically trained on medical datasets and fine-tuned by expert clinician input. This could be an effective method of reducing hallucinations and would allow the tailoring of LLMs to specific fields of medicine.

Conclusions

Due to its vast potential, LLM integration into routine clinical practice is no longer a question of if, but when. As technology advances, the integration of LLMs with other AI tools

XSL•FO
RenderX

possessing multimodal analysis capabilities (text, audio, and image) will follow suit. These advances offer significant opportunities in terms of patient care. However, robust legal frameworks will be necessary to guide their use on a national scale, and institutional governance is key to their implementation for everyday use. Indeed, an informed approach to using these tools, as well as significant efforts in terms of capacity-building, are primordial to avoid falling victim to their well-identified shortcomings.

Abstract

Physicians could improve the efficiency of the health care system if a reliable resource were available to aid them in better understanding, selecting, and interpreting the diagnostic laboratory tests. It has been well established and widely recognized that (1) laboratory testing provides 70%-85% of the objective data that physicians use in the diagnosis and treatment of their patients; (2) orders for laboratory tests in the United States have increased, with an estimated volume of 4-5 billion tests per year; (3) there is a lack of user-friendly tools to guide physicians in their test selection and ordering; and (4) laboratory test overutilization and underutilization continue to represent a pervasive source of inefficiency in the health care system. These inappropriate test orders not only lead to slower or incorrect diagnoses for patients but also add a significant financial burden. In addition, many ordered tests are not reimbursed by Medicare because they are inappropriate for the medical condition or were ordered with the incorrect International Statistical Classification of Diseases and Related Health Problems, Tenth Revision diagnostic code, not meeting the medical necessity. Therefore, current clinical laboratory test ordering procedures experience a quality gap. Often, providers do not have access to an appropriate tool that uses evidence-based guidelines or algorithms to ensure that tests are not duplicated, overused, or underused. This viewpoint lays out the potential use of an automated laboratory clinical decision support system that helps providers order the right test for the right disease and documents the right reason or medical necessity to pay for the testing.

Introduction

Laboratory testing plays a key role in clinical decision-making and physician orders for laboratory tests are increasing [1,2]. It is estimated that at least 20% of the 4-5 billion lab orders submitted annually in the United States are inappropriate. Studies have shown that overutilization and underutilization of laboratory tests occur 20.6% and 44.8% of the time, respectively [3]. This inappropriate testing not only leads to incorrect or delayed diagnoses but also significantly adds a financial burden on the health care system. This situation is expected to worsen as the available lab tests menu grows, especially in the areas of molecular diagnostics and genetic testing. Due to a lack of physician test information, education, and insurance coverage questions, ordering less effective and sometimes obsolete tests over newer tests that are more sensitive and specific remains a major problem [4]. This inappropriate testing not only led to incorrect or delayed diagnoses but also significantly added financial burden. The situation is expected to get worse as the number of lab tests is growing, especially in molecular diagnostics and genetic testing. The introduction of an automated

XSL•FO
RenderX

clinical decision support system (CDSS) that guides physicians to order the most appropriate test(s) for their patients while simultaneously providing both medical necessity requirements and applicable diagnostic codes will be a vital tool to improve test ordering and reimbursement efficiency.

Medicare and commercial health-care plans all require that ordered tests are accompanied by appropriate *International Statistical Classification of Diseases and Related Health Problems, Tenth Revision* (*ICD-10*) diagnostic codes that meet medical necessity rules. These requirements make it a complex process for providers to decide which tests to order, provide diagnostic information, and obtain previous authorization if required, so that test bills and payments are efficient and timely [5,6]. Given the rapidly growing demand for tests, especially molecular and genetic testing, the lack of a reliable laboratory CDSS will compound this already complex process.

When physicians fail to select and order the most appropriate test(s) based on the patient's health condition and further fail to provide the proper diagnostic codes to support medical necessity, laboratory billing will most certainly fail. The patient may then be held responsible for the laboratory charges and the laboratory will be caught in the middle of disagreements between the insurance company, the treating physician, and the patient in determining the responsible party for the laboratory charges. Ideally, every test ordered and procedure performed by the lab should be paid or reimbursed by health insurance. However, many ordered tests are not reimbursed, primarily due to a lack of medical necessity. This issue arises from ordering the wrong test that does not meet medical necessity criteria or failing to provide the correct diagnostic code for the disease or health condition. Therefore, the current clinical laboratory test-ordering procedures suffer from a quality gap and require an automated system to address this issue.

This viewpoint discusses the use of an automated laboratory CDSS that helps providers order the right test for the right disease and documents the right reason or medical necessity to pay for the testing.

Inappropriate Test Ordering

Inappropriate testing encompasses both overutilization and underutilization, both of which can affect quality patient care and health care expenditures. Overutilization includes tests that are ordered but not indicated, tests that are ordered at the incorrect time in the clinical course, or tests that are ordered too frequently. Conversely, underutilization refers to tests that are indicated but not ordered, or those that are not ordered at the appropriate time to positively impact patient care [2,5]. Both can have an adverse impact on the quality of patient care and health care costs because of downstream consequences such as additional diagnostic testing, repeat testing, imaging, prescriptions, surgeries, or prolonged hospital stays. It is estimated that more than three hundred million patients visit the laboratory annually and that at least 23 million of these patients are affected by inappropriate test ordering and test interpretation. The reports on the Commonwealth Fund Survey of Public Views of the US Health Care System (2012) found that more than 23% of laboratory tests ordered by physicians were duplicated or repeated, which increases the cost of care by further delaying or confusing the patient's diagnosis and care. It is also reported that overutilization and underutilization of laboratory tests occurred 20.6% and 44.8% of the time, respectively [2].

In 2011, a survey conducted by the Centers for Disease Control and Prevention among primary care physicians found that 14.7% had uncertainty in selecting and ordering the correct test and 8.3% had difficulty interpreting tests [7]. Physicians' lack of access to information about the availability of specific tests, the limitations of tests, and insurance coverage might play a major role in the underutilization of tests, whereas medical malpractice, selecting obsolete testing, and use of certain aspects of computerized provider order entry are documented factors leading to overutilization [3,4].

Economic Impact of Test Misutilization

Expenditures for health care in the US were approximately $4.1 trillion in 2020, which is an increase of 9.7% from 2019, and it accounts for 19.7% of the total gross domestic product. If the trends continue, health care costs are projected to increase to $6.2 trillion by 2028 [7]. Hospital and clinical service expenditure also showed rapid growth in 2020 and accounted for approximately $2.08 trillion of the total cost of health care. Although laboratory testing accounts for only a fraction of health care expenditures, 94% of objective and structured data in the electronic medical record (EMR) are obtained from a clinical laboratory [8]. Moreover, it is estimated that 60%-70% of all clinical decisions are based on the results of laboratory testing [9,10]. Considering 60% as the rate of influence on the clinical decision, it can be estimated that $1.2 trillion of health care spending is influenced by laboratory testing. Therefore, inappropriate testing not only leads to incorrect or delayed diagnoses but also significantly adds financial burden. 4-5 billion tests are performed annually in the United States. Unfortunately, it is estimated that at least 20% of the lab orders submitted are inappropriate [2]. The situation is expected to get worse as the number of esoteric lab tests is growing, especially in the areas of molecular diagnostics and genetic testing.

Ideally, every test performed by the laboratory should be reimbursed. However, many billed tests are not reimbursed due to a lack of documentation ensuring medical necessity. In many cases, the denial of the reimbursement is due to the submission of improper diagnostic code(s) for the disease or health problem being tested for. Therefore, current clinical laboratory test ordering procedures experience an information gap and there is an urgent need for an automated system to improve test utilization for economic sustainability in health care.

Need for Clinical Decision Support System in Clinical Laboratory

Selecting and obtaining authorization for appropriate medical tests is an ongoing and growing challenge in many specialties, including radiology, cardiology, pulmonology, and pharmacology. With typical radiology and diagnostic imaging costs higher than those for laboratory testing, the US government

XSL•FO
RenderX

has prioritized approval of a reimbursement reward system for insurance providers that use a CDSS to improve imaging utilization. For example, there is a 2015 “Advanced Imaging Bill” which mandates that government-approved imaging services will only be reimbursed if the insurance claim confirms that appropriate-use criteria were consulted or a CDSS was used. The bill also recommends the use of CDSS for other diagnostic test ordering, if available [5,11,12].

CDSS is currently also available in cardiology, medication management, oncology, and urology. These broad and growing applications along with expansive and expensive specialized lab testing strongly indicate that there is a substantial need for an expert laboratory CDSS to aid health care providers, care managers, and payers in selecting, ordering, and approving laboratory tests and reducing inappropriate testing.

Currently, there are some partially developed and semimanual lab CDSSs that help physicians order laboratory tests; however, these approaches are provider-driven and require inconvenient interactive user questions to access the information needed [10]. Unlike radiology CDSSs, these systems do not provide any scoring system for tests based on medical evidence, clinical relevancy, or medical necessity. Incorporating a scoring system based on test indications and providing information on supportive diagnostic codes can help automate the laboratory test ordering process and has positive impacts on test utilization, medical necessity documentation, claim verification, and payment processing. These developments strongly indicate that there is also a substantial need for a laboratory CDSS to help health care providers in selecting and ordering the appropriate laboratory tests, reduce inappropriate testing, aid providers in easier and more automated payment processing, and finally get better and on-time health care to patients [4,5,13,14].

Solution to This Problem

A potential solution is to develop a laboratory CDSS that will aid providers in selecting and ordering the right diagnostic tests with which to manage patient health care. The CDSS will help laboratories process the order, process the sample, and report accurate results on-time delivery to the ordering provider. The CDSS will provide information regarding the appropriate diagnostic *ICD-10* code(s) to meet the medical necessity. The CDSS will also provide a medical evidence-based scoring system based on clinical utility. A CDSS that provides the testing indication(s) to complement the provider’s notes and is electronically interfaced with EMRs, electronic hospital records, and billing systems to automate processes like medication management and radiology CDSS is desirable [4,5,14].

Laboratory Decision System (LDS), developed by Medical Database Inc, is one of the available automated CDSS. LDS is an algorithm-based test selection and ordering database for physicians, health care providers, insurance and managed care companies, and billing services. LDS is expertly developed to help system users understand, select, order, and use laboratory tests for disease diagnosis and management using evidence-based guidelines and industry best practices. The system uses our proprietary scoring system developed by our editorial board (60 pathologists and PhDs), designed to rank testing recommendations based on disease, clinical relevance, medical necessity, and testing indication. Each time an order is placed via the LDS platform, it automatically includes the appropriate diagnostic *ICD-10* code and Local Coverage Determinations (LCD) or National Coverage Determinations (NCD) to meet medical necessity for reimbursement. Included in the robust database are all commercially available tests (over 2300 diagnostic tests), including genetic and proprietary tests [5].

The LDS rates and scores potential tests for any given disease and assigns an easily interpretable numerical and color-coded score based on clinical relevance, medical necessity, and testing indication. Tests with scores of 5 or above (10 being the highest score) meet medical necessity, while those with scores of 4 or less do not. LDS also follows Medicare’s medical necessity guidelines by using testing indications such as “initial testing indication” to allow providers to better characterize the patient’s disorder based on initial test results before ordering overly complex and expensive tests. Appropriate tests use indication labels, for example, diagnostic, disease management, monitoring, and alternative tests, categorizing each test with the right indication or reason for testing to avoid using providers’ charts and notes that make it difficult to automate the system [4,5]. When assessing the effectiveness of LDS in improving test utilization and reimbursement with 96,170 laboratory requests comprising 374,423 test orders from a reference laboratory, 44,671 tests were accompanied by *ICD-10* that are described by Medicare as “never covered” because of the lack of a system to check or support the medical necessity of each order. A total of 160,449 tests were subject to a Medicare policy review from which 112,400 tests met coverage criteria, and 48,049 tests did not. These orders were then reevaluated using LDS. Of the original test order sample, 91.5% had an associated LDS score. Of these scored tests, 47.8% met coverage and 43.73% failed to meet coverage, according to the LDS Ranking System. Importantly, LDS provided recommendations for alternative diagnostic *ICD-10* codes or tests which could have aided physicians in choosing a more appropriate test or submitting a different *ICD-10* diagnostic code to meet medical necessity. Around 96.4% have an alternative *ICD-10* code or a test score above 5, meeting medical necessity. The LDS system recommended 80.5% which would meet Medicare policies, demonstrating that the LDS system would correct inappropriate orders if used as a testing utilization management system [5]. However, more systemic testing of the platform is needed to evaluate the effectiveness of test utilization, medical necessity verification, and payment processing.

Since the LDS platform has been built to interface with EMRs, electronic hospital records, and laboratory information systems (LIS), the content can be accessed directly through these systems, allowing orders to be sent directly to laboratories for testing coordination. Accordingly, when using the LDS platform, every test ordered will automatically include a medical necessity score, the correct testing indication, and the appropriate *ICD-10* and CPT codes, all of which also support adjudication for bill payment. An outline of the use of computerized provider order entry of LDS is elucidated in Figure 1. In addition, each test

XSL•FO
RenderX

ordered through the LDS platform will provide testing indications to support the purpose of the testing, thereby reducing manual submission of "medical necessity" review data, including reasons for test ordering (scripts, notes, charts, etc) and adding system automation with lower costs, faster throughput, and higher performance [4,15].

Figure 1. Test ordering using LDS automates the selection of appropriate tests based on clinical relevance and integrates the International Statistical Classification of Diseases and Related Health Problems, Tenth Revision and LCD codes to facilitate reimbursement. LCD: Local Coverage Determinations; LOINC: Logical Observation Identifiers Names and Codes; NCD: National Coverage Determinations.

XSL•FO
RenderX

Conclusion

In conclusion, there is a clear and immediate need for an LDS system similar to that which is used in radiology and medication management, which can aid providers in selecting the right test for each disease or condition while assigning the correct *ICD-10* code, right Local Coverage Determinations and National Coverage Determinations to meet the medical necessity and right testing indication covering the reason and use of ordered test(s). The available LDS system developed by Medical Database, described in this viewpoint study may assist providers in making appropriate utilization decisions while also supporting laboratories in reimbursement and streamlining claim verification for payers, all of which combined will potentially make the laboratory industry and overall health care more efficient and cost-effective.

Abstract

In this viewpoint, we argue that recent studies using clinical public databases have revolutionized our understanding of hidradenitis suppurativa (HS), a chronic inflammatory skin condition with significant impacts on patients' quality of life. Our key messages are as follows: (1) these databases enable large-scale studies integrating genetic, epidemiological, and clinical data, providing crucial insights into HS's genetic predispositions, comorbidities, and treatment outcomes; (2) findings highlight a strong genetic component, with mutations in the γ-secretase complex playing a key role in HS pathogenesis and shaping targeted therapies; (3) studies also reveal elevated risks for comorbidities like obesity, diabetes, cardiovascular disease, and systemic inflammation in patients with HS, with diet-driven inflammatory pathways potentially exacerbating disease severity; (4) while these databases offer unprecedented research opportunities, limitations such as data representativeness and quality must be considered; (5) nonetheless, their benefits outweigh potential drawbacks, allowing the identification of rare comorbidities, disease progression patterns, and personalized treatment strategies; and (6) increased funding for HS research is crucial to harness these databases' full potential, develop targeted therapies, and ultimately improve patient outcomes. As HS's impact is disproportionate to current research investments, we believe advocating for more resources and addressing database limitations will be key to advancing HS understanding and care.

hidradenitis suppurativa; clinical public databases; disease progression; patient data; HS

Hidradenitis suppurativa (HS) is a debilitating chronic inflammatory skin condition that significantly impacts patients' quality of life. Despite its profound effects, the pathogenesis of HS remains poorly understood [1]. In this viewpoint, we aim to highlight how recent advancements in clinical public databases have provided researchers with a powerful tool to explore the genetic, epidemiological, and clinical aspects of HS (Table 1). We argue that these databases have enabled large-scale studies integrating diverse patient data, yielding crucial insights into the disease's genetic predispositions, comorbidities, and treatment outcomes [2].

One of our key messages is that studies using clinical public databases have revealed a strong genetic component in HS. By analyzing data from diverse populations, researchers have identified genetic factors, such as mutations in the γ-secretase complex, that predispose certain individuals to develop HS [3,11]. We believe these genetic insights are not only expanding our understanding of HS pathogenesis but also shaping the development of targeted therapies [11]. Furthermore, we emphasize that clinical databases have shed light on the complex relationship between HS and various comorbidities. Studies have shown that patients with HS have a significantly higher risk of developing obesity, diabetes, cardiovascular disease, and even gout [4,6,12,13]. Notably, diet-driven inflammatory pathways, particularly those involving interleukin-17 and interleukin-1β, have been implicated in exacerbating HS severity [12]. The interplay between obesity, immune checkpoint inhibitors, and psoriasiform eruptions in HS further highlights the role of shared inflammatory pathways in disease exacerbation [13]. These findings underscore our view that a holistic approach to managing HS is needed, addressing both the dermatological and broader health risks faced by patients.

While we believe the insights gained from clinical public databases are invaluable, it is essential to consider potential limitations and counterarguments. One concern is the representativeness of the data within these databases. We argue that ensuring diverse and inclusive patient populations is crucial to avoid bias and generate findings applicable to the broader HS community [7]. Additionally, the quality and consistency of data entry across different health care settings may vary, potentially impacting the reliability of the results [5]. Furthermore, biases may exist in terms of the ethnic and geographic diversity of the data, which may skew the results for certain populations. We believe expanding the scope of these databases to include more diverse patient groups will be essential to ensure that the findings are broadly applicable and not limited by sample biases.

Despite these challenges, it is our view that the benefits of using clinical public databases in HS research far outweigh the limitations. These databases provide access to large, diverse patient populations and enable the identification of rare comorbidities and treatment outcomes that may not be apparent in smaller clinical settings. Moreover, longitudinal data captured in these databases allow researchers to study disease progression and identify early diagnostic markers, paving the way for timely interventions and personalized treatment plans [8]. We argue that researchers should focus on making improvements to database infrastructure, such as ensuring data consistency and addressing gaps in representation, to maximize their utility for future studies.

As we continue to harness the power of clinical public databases, we believe it is crucial to prioritize HS research and allocate adequate funding. The Global Burden of Disease study has

XSL•FO
RenderX

highlighted the significant impact of HS on patients' lives, yet research funding for HS remains disproportionately low compared to other skin diseases [9,10]. We argue that increased investment in HS research will accelerate the development of targeted therapies and improve patient outcomes. Public health initiatives aimed at increasing awareness of HS and its comorbidities, along with funding to support further research, will be vital to driving innovation and improving patient care.

In conclusion, it is our view that clinical public databases have revolutionized HS research by providing unprecedented access to large-scale, diverse patient data. The insights gained from these databases have deepened our understanding of the genetic susceptibility, comorbidities, and treatment outcomes associated with HS. As we move forward, we believe it is essential to address the limitations of these databases, ensure inclusive patient representation, and advocate for increased funding for HS research. By harnessing the full potential of clinical public databases, we can unlock new avenues for personalized medicine and ultimately improve the lives of individuals affected by this challenging condition.

Abstract

Internet-based research has exploded in popularity in recent years, enabling researchers to offer both investigations and interventions to broader participant populations than ever before. However, challenges associated with internet-based research have also increased—notably, difficulties verifying participant data and deliberate data manipulation by bot and spam responses. This study presents a viewpoint based on 2 case studies where internet-based research was affected by bot and spam attacks. We aim to share the learnings from these experiences with recommendations for future research practice that may reduce the likelihood or impact of future attacks. The screening and verification processes used are presented and discussed, including the limitations of these. Based on our experience, security and screening within internet-based research platforms are partly effective, but no solution is available to protect researchers completely against bot attacks. Implications for future research and advice for health researchers are discussed.

Introduction

Overview

The internet and digital technologies have irretrievably changed the conduct of research. Whether it be participant engagement, digital intervention delivery, data collection, or distribution of findings, technology has allowed researchers to engage in wider-reaching recruitment. Technology has also enabled people to access and participate in research that may not have been previously possible. In particular, health researchers have embraced internet-based recruitment to invite participation from varied population groups easily and to collect data from large samples.

There has been a significant increase in sample sizes in the last decades, intending to increase statistical power, replicability, and generalizability of research findings [1]. The adoption of open science practices and the emergence of global collaborative efforts, such as the Human Connectome Project [2] and the UK Biobank study [3], including tens of thousands of participants, has facilitated the pooling of resources and increased the overall sample sizes in research studies. However, with the increase in public accessibility of internet-based studies comes a potential increase in poor quality or false participants, ranging from

XSL•FO
RenderX

careless respondents who respond with insufficient effort [4] to malicious responses such as automated attacks in the form of computer-programmed bots [5,6].

Bots can be fully automated to target internet-based research via automated malware or malicious algorithms [7], or they may be "hybrid" where there is an element of human control. An example of a hybrid bot is when the human may complete the initial survey screening questionnaires and then allow an automated bot or algorithm to complete the remainder of the survey. Bot attacks have existed since the early 2000s and are becoming increasingly common. This increase may be linked to the rise of internet-based paid research panels and crowdsource platforms such as Amazon Mechanical Turk, which bots can leverage. Whether the bots are automated malware or human respondents who are completing surveys for financial gain without meeting study inclusion criteria [8], it is irrefutable that caution must be exercised when conducting an internet-based or remote study [9,10].

Bot attacks must be identified as they impact the integrity of datasets [5,11,12], creating a situation where ineffective interventions may appear effective, and conversely, effective interventions may seem ineffective. Similarly, one of the significant risks of undetected bot attacks is the potential to misrepresent populations [5,13] and influence decision-making based on erroneous data. Misrepresentation is particularly problematic for vulnerable [14] and at-risk populations such as Indigenous communities, who are often poorly serviced by many existing interventions [15], or populations where new effective interventions are desperately needed [13,16]. Thus, misrepresentations of bots as members of this population could have dire consequences.

This paper discusses the viewpoints of strategies researchers can use to help reduce the impact of bots on research. Like several recent papers [5,13,17-21], the researchers were impacted by bot attacks on 2 independent projects hosted on different platforms at 2 institutions. We present case studies (CS1 and CS2) of the 2 research projects (see Multimedia Appendix 1) that were affected by bot attacks and demonstrate the impact these would have had on the demographics of the final dataset. We share the steps the research teams took to identify potential bot participants, outline strategies to mitigate the bots' effects and reduce the chances of bot attacks in future projects, and provide recommendations for other researchers.

Ways to Identify Bot Responses

Several signs in both case studies indicated likely bot attacks—both in terms of researcher review of the dataset and the survey metadata and through software flagging functions. We also attempted to develop an algorithm to predict the likelihood of the participant being a bot to help determine authentic participants from bots. These strategies are discussed further.

Researcher Strategies to Identify Bots

In both studies, recruitment appeared far more efficient than expected, particularly as there was no targeted advertising and the recruitment methods used were broad. Both studies had high numbers of participant registrations in a brief period, with registrations frequently being close together (often less than minutes apart).

Second, study participant demographics were disproportionate to the sample pool, and populations often hard to recruit were overrepresented. As this was more subtle than the high number of registrations, this may not have been detected until data analysis was underway if unusual recruitment patterns were not present. Overrepresentation was particularly obvious for CS2, where we had planned to purposefully recruit based on ethnicity and monitored to ensure we were successful in this recruitment but had yet to start targeted recruitment. It is noted that although the proportion remained high in the corrected dataset, this was overinflated due to the small sample size and likely would not have remained proportionally high once higher numbers or participants were recruited.

Third, a review of participant email addresses indicated that most suspected bot attacks had emails that followed similar patterns (eg, a combination of letters and numbers followed by the exact email domains) or were nonsensical. While not all email users choose not to use their name in their emails, and the desire to protect against identity theft means that some people do not have emails that make sense, it was the similarity between the email addresses that highlighted the differences between suspected bots and the participants that we believed to be genuine.

Finally, unusual responses in the internet-based surveys also highlighted potential bot responses. Specifically, random answering for survey questions as evidenced by inconsistent or incongruent responses, a lack of answers to qualitative or text responses, and patterned survey responses indicated likely bots.

Use of Survey Platform Data

In terms of using the functionality of the survey platforms, several additional strategies can be used to determine if a bot attack has occurred. Some survey platforms can flag surveys that are likely bots, so this should be used where possible. Although responses are flagged, researchers still need to review the responses as above to identify atypical patterns of responses. While this requires researchers to review survey responses, the flagging system can potentially reduce the time required to identify bot attacks.

Potential Statistical Prediction to Identify Bots

Overview

For CS2, there were two parts to the study; participants were invited (1) to complete the "research" questionnaire, which consisted of 8 forms, and (2) to use the internet-based intervention component of the study accessed through a second external website using their contact details. By cross-validating the information from the intervention platform with the initial research survey data (N=503), we obtained confirmation of true participants (n=27). However, we could not be sure whether the high number of remaining participants were bots or actual participants who did not continue to the next part of the study, although we assumed they were bots.

XSL•FO
RenderX

Yet this scenario presented us with a unique opportunity to attempt to create a bot detection algorithm to distinguish bots from genuine participants in CS2 better using strategies previously recommended in the literature [18,22]. To achieve this, we assigned suspicion scores on a scale of 0-10 to responses that we evaluated as being potentially anomalous based on the following criteria:

Survey Completion Time

We tracked the completion rates, completion times of individual forms within the survey, and the time difference between the initial and final form completion. A weak bimodal distribution appeared for completion times in CS2, allowing us to apply a higher suspicion score to completion times of less than 5 minutes.

Email Address Analysis

We scrutinized patterns in email addresses, such as random strings of letters and digits, along with unusual domain names, to identify suspicious email patterns typically associated with bots. Higher suspicion scores were applied to unusual email address combinations.

Conflicting Response Analysis

We evaluated responses to specific correlated survey questions to detect inconsistencies that might indicate automated responses. For instance, we sought contradictory answers to 2 questions concerning the frequency of experiencing "not being able to stop or control worrying" and "worrying too much about different things" over the past 2 weeks. Greater negative correlations between paired questions were assigned higher suspicion scores.

To construct the bot detection model, we used the extreme gradient boosting (XGBoost; The XGBoost Contributors) algorithm with a logistic regression base model for binary identification of bots and participants. XGBoost is a scalable tree-boosting system that has shown excellent performance in classification tasks due to its proficiency in managing high-dimensional data and capturing intricate patterns [23,24]. We partitioned the dataset, allocating 80% for model training and 20% for testing model performance. Hyperparameters were fine-tuned through experimentation and cross-validation to attain optimal performance. We used receiver operating characteristic curve results to optimize accuracy, sensitivity, and specificity by adjusting the classification threshold. After optimization, the model achieved an overall accuracy of 0.937, with a sensitivity of 0.967 (reflecting a high rate of bot detection), but a specificity of 0.400 (reflecting a poor rate of actual participant detection), for a classification threshold of 0.25. Hence, the optimized model was heavily biased toward detecting potential bots and unable to identify true participants consistently. The model's balanced accuracy was moderately low at 0.683, reflecting the challenge of simultaneously identifying true positives and true negatives.

Based on this model, the most important features in order of predictive use were the time difference between the first and last form completions within the baseline survey, the time difference between adjacent forms from "unique" participants, the total completion time of the overall survey, the email suspicion score, and conflicting responses for correlated questions. We also ran univariate logistic regressions for individual features to validate the XGBoost model results. Heavy 0 inflation (ie, high numbers of participants with suspicion scores of 0) and poor discriminability were present in each feature, making it impossible to identify bots accurately even when features were combined.

To perform supervised learning this way, we assumed a binary classification of participants versus bots. In reality, the data were imperfectly labeled. Instead of labeling participants as "not bot" or "bot," the best we could achieve was labeling them as "not bot" or "maybe bot." Because the study comprised the internet-based research questions and the internet-based intervention, we used the login and intervention usage data to confirm some true participants (as the intervention website required interaction with diary components and activities, thus confirming a true participant). Nevertheless, there remained a high degree of uncertainty regarding the identity of the remaining participants who only completed the first baseline research questionnaire but did not proceed to log into the intervention. Thus, the bot detector's accuracy is probably exaggerated.

Ways to Manage a Bot Attack

Researchers should regularly monitor recruitment and data collection to aid in the early identification of bot attacks. Close monitoring is critical soon after studies are advertised on the web, as the risk of a bot attack, based on these 2 studies, seems to occur soon after study advertisement. While frequent data monitoring will not stop a bot attack, it may reduce the breadth of the attack by being able to intervene early. Researchers can monitor data manually by regularly checking recruitment or by setting up alerts for new enrolments, which will signal if a high volume of enrolments occurs over a short time.

Close or Pause the Survey

Once a bot attack is detected, it is essential to close or pause the survey immediately. In both case studies, new surveys were created and circulated with additional security measures in place, including location screening features, CAPTCHA coding, the use of fraud scores algorithms, and referral restrictions if recruitment occurs through social media (further strategies are discussed in the section "Ways to counteract a bot attack"). Closing or pausing the survey ensures that no new bot enrolments can occur (although settings may allow incomplete surveys to be completed) and extra security measures can be implemented.

Seek Institutional Support

After identifying the bot attack, several actions were taken to help the research teams consider what to do next. Actions included notifying the respective ethics committees about the attack and seeking consultation and advice about responding. Despite this surge in internet use for health research, there remains limited guidance from health research ethics committees on managing bot attacks or ensuring the validity of internet-based research studies. The emergence of large-scale

XSL•FO
RenderX

digital research and artificial intelligence have presented unique challenges in research ethics and safety. Artificial intelligence (AI) and "big data," particularly digital data, present unique ethical considerations, which institutional research ethics boards may not be adequately equipped to deal with [25]. For example, the issue of transparency is unique to contemporary AI models, as they are often considered "black boxes" where the user is unaware of how the model has reached its conclusion [26]. Accountability remains a complex issue as it is unclear who should be held responsible when AI is involved [27]. In this context, we believe retaining autonomy and "human control" of digital data is paramount. AI can also blur the concept of free and informed consent, and managing privacy becomes more challenging with AI's ability to identify individuals even after data deidentification [28]. Data bias is also a concern as AI may not always detect or could potentially generate biased results, including harmful gender and racial biases [29]. It is crucial to continue addressing these ethical challenges to ensure responsible and safe implementation of AI technologies.

In both our case studies, several ethical dilemmas arose. The first dilemma was the issue of reimbursement. As there is often a set budget for participant reimbursement, an ethical dilemma arises when the number of claims exceeds those budgeted. Specifically, in studies where actual enrolments exceed planned enrolments, there could potentially be hundreds of people who cannot be reimbursed if the study protocol outlines reimbursement of all respondents regardless of data quality. The second dilemma was the inability to differentiate between bots and actual participants in a way that could 100% confirm which responses were "real" and which were not. Failure to accurately identify between participants and bots could lead to a risk of reimbursing bots and erroneously excluding reimbursement of actual respondents due to budgeting constraints.

Finally, there were concerns about potential reputational risks for the researchers and their academic institutions if the research team reimbursed "fake" responses or missed payment for "real" participants. The respective university ethical and legal teams were consulted about researcher obligations to compensate based on completed answers, even if suspected bot attacks generated these. The standard advice was that the bot attack was a misrepresentative response, and therefore, there was no obligation to compensate, given that the terms of research participation had not been met.

In CS1, where participants were to be sent vouchers for compensation, careful screening of voucher claims revealed only 4 valid registrations (out of over 1200 claims), which were subsequently paid. Where participant contact details were available in CS2, we gained ethical approval to recontact participants to indicate that there had been an attack on the study. We asked participants to complete their baseline data collection again to obtain their compensation. The recompletion rate was approximately 55% and no complaints were received about this by the researchers or the ethics committee.

Remove Data

Where there was a high probability of being a bot participant, these data were removed from the dataset, and a record was made of this decision. This decision was based on the above identification parameters. Where it was difficult to tell if the participant was a bot-participant or a legitimate participant, this was noted to allow further scrutiny during the longitudinal follow-up and for reporting in publications as appropriate. It is noted that in both case studies, 2 researchers were involved in each review of data and the decision to remove participants based on being a bot. It was also determined that it was important to do this before data analysis occurred, document all research decisions, and inform the respective ethics committees.

Ways to Counteract Bot Attacks

Plan Ahead

We believe that all researchers involved in internet-based research should have a bot-management protocol in their data management plan. This could be based on protocols such as Ballard et al [11] and include the frequency of monitoring enrolments for bot attacks, steps to take when the survey is active if a bot attack is suspected, and a data handling and analysis plan for the study and that includes planning for bot-related and suspicious data. There should be a clear justification for removing data, and the dataset should be reviewed independently by 2 reviewers, including any decision made to remove data. Decisions should be documented, and publications related to the study should disclose the level of data removal related to the bot attack. Similarly, ethics committees who have approved the study should be consulted and informed about bot attacks, given the impact on research integrity.

Study Advertisements

The researchers in this study and others [9,18,30] believe that studies that are advertised on social media, particularly media where bots are highly active and reach are widespread (such as Twitter or Facebook), are more likely to experience bot attacks. The placement of study advertisements should be specific to the study population, where possible, and highlight the benefits of participating in the research other than compensation. Settings on survey platforms can also limit access to pages via routes other than where they were initially posted; for example, in CS1, settings were changed so that only participants who accessed the survey via the Facebook pages where the links were posted were included in the dataset. In addition, only those who accessed the voucher registration page via the survey could enter their details. Using previously verified distribution lists, such as those associated with professional or patient organizations, may reduce the likelihood of bot attacks as the advertising is more targeted.

Participant Information Sheets and Consent Forms

Participant information sheets and consent forms should highlight the steps researchers will take if they believe a participant has misrepresented themselves. Currently, participant information sheets often outline the inclusion and exclusion criteria and may ask that the participant indicate that they meet these criteria; however, there is no explicit statement about data management for suspected bot attacks. Upon reviewing the

XSL•FO
RenderX

participant information sheet for CS2, the ethics committee felt that the wording and context did sufficiently imply that reimbursement was given only if the questionnaires were completed as part of the intervention study, so this provided adequate grounds for researchers to omit reimbursement to participants who did not complete the questionnaires as part of the fuller study. Nevertheless, an ethics amendment was made where the wording was changed to stipulate that reimbursement more clearly was only given if the questionnaires were completed and the study intervention was used as part of participation.

For future studies, we would recommend the inclusion of text such as the following:

> *Any data that is thought to be generated by a bot or non-human means, is a duplication beyond what is required by the study, or is misrepresentative may be removed by the research team. If this occurs, study compensation for participation, as outlined in this participant information sheet, will not be offered. If you believe your data has been removed unfairly, you may discuss this with the lead researcher, who may ask you for proof of the legitimacy of your claim. If there are issues with data collection, you may be contacted to complete parts of the research again, which you may choose to decline.*

Consent forms should also include reference to this, such as "I understand that if my data is believed to be misrepresented it may be removed from the study and I may not receive compensation for participation." Before including this in external documents, we recommend consulting with your institutional legal team and ethics committee.

Prescreening of Participants

Designing a 2-step registration process that requires screening for study eligibility prior to accessing the survey and that includes multifactor authentication for identity validation may be 1 way to counter web-crawler bots. A more thorough strategy could be prescreening participants manually via a phone call, but this increases the time intensity of a study [21] and may also create a hurdle for participation by requiring additional steps to be completed. Further, commercial tools for identity verification from public records may also be used depending on the location of the study, ethics committee approval, and the researcher's ability to access these. However, these tools rely on up-to-date public records and prevent anonymous participation, which again may create barriers.

Compensation of Participants

Offering financial compensation for research participation is a common strategy when engaging in health-related research, encouraging a breadth of responses [31] and helping to reduce the impact of self-selection bias [32]. Compensating participants is considered an ethical approach to ensuring widespread health research engagement and facilitates participation by financially disadvantaged participants [33,34]. Compensation also recognizes the time participants have contributed to the research project and the value of their contribution. However, compensation means that research can also attract participants who may not be interested in the outcome of the research and are participating for other reasons.

Advertising compensation in study advertisements may increase the likelihood of studies being targeted by bots [5,6,18]. Likewise, direct compensation for internet-based data collection increases the risk of a bot attack, which may be mitigated by offering a prize draw instead. However, a prize draw may be less effective for recruitment [35], may not fairly compensate participants for their time, and may be less likely to recruit or may greater disadvantage more some individuals [36]. Alternatively, offering compensation contingent on completing specific tasks may reduce the likelihood of fraudulent participation, particularly if compensation payment is only made at the end of the study.

Ethics committees recommend offering compensation relative to the degree of involvement of the participant. For example, a 5-minute survey may only be eligible for a prize draw, whereas a study with an in-person 3-hour visit that requires blood tests and medical scans will warrant a higher compensation. However, there is limited guidance on what compensation is expected for different activities, and research teams arbitrarily determine compensation. Thus, studies where researchers offer a higher level of compensation for less effort (such as a short internet-based survey), might be more appealing to bot attacks. Given this, we would advocate for more explicit guidance on research compensation, particularly for internet-based studies.

Clarifying participant identity to claim compensation may also be another barrier for financially motivated bot attacks. Examples of this could be participants being asked to provide identification at the end of the survey to claim compensation and to ensure the participant is a person or the research teams sending vouchers to a postal address rather than an email address. Another potential way to determine authenticity may be using electronic bank transfers to a confirmed bank account rather than digital vouchers similar to case transfer programs that have been trailed in health research [37]. Alternatively, cryptocurrency could also be effective, as the process of claiming blockchain-based rewards could involve complex cryptographic tasks or multifactor authentication methods that are easy for humans but difficult for bots. Cryptocurrency transactions are also publicly verifiable by default on the blockchain, providing a transparent record of each payment (note that cryptocurrency has not yet achieved sufficiently widespread adoption to enable this method, and its use could potentially be seen as contentious [38,39]). Likewise, the requirement to share personal banking information may be a barrier to participation or could preclude people who do not have the financial fluidity to experiment with or access cryptocurrency, which has often been associated with people with more financial freedom [40]. Thus, the use of cryptocurrency may only be viable in limited situations. These strategies could reduce the potential for bots or hybrid bot attacks to be paid and could prevent participants from claiming multiple compensations for multiple completions of the same survey.

XSL•FO
RenderX

Enhanced Security Settings

Researchers should familiarize themselves with the security options within their survey platforms to reduce bot attacks. Security options include activating settings to reduce multiple responses from the same participant, bot detection features, and CAPTCHA settings. For CAPTCHA, Qualtrics (Qualtrics International Inc) generates scores for each participant on a 0 to 1 scale based on several variables. Scores less than 0.5 are likely bots. It was noted that in the case studies above, this was not enough to deter bots but was a method of helping to identify potential bots. RelevantID settings also use code to determine if participants are taking the survey multiple times, allowing researchers to remove duplicate participants.

Crafty Survey Development

Two survey design steps may help make it more difficult for bots to access surveys. The first requires registration with an email address, and then potential participants must validate their email address to log on to the internet-based survey. This registration requires more actions to log in, which makes it harder for less sophisticated bots to access the survey. However, as noted in CS2, bots or hybrid bots may be able to overcome this. Additionally, initial screening or inclusion criteria could be set up as individual questions that are randomized in order, and the correct answers need to be selected for inclusion in the final dataset. An alternative could be using questions that require 2 answers that are linked and require only certain answers to indicate a valid participant. An example could include selecting a country of origin from a drop-down list and then entering a postcode [20] which the research team check to validate if this is a real participant.

Surveys can also include questions that are only likely to be completed by bots, not participants. These are called “honey pot” questions, and each survey platform has a different way of creating them. For example, a field may be created that is invisible to humans, but can be detected by a bot. It is also noted that creating these questions in some coding software may be easier for a bot to detect, and recent internet-based threads have recommended that JavaScript (Mozilla Foundation) be the preferred coding platform for creating these fields.

The inclusion of text-based questions that need answering may also help with the identification of bot participants. Examples of this could include a series of questions requiring a typed answer about the country’s capital, what year it is, the city the person lives in, and basic mathematical equations such as “What is one plus three?” Question format can also increase the chance of detecting a bot by directing participants only to select a specific number of items from a list where all items could be answered.

Kay and Saucier [41] have created an internet-based database of 660 items that can be used to detect careless or insufficient-effort responders in survey data. The authors propose that the best way to identify participants who respond in a misleading or invalid way is to add frequency and infrequency items. Frequency items should be endorsed almost by every respondent (eg, it should be illegal to kill an innocent person), and infrequency item statements should be endorsed by almost no respondents (eg, when someone tells a funny joke, I feel angry) [41]. Thus, failure to endorse a frequency item or an infrequency item would likely indicate a bot.

The final recommendation is randomization of survey items or questions that make it difficult for bots to “predict” the question and answer “appropriately,” thus making it easier to identify nonsensical surveys. Similarly, including free text or open text questions may also help to identify bots versus actual participants, as bots are less likely to complete these meaningfully or may replicate answers. Thus, reviewing qualitative answers for quality or content duplication may help identify a bot. Additionally, including qualitative answers may make bot responding more challenging and provide more insights for future research not captured in closed-text answers [14]. It is noted that these strategies individually will not necessarily prevent hybrid people-bot attacks but will increase the difficulty of survey completion. If multiple strategies are used, it will likely be more deterring for the bot and make it easier to identify bot-responding.

Metadata

The use of IP address tracking may be helpful to identify actual participants compared to bots. Coupled with location filters, IP address tracking can help determine when multiple attempts are made of the same survey and when the participant is not within the geographical catchment of the survey. However, it is noted that virtual private networks can circumnavigate this, and IP address tracking alone is not foolproof. Some ethics committees consider IP addresses to be identifiable information that must be disclosed during the informed consent process if collected. Using this strategy should be approved by the overseeing ethics committee. For further details on using IP addresses to mitigate bots’ effects, see White and Brodhead [8].

Asking participants to provide information that is matched to their IP address or metadata could also be another strategy to validate real participants. This could include strategies such as asking what country the person is in and matching it to an IP address or geolocation or to confirm the time where they are and match it to survey functions which capture the times of both the participant’s browser and the server of the host institution to detect discrepancies [20].

Challenges

Overview

There is likely no foolproof way to detect bots and determined bot users could overcome many of these strategies through a human answering some of the screening questions and then running the bot script. Thus, bot-attacks in internet-based research are an ongoing problem to manage. There are also several ethical issues when identifying potential bots.

Decreased Anonymity

Requiring participants to provide a form of identification prevents researchers from collecting anonymous responses. This may be particularly problematic for studies where participants may be reluctant to participate due to fear, stigma, or where the behavior being studied is illegal [42]. There are strategies to

XSL•FO
RenderX

reduce the impact of the potential to be identified, such as the software randomly allocating codes that are not tied to answers or a researcher who does not have access to the survey data (or even the topic) being the contact person for voucher claims. Researchers working in areas where stigma and shame are common may be reluctant to design surveys where participants may need to be identified; however, there is research showing that larger incentives and greater privacy do not necessarily equate to disclosure of more sensitive data [43] and greater anonymity may impact the accuracy of internet-based surveys [44]. Thus, protecting participant identity through deidentification may be the preferred route to prevent bots and increase survey accuracy.

Removal of Data

Removing bot data is important for research integrity, but this should be done cautiously so as not to remove data belonging to valid participants. This is particularly valid when considering removing data with incomplete answers (particularly qualitative answers), as this may result in removing data from people who may struggle with literacy but also misrepresent attrition and engagement—both critical issues in digital interventions [45-47].

Data removal should be done by 2 independent, blinded researchers and disclosed in publications to ensure transparency and rigor and decrease biases. Similarly, sharing the processes around managing bot-suspected material will aid the research community in developing a consistent approach to bot-data management. Specifically, we believe that researchers should report the methods used to determine bot data, the percentage of data removed due to the data being bot-generated, and the percentage of any suspicious remaining data. As such, we need consistent community guidelines for handling and reporting bot-related data and research impact.

Abusive Responses or Researcher Protection

Soon after the early closure of one of the studies, the researchers began to receive requests for participation compensation. When "participants" were told that there would be no compensation due to suspected fraudulent behavior, researchers began to receive abusive messages. While this is often not at the level of abuse that has recently been disclosed with the rise of the internet [48,49], receiving such abuse is a risk to the well-being of researchers [50,51]. Given this, a plan is needed to determine if and how to respond to such communications and ensure the researcher's well-being [50,51].

Discussion

Principal Findings

This study presents 2 case studies of bot attacks encountered by our research team and the strategies we used to counter them. Moreover, it underscores the critical challenge facing internet-based survey research, which remains highly susceptible to various forms of malicious interference. Unless novel technologies are developed to counter these threats, the challenge of obtaining trustworthy survey data over the internet will likely become more difficult in future years. Our hope is that this paper can serve as a warning, helping to drive the changes needed to protect the integrity of internet-based survey research moving forward.

As technology evolves, so too will the sophistication of bot attacks. As such, bots are here to stay. Therefore, researchers will need multiple, regularly updated strategies to combat and manage bots' effects, including institutional support and ethics committees knowledgeable in this space. It is likely that health research will need to consider multiple bot prevention strategies, use multimodal recruitment and data collection, and develop clear guidelines to help researchers manage bot-related data in internet-based research.

Authentic participant data are valuable, and therefore, researchers need algorithms and a decisional process to detect bot data. A method that is overly sensitive to bots may remove actual participants unnecessarily, thus reducing the size of the dataset and may result in the study being underpowered. On the other hand, an algorithm or decisional process with low specificity may allow an excessive number of bot data to be included, reducing data quality and increasing study costs through compensation paid to nonauthentic participants. Further, bots are likely to provide either extremely noisy or biased answers that negatively impact data quality. When creating a bot detection algorithm, it is up to the researcher to decide whether they wish to prioritize sensitivity (the ability to detect participants) or specificity (the ability to detect bots).

When attempting to develop an appropriate algorithm to detect bots, we faced severe issues with zero-inflated data where most participants—whether bots or not—registered a suspicion score of 0 for multiple variables. This indicates a lack of information about the methods used to create the bot. It highlights the possibility that the attack was performed by human actors responding manually to each survey, making it seem more authentic. Yet even with perfect knowledge of our artificial bot dataset, any bot detection algorithm trained on this dataset would endure from severe overfitting issues, as the attack strategies used will likely differ from those used for another project. Consequently, our detection algorithm probably would not generalize well to real-world attacks, except for similarly designed REDCap (Research Electronic Data Capture; Vanderbilt University) surveys. To make this even more challenging, each of the survey tools currently available to researchers (such as Qualtrics, REDCap, or SurveyMonkey) have different programming interfaces and database structures that would each require a unique version of the bot detection algorithm that is configured to their setup. Hence, we remain unaware of any tool that provides sufficient accuracy for bot detection across the wide range of currently used survey tools. Detection is made more difficult by imperfect participant labeling. For example, researchers can rarely be completely certain that an email address belongs to a bot, even in the presence of "obvious" signs such as random strings of letters or digits. Genuine participants wishing to preserve their anonymity on the web may create a dummy email address for responding to surveys or use "hide my email address" systems, which can also create unusual email handles. The best way to counter fake email addresses is by screening potential participants beforehand and sending a private, individual survey link to prescreened addresses rather than making the link

XSL•FO
RenderX

publicly available [18]. However, this may not be practical for all projects as it can be labor-intensive and as highlighted in CS2, is not foolproof.

Implications

Health research often engages vulnerable populations, and special care must be taken to protect privacy and ensure appropriate risk management is available where needed—including the detection of bots that may skew findings. One vulnerable group are the Indigenous populations. Health research must be responsive and capture the needs of indigenous populations who often experience poorer health outcomes. In CS1, bot responses identified as Māori (the Indigenous population of New Zealand) made up 30% of the sample, and after bot measures were in place, the percentage identifying as Māori was 10%. In CS2, "bot" responses inflated the participants that identified as Māori to almost 4 times what we expected in recruitment based on the population composition. Had we not identified the bot, we would have been quite confident in the analysis we made relating to Māori participants, given the high number, despite these results being unrelated to Māori at all. Therefore, there is a risk that failure to detect and adapt to bot technology could lead to misinformation and contribute to poorer outcomes for indigenous populations based on misinformed conclusions.

Given this, we encourage researchers to consider whether internet-based surveys are the best way to obtain a representative sample with high data accuracy. Internet-based recruitment may preclude some people, and although we increasingly see people being connected on the web, regular data connection, access to technology, and technology literacy may not yet be everyone's privilege, including vulnerable communities. This is particularly pertinent for those where the digital world may be at odds with core and cultural values [52] or where surveys may not accurately capture experiences [53]. Instead, the use of multimodal surveys may reach a broader group, including those who may not be aware of internet-based surveys, may be more responsive to the needs of communities, and may be able better to manage the impact of bots [14].

Recommendations

From our experiences and literature review, it would seem prudent to develop clear guidelines for conducting internet-based research to reduce the risk of bot attacks and increase the robustness of internet-based research. There are currently few guidelines that exist to guide practice in this area. The Association of Internet Researchers released their latest ethical guidelines for internet research in 2019 [54]. The guidelines provide useful information about data management and security, and consider some of the critical issues that we discuss in our paper, including how to protect the researcher where the researcher's public identity is known; specific ethical topics such as accountability, trust, and transparency which have different considerations for internet-based research; and issues related to the accuracy of data including in-built biases from algorithms used for collection and how to use metadata. The EQUATOR (Enhancing the Quality and Transparency of Health Research) network refers to 3 reporting guidelines relating to digital health research—the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) checklist—a checklist for reporting results of internet e-surveys [55]; the CONSORT (Consolidated Standards of Reporting Trials)-EHEALTH to standardize the reporting of evaluations of web and mobile interventions [56], and the iCHECK-DH (Guidelines and Checklist for the Reporting on Digital Health Implementations) which is a guideline and checklist on how to report digital health implementations [57,58]. However, these EQUATOR guidelines refer more to the reporting of the internet-based study than the conduct and do not refer to bot attacks or management [59]. We advocate for developing standardized guidance for researchers conducting internet-based research that describe key considerations and a standardized approach to ensuring data accuracy and validity. These guidelines should also include recommendations for reporting when bot attacks may have occurred and how researchers should handle data with regard to this. While we recognize that bot attacks are likely to be ever-evolving and are likely to outpace the development of guidelines, we believe it would still be useful for guidelines or discussion documents for researchers for strategies to mitigate or minimize the potential effects of bots. Similarly, these guidelines or discussion documents may include points to help researchers determine if the strategies required to minimize bot attacks and the probability of obtaining valid data outweighs the risk of an attack, thus determining if internet-based health research is viable.

Future Directions

Bot attacks will likely become more widespread and more difficult for researchers to detect as botware and attack algorithms become more sophisticated. The experiences of our research group and others [5,13,17-19] highlight a critical, growing problem that deserves more focused researcher attention. Nevertheless, internet-based research has many advantages, such as the ability to reach large numbers of participants and the ability to complete the research remotely. Our experiences should not deter researchers from conducting internet-based research studies. Instead, our paper is a call to action to raise awareness and encourage researchers to consider the risks and benefits of internet-based research. We recommend developing guidelines around detecting and managing bot data in internet-based surveys to help raise awareness of these issues, provide guidance around survey design and data management, and encourage transparency in reporting data that bots may have impacted.

Researchers should also consider the recent exponential development of large language models (LLMs) such as ChatGPT (OpenAI) [60]. Unlike manually programmed bots, LLM-assisted bots can interpret and respond to surveys more coherently, making LLM responses more challenging to detect. This also allows attackers to automate responses to qualitative questions, a task previously reliant on human guidance. We believe it is only a matter of time before LLM-assisted bots become sophisticated enough to respond to any survey design. Consequently, it may become impossible to trust any results obtained from public survey links. Therefore, we recommend that researchers begin implementing more effective security strategies if they have not already done so.

XSL•FO
RenderX

A question that arises at this point, and a potential focus for further research, is whether bot attacks are generalizable across different parts of the world, as different countries have varying protocols for paying research participants [61]. Our experience also suggests that all current research platforms may be vulnerable to illegal bot attacks, and the associated responsibility of software developers to ensure the security and privacy of people is paramount. Thus, bot attacks are likely to be a global issue.

Conclusions

While internet-based research studies increase the ease of participant recruitment and accessibility to a diverse range of respondents, the rise of sophisticated bot programmers and algorithms to automate survey responses risks invalidating internet-based research. Careful planning of internet-based research study designs and incorporating measures to minimize bot responses, such as using a mix of closed, open-ended, and randomized questions, is necessary to protect internet-based studies from bot attacks. However, these measures should be weighed against the risk of inadvertently disqualifying or turning away real, genuine participants. There is an urgent need for standardized practices and guidelines to be developed to provide researchers with clear guidance on safeguarding against bot attacks and actions to take if a bot attack is suspected. As bot attacks are here to stay, this paper aims to raise researchers' awareness and create a call to action before the problem becomes more widespread and challenging to manage.

Authors' Contributions

LD, NH, MP, AK, and AHYC performed the conceptualization. LD, NH, and HW contributed to the data curation. NH, HW, and LD did the formal analysis. LD, NH, AK, and AHYC did the methodology. LD, NH, AK, and AHYC contributed to the investigation. NH contributed to the software. NH and MP contributed to the validation. LD, NH, AK, HW, and AHYC contributed to writing the original draft. LD, NH, AK, MP, HW, and AHYC contributed to writing—reviewing and editing.

Abstract

In rural Australia, recent trends reveal an exponential increase in the rates of physical inactivity, central obesity, metabolic syndrome, and cancer in the population. The limited rural health workforce, which is struggling to meet this growing burden, is boosted by digital technologies such as My Health Record, Cardihab, Healthdirect, and MindSpot, all of which offer opportunities for improved diagnostics, monitoring, and management of chronic diseases. However, implementing proven digital health technologies in rural communities has been challenging on numerous fronts. This perspective aims to (1) highlight the rural health gap and propose a way forward in implementing evidence-based digital health technologies in the rural, regional, and remote communities of Australia and (2) guide future rural health policy.

KEYWORDS

rural health inequities; digital health adoption; telehealth services; chronic disease management; socioeconomic disadvantage; health workforce; shortages digital literacy gaps; equitable access to care

Rural Health Gap

Approximately 7 million Australians (28%) and 260,000 (32%) First Nations peoples live in rural, regional, and remote (RRR) areas [1,2] (Figure 1 [3]). These regions encompass more than 1700 small towns with populations under 10,000 people [2]. The leading causes of the rural burden of disease are central obesity, type 2 diabetes, coronary heart disease, suicide and self-harm, chronic obstructive pulmonary disease, and lung cancer [4]. Cardiovascular disease is a significant health problem in RRR regions in Australia, where prevalence rates are approximately 20% to 30% higher than in urban areas [4]. Other significant health challenges across RRR communities include chronic kidney disease and dementia and other mental health disorders [5]. As a result, individuals residing in RRR regions experience an age-adjusted mortality rate that is 2.3 times higher than that of those living in major cities [6]. This viewpoint aims to guide policymakers on how to leverage digital health, using global evidence and strategies, to reduce RRR region health inequities.

Several social determinants of health contribute to health disparities in RRR areas, including chronic unemployment, lower educational attainment, historical social injustices, and limited access to fresh fruit and vegetables [7]. For instance, the year 12 completion rate is the lowest in very remote areas compared with that of major cities (55.5% vs 79.4%) [1,8]. Similarly, the median weekly income declines with remoteness, from AUD $1915.2 (the conversion rate at the time of the study was AUD $1=US $0.65) in major cities to AUD $1362.7 in very remote areas [1,8]. The availability of health care professionals also varies substantially, with very remote areas having approximately 205 full-time equivalent doctors per 100,000 people, compared with 427 full-time equivalent doctors per 100,000 in major cities (Table 1) [1,8]. Medicare data from

XSL•FO
RenderX

2022 to 2023 show that general practitioner (GP) visits were lowest in remote and very remote communities, while hospitalization rates (eg, for end-stage renal disease) were almost twice as high in very remote areas and 1.3 times higher in remote areas, with no improvement since 2013 to 2014 [9].

Figure 1. Australian map by remoteness. Adapted from [3].

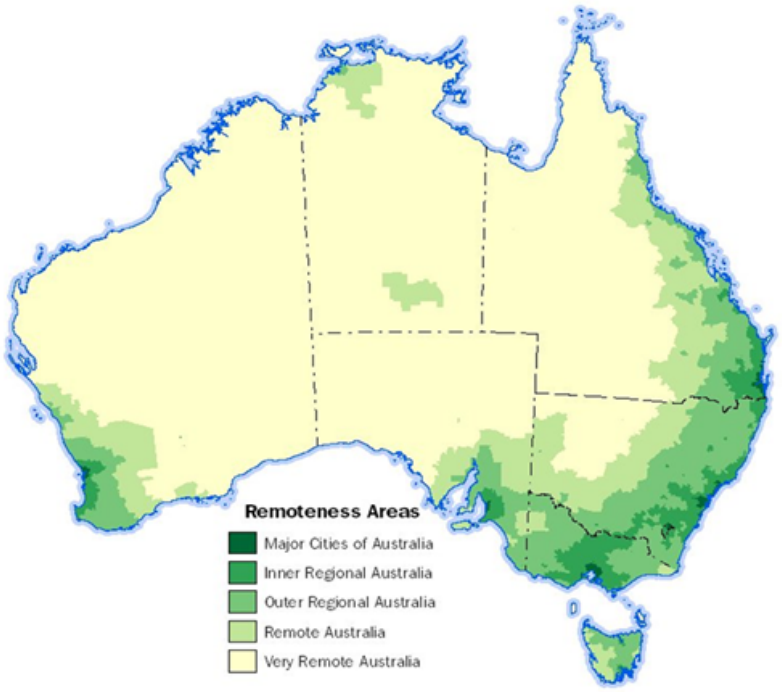

Table 1. Sociodemographic and health workforce profile of Australia by remoteness [1,8].

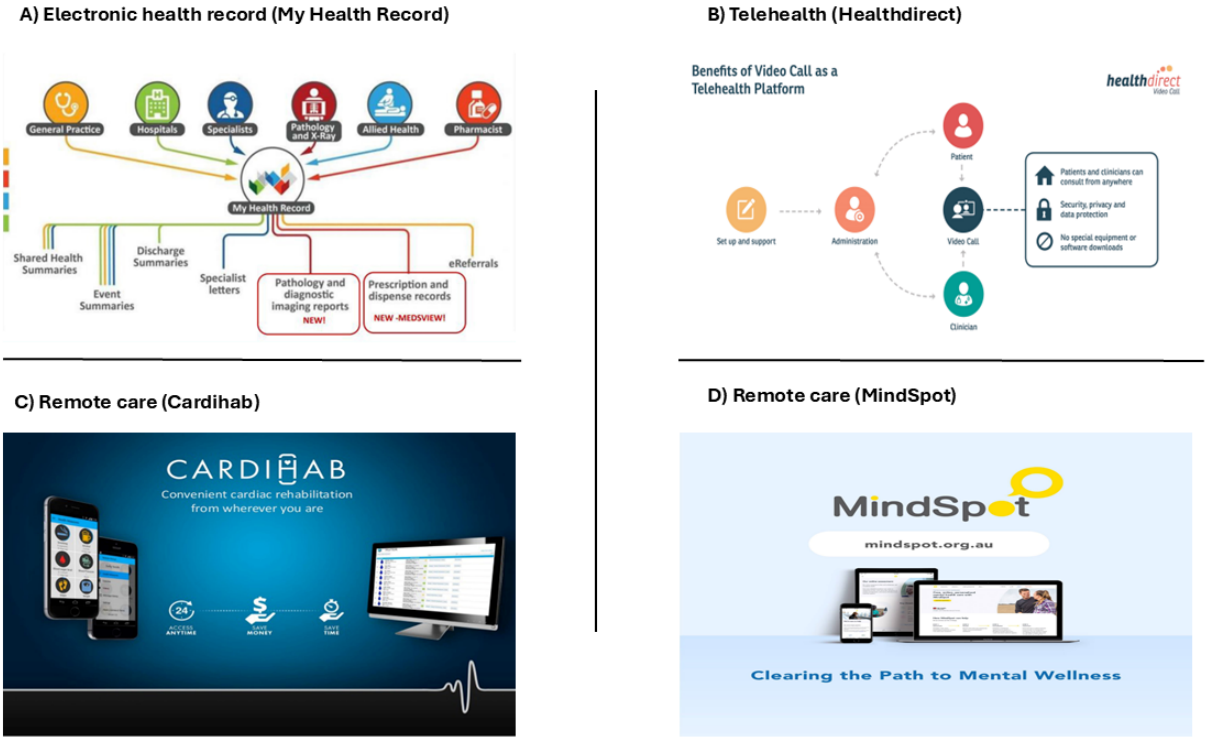
Variables	Major cities	Inner regional	Outer regional	Remote	Very remote
Population size (%)	72	18	8.1	1.2	0.8
Year 12 completion (%)	79.4	74.5	67.6	69.2	55.5
Median weekly household income (AUD $)	1915.2	1637.6	1391.0	1478.7	1362.7
Health care workforce (medical practitioners), FTE[a] per 100,000	427	311	285	285	205

[a]FTE: full-time equivalent.

Evidence-Based Digital Health Technology

Health care is increasingly being delivered in a technology-driven environment [10]. In Australia, digital health technologies are transforming health care delivery, with significant advancements in electronic medical records (EMRs), telehealth, and remote patient monitoring [11]. EMRs have been widely adopted within GP practices, hospitals, and other service providers, facilitating seamless transfer of patient records among health care providers. Studies indicate that EMR adoption rates in RRR areas often surpass those in urban settings. For example, a 2012 study found that 56% of RRR region practices had adopted EMRs compared with 49% in urban areas [12]. Similarly, another study reported that solo practices in RRR regions were more likely to adopt EMRs than their urban counterparts (41% vs 33%) [13]. My Health Record, a Medicare-funded national digital system, improves care continuity by providing comprehensive, accessible patient information across health care settings (Figure 2) [14].

Telehealth services have also grown substantially, particularly with Healthdirect, a national service funded by federal, state, and territory governments [11]. Healthdirect operates as a "virtual front door," triaging patients, providing self-care advice, and connecting them to necessary health services. Several regions, including Victoria's Northern Health, have implemented "Virtual Emergency Departments" using telehealth to triage patients efficiently [15]. The use of telehealth has extended to innovative outpatient care models, such as the Royal Prince Alfred Hospital's "Spirituals." In the Aboriginal Community Controlled Health Organisation sector, telehealth supports culturally appropriate health care through methods like "Store-and-Forward." Specialized imaging captures patient data and forwards them to specialists for diagnosis and treatment, supporting complex conditions like heart, eye, ear, and diabetes care [16].



Remote care technologies such as remote patient monitoring and digital therapeutics help in effectively managing chronic conditions and reducing hospital admissions in RRR settings [11]. For example, Cardihab delivers personalized digital cardiac

XSL•FO
RenderX

rehabilitation, enabling clinicians to monitor patient progress through an online portal [17]. Mental health digital therapeutics, provided by services like Mental Health Online, MindSpot, and THIS WAY UP offer stand-alone or blended care options [18]. Blended care enhances flexibility, supports RRR access, and integrates digital tools into traditional pathways for cardiac and mental health services [19]. Hospitals also leverage remote patient monitoring, with the Royal Prince Alfred Hospital's "Virtual Hospital" providing 24/7 multidisciplinary care [20]. The Virtual Clinical Care program in South Australia is another example, aimed at reducing preventable hospital admissions through early intervention and continuous monitoring [21].

Artificial intelligence (AI) integration in health care is still limited, mostly restricted to research settings rather than widespread clinical use [22]. The health sector is one of the least mature industries in terms of AI implementation both in Australia and internationally [23,24]. AI analyzes data to support decisions; telehealth delivers care remotely. Together, they enhance access, efficiency, and personalization [25].

Figure 2. Four available digital platforms in Australia: A) My Health Record securely stores key health information, accessible anytime by patients and healthcare providers, including during emergencies; B) healthdirct operates a 'virtual front door' service. It triages patients, provides advice on how they can manage their condition on their own ('self-care'), and connects them to health services; C) Cardihab is a digital-based cardiac rehabilitation service for patients recovering from a cardiac event or procedure; D) MindSpot is free, confidential psychological assessments and treatments, and access to qualified therapists via online or telephone.

Implementing My Health Record, Healthdirect, Cardihab, and MindSpot

In 2022, nearly half of RRR Australian regions experienced significant broadband or mobile internet connectivity gaps [6]. RRR Australians face ongoing challenges with internet connectivity, especially in terms of video connectivity, and limited digital literacy, despite the narrowing of the urban-rural digital access gap [26]. Implementing My Health Record, an electronic health record (EHR) system, has been challenging on many fronts (Table 2). Issues relate to usability, safety, and the burden it places on physicians [27]. Other challenges of EHR implementation include data entry issues, inadequate alerting systems, and problems with interoperability [27]. Other concerns include high implementation costs, EHR standardization issues, resistance to change, and initial system use reducing productivity [28]. One survey found that most people (71.2%) knew little about My Health Record, and 29.4% had opted out of the system [29]. My Health Record improved access to information, but health literacy gaps, language barriers, and medical jargon caused misinterpretation and sharing issues. Studies need to assess whether the My Health Record improved Australia's health care as per the objectives of the 2012 Act [30].

XSL•FO
RenderX

Table 2. Resources required for the 4 digital health platforms in Australia [17,31-33].

Resources required	My Health Record (electronic health record)	Healthdirect (telehealth)	Cardihab (remote care)	MindSpot (remote care)
Internet	✓	✓	✓	✓
Broadband connections	✓	✓	✓	✓
Electricity	✓	✓	✓	✓

Normal phone		✓		✓
Smart phone	✓	✓	✓	✓
Computer or tablet	✓	✓	✓	✓
Trained staff	✓	✓	✓	✓
IT staff	✓	✓	✓	✓
Health staff	✓	✓	✓	✓

Healthdirect Australia offers nurse-led telephone triage, crucially supporting RRR areas facing GP shortages and limited health care access. The service helps patients determine the most appropriate level of care, reducing unnecessary emergency department visits [34]. Healthdirect specializes in providing virtual health information, advice, and referral. However, the implementation of such digital health services can be challenging. A key barrier to implementing is the complexity of navigating Australia's health care system [35], where coordination between primary and specialist care is poor, especially affecting access in underserved and RRR communities, according to the Grattan Institute report [36]. This leads to missed follow-ups and fragmented care, especially for patients with chronic or complex conditions [36]. Failure to involve a patient's GP in all aspects of patient care can disrupt continuity of care and compromise the provision of high-quality, cost-effective care [37], particularly in Australia, where the health care system heavily relies on GPs for primary care. A theoretically based implementation plan that can be reported transparently is another pressing requirement [38]. Furthermore, allocating resources to implement the intervention within routine care can also pose difficulties [38].

Cardihab offers digital cardiac rehabilitation [38], improving access and participation in RRR areas, where travel distances historically limited program engagement. In North Queensland, inadequate discharge planning and referrals limit cardiac rehabilitation access for hospital-treated patients [39]. Cost-effectiveness shows savings via fewer rehospitalizations, but sustainability requires continuous Medicare funding and digital skills training for clinicians and patients [40,41]. Despite these benefits, integrating digital cardiac rehabilitation into routine health care remains challenging. Service underuse persists due to a combination of patient and provider factors. Barriers include high costs, staff resistance, training demands, usability issues, data privacy, technical limitations, migration difficulties, and interoperability challenges [38]. National data show that among the 49,900 eligible patients between 2013 and 2015, only 30% were referred to cardiac rehabilitation, and of those referred, fewer than one-third (28%) attended the program [42].

MindSpot delivers online therapy to underserved RRR Australians [43], effectively reducing depression and anxiety symptoms comparable to face-to-face psychological care [44]. Despite these benefits, uptake remains disproportionately low; only 18.9% of registrants are from RRR areas, where approximately 29% of Australians live [45]. Barriers include persistent digital access issues, cultural acceptability concerns, and limited targeted promotion in Indigenous and farming communities [46]. Furthermore, evidence is lacking about the effectiveness of digitally delivered mental health care in real-world settings [45]. Challenges related to the collection of outcome data also persist [47], highlighting the complexities of implementing digital health services in RRR settings.

Additional Examples of Telehealth and AI in RRR Settings

Telehealth is also being leveraged beyond these 4 platforms. For example, the Royal Flying Doctor Service delivers telehealth consultations to remote patients for chronic disease management and mental health, reducing emergency retrievals [48]. The Northern Territory Health Department outlines a structured approach to early detection and management of type 2 diabetes in Aboriginal youth [49]. This includes referral pathways and screening protocols that align with telehealth-enabled services, such as diabetic obesity screening [49]. In addition, Healthy Rural Hearts telehealth in NSW delivers personalized nutrition therapy for cardiovascular disease risk, although its effectiveness and patient engagement are still under evaluation [50].

A systematic review finds evidence of the promising potential of portable ultrasound in RRR Australia, enabling nurses to capture scans and receive automated reports for obstetric and cardiac diagnostics [51]. For example, studies in remote Indigenous communities have shown feasibility and improved diagnostic capacity when nurses use portable ultrasound devices under tele-supervision from specialists [51]. This approach reduces the need for patient travel, supports timely clinical decision-making, and strengthens local health care capacity in under resourced areas. AI-supported triage tools in Healthdirect call systems also show promise, as evaluated in a 2025 Macquarie University usability study of the Triage Platform

XSL•FO
RenderX

[52]. The platform can aid in detecting high-acuity cases but is still in the pilot stages, needing further validation, especially in RRR areas [52].

Current Utilization

Australian residents who are registered with Medicare or an individual health care identifier can access My Health Record via their mobile app or via the official webpage [53,54]. Mental Health Online provides tailored cognitive behavioral therapy programs for anxiety, depression, posttraumatic stress disorder, and obsessive-compulsive disorder, guided by its Electronic Psychological Assessment Screening System [55]. My Health Record is particularly valuable for continuity of care when patients need to travel across large distances for specialist consultations. Rural GPs report improved care coordination, especially for patients with complex multimorbidities, where local facilities cannot provide specialist services [36]. Rural solo practices adopt centralized health records more than metropolitan groups owing to benefits in sparse referral networks [34]. However, full integration is limited because of persistent opt-out rates in remote areas, partly due to mistrust and low awareness [11]. Healthdirect offers 24/7 helplines and online resources, providing Australians with accessible, trusted, and quality health information and advice [54,56]. Cardihab has been used by Australian private health insurers, clinicians, and patients in Queensland, Victoria, and South Australia [57]. Cardihab, a class I medical device registered in Australia, is being implemented nationwide to support cardiac rehabilitation services [58]. In 2023, 27% of MindSpot users were from RRR areas [59]. Mindspot provides mental health services to underserved populations, including Indigenous Australians, those facing access barriers, and residents outside major cities [60]. THIS WAY UP offers evidence-based online mental health courses, supporting RRR region practitioners and providing culturally safe tools for Indigenous communities via the WellMob portal [61].

International Case Studies

In Canada, the Ontario Virtual Care Program, initiated in 2006 and supported by the Ontario Telemedicine Network, introduced virtual visits to assist patients in remote locations [62]. This initiative aimed to enhance access to care and improve continuity and coordination of services. The program has evolved to integrate virtual care services within the health system, benefiting underserved populations, including those in RRR communities [63]. Additionally, the Ontario Virtual Care Program enhances sustainability by enabling policymakers to iteratively adapt service delivery models to RRR realities [64].

In Finland, the OuluHealth ecosystem in northern Finland brings together stakeholders from the health sector to facilitate cooperation and improve health and social care services. Collaboration in medicine, wireless technology, ecosystem enabling, and big data facilitates rapid responses to digital health challenges, effectively addressing societal needs [65]. Integrated digital health models with robust infrastructure can improve health care access and continuity in remote regions.

The Framework for Digital Health Equity study [66] emphasizes that equitable digital health solutions must address barriers for marginalized, Indigenous, and older adults in rural US communities. Ensuring these groups have access to technology and the necessary digital skills will be crucial in reducing health care disparities and promoting digital health equity.

Evaluation Approaches

The evaluation of digital health programs in RRR regions relied on a mixed methods design that incorporates the following:

- Service use data (eg, Medicare claims or platform analytics) to quantify reach and uptake [67]
- Health outcomes (eg, hospital admission rates or disease-specific metrics such as HbA_{1c} also known as glycated hemoglobin levels for diabetes) [68,69]
- Economic evaluations assessing cost-effectiveness considering patient travel, workforce efficiency, and avoided hospitalizations [40]
- Qualitative feedback from patients, clinicians, and community leaders in RRR areas to assess cultural safety, usability [70], and trust

Way Forward

Implementing digital health services in RRR areas is a complex task requiring careful planning and strategic investment (Figure 3 [15,53,57,71,72]) [26]. Rural communities' needs must be assessed to identify current and future essential clinical services [41,73]. This will involve a cross-sectional survey, community consultation, and data analysis [41,73]. Analyzing ethical risks, privacy, security, consent, and regulations can enhance telehealth governance and strengthen digital health policy recommendations [11,74]. Furthermore, systematic data collection would enable benchmarking, monitoring, and ethical oversight, driving continuous improvement across digital health services [75]. Federal and state health authorities must prioritize RRR region–specific data and programs to address unique needs [2]. Once the needs and current capacity are identified, a plan to roll out digital services needs to be developed to complement the existing clinical practice. One such project was the implementation of electronic prescribing infrastructure in 2021, where 36% of GPs generated e-prescriptions, and 95% of the Pharmaceuticals Benefits Scheme pharmacies dispensed them [11]. RRR health service implementation is expensive because of the costs incurred through infrastructure, equipment, skilled workforce, tailored interventions, multilevel strategies, local leadership, and advocacy needs [76,77]. Socioeconomic, connectivity, literacy, and funding gaps worsen RRR region digital health disparities, necessitating inclusive, equity-focused strategies [78-80]. Government subsidies for devices and training programs for RRR health care workers can help reduce barriers and strengthen digital health adoption [81,82]. Government funding; partnerships (policymakers, health care providers, and technology developers) with the private sector; and innovative financing models should be explored to cover these costs [76]. Effective implementation of digital health in RRR areas requires long-term Medicare funding, strengthened public-private partnerships, and targeted workforce training.

RenderX

Equitable policies, reliable infrastructure, and practical integration of telehealth, EHRs, and remote monitoring are essential. Overcoming RRR region digital health barriers in Australia requires community engagement, device subsidies, digital literacy, and socioeconomic support for sustainable, accessible, and culturally appropriate care. Coordinated planning, cost management, and sustainable funding enhance efficiency, scalability, and long-term impact of digital health services in underserved RRR communities. Future research should co-design dietary interventions combining community-based support with digital approaches for greater effectiveness [50]. By aligning digital health initiatives with the realities of RRR region practice, Australia can move closer to bridging the health gap and ensuring equitable access to care for all communities.

Figure 3. The key implementation steps.

Acknowledgments

The authors sincerely thank the epidemiology team at the Rural Health Research Institute (RHRI), Charles Sturt University, which includes MMH, KYA, TS, AEA, MAM, MJAS, UKM, SBA, and SG, for their valuable insights and thoughtful suggestions.

Authors' Contributions

SM conceived the idea and conducted the literature review. SM extracted the data and wrote the first draft of the manuscript, which was critically revised by the Epi team and AR, focusing on improving cultural sensitivity, methodological appropriateness, respect for cultural values, and ensuring ethical considerations. All authors approved the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Poststroke depression (PSD) is a common complication following stroke. In recent years, several systematic reviews have evaluated the effects of moxibustion and acupuncture on PSD; however, their findings have been inconsistent.

Objective: This overview of systematic reviews aimed to assess the methodological quality, reporting quality, and strength of evidence of existing systematic reviews on acupuncture and moxibustion for PSD. In addition, this study also analyzed the limitations of previous studies and suggested directions for future research.

Methods: Systematic reviews concerning acupuncture and moxibustion for PSD published before August 10, 2024, were identified from 8 databases, including PubMed, Embase, Cochrane Library, Web of Science, China National Knowledge Infrastructure, Wanfang, VIP Database, and Chinese Biomedical Literature Database. Eligible studies included systematic reviews and meta-analyses of randomized controlled trials comparing moxibustion and acupuncture for the treatment of PSD. The methodological quality, reporting quality, and evidence quality were evaluated using AMSTAR 2 (Assessment of Multiple Systematic Reviews-2), PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020, and GRADE (Grading of Recommendations Assessment, Development and Evaluation), respectively. The corrected covered area was calculated to assess overlap among the included primary studies.

Results: A total of 24 studies were included. According to the Assessment of Multiple Systematic Reviews-2 assessment, all studies were rated as having “low” or “critically low” methodological quality. Based on PRISMA, 1 study demonstrated seriously inadequate reporting quality, while 21 studies had partially inadequate reporting quality. The quality of evidence in the included reviews ranged from very low to moderate. Most of the primary outcomes exhibited mild to moderate overlap among studies.

Conclusions: Most of the included systematic reviews indicated that acupuncture may be beneficial for PSD. Nevertheless, the methodology, reporting, and evidence quality of these reviews require improvement. Stronger evidence will depend on the conduct of larger, multicenter, rigorously designed randomized controlled trials, as well as high-quality systematic reviews.

Trial Registration: PROSPERO CRD42024576753; https://www.crd.york.ac.uk/PROSPERO/view/CRD42024576753

KEYWORDS

acupuncture; humans; poststroke depression; systematic review; moxibustion

Introduction

Poststroke depression (PSD) is a prevalent neuropsychiatric complication following stroke, characterized by depressed mood, loss of interest, and diminished quality of life during the recovery process [1]. PSD not only impairs patients’ quality of life but also exacerbates cognitive dysfunction, delays neurological recovery, and elevates the risk of recurrent stroke and mortality [2]. The pathogenesis of PSD remains incompletely understood but is thought to involve a combination of stroke-induced damage to emotional regulatory brain regions, resulting in neurotransmitter imbalances, reduced ability to perform daily functions, and insufficient social support [3].

Globally, the prevalence of PSD ranges from 17% to 34.3% [4]. Its incidence is influenced by factors such as age, gender, education level, marital and economic status, and stroke type [5]. The mainstays of Western medical management for PSD include pharmacotherapy, most notably selective serotonin

XSL•FO
RenderX

reuptake inhibitors and norepinephrine-dopamine reuptake inhibitors, and psychotherapeutic approaches such as cognitive-behavioral and interpersonal therapies [6,7]. However, pharmacotherapy is frequently associated with adverse effects such as dry mouth, constipation, dizziness, somnolence, sexual dysfunction, and, in some patients, lack of efficacy or development of drug resistance [8-10].

Acupuncture, an integral part of traditional Chinese medicine, has demonstrated beneficial effects for PSD. Clinical evidence suggests that acupuncture can alleviate depressive symptoms, improve quality of life, and reduce the adverse effects induced by pharmacological agents [11,12]. The putative mechanisms include modulation of neurotransmitter systems, enhancement of cerebral blood flow, and regulation of immune function [13]. Numerous clinical trials and case studies point to acupuncture and moxibustion as effective interventions for PSD [14,15]. In recent years, multiple systematic reviews have synthesized the evidence on acupuncture and moxibustion for PSD, occasionally yielding inconsistent or conflicting results [16,17].

Therefore, this study presents an overview of systematic reviews that comprehensively summarizes the current state of research on acupuncture and moxibustion for PSD. By synthesizing existing evidence, it aims to provide a scientific foundation for clinical practice, clarify methodological limitations of previous studies, and propose recommendations for future research.

Methods

Protocol and Registration

The protocol for this overview of systematic reviews was registered with PROSPERO (International Prospective Register of Systematic Reviews; CRD42024576753). The reporting of this study adheres to PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines [18].

Data Sources and Search Strategy

A total of 8 electronic databases were searched: PubMed, Embase, Cochrane Library, Web of Science, China National Knowledge Infrastructure, Wanfang, VIP Database, and Chinese Biomedical Literature Database. The search included records published up to August 10, 2024. Keywords used were acupuncture, moxibustion, electroacupuncture, manual acupuncture, acupoint catgut embedding, systematic review, meta-analysis, and PSD. Detailed search strategies for each database are provided in Table S1 in Multimedia Appendix 1.

Eligibility Criteria

Studies were included if they met the following criteria: (1) systematic reviews or meta-analyses of randomized controlled trials (RCTs) or quasi-RCTs focused on acupuncture and moxibustion for PSD; (2) participants diagnosed with PSD, confirmed by computed tomography or magnetic resonance imaging, regardless of gender, age, ethnicity, education, or economic status; (3) interventions applied to the experimental group included acupuncture, moxibustion, electroacupuncture, manual acupuncture, acupoint catgut embedding, or transcutaneous electrical acupoint stimulation, alone or in combination with Western medicine or basic medications. Control groups received interventions other than acupuncture or moxibustion (eg, Western medicine, placebo, and sham acupuncture) to compare the efficacy of acupuncture with other treatment methods or placebo in the treatment of PSD; (4) main outcome indicators included overall effectiveness rate, Hamilton Depression Rating Scale (HAMD), Self-Rating Depression Scale (SDS), and the modified Edinburgh-Scandinavian stroke scale scores; and (5) no restrictions were imposed on the duration of the follow-up period (Table S2 in Multimedia Appendix 1 [16,19-41]).

Exclusion criteria were (1) systematic reviews or meta-analyses that did not include RCTs; (2) studies involving patients without a clear diagnosis of PSD; (3) control group interventions that included acupuncture; (4) duplicate publications; (5) protocols for systematic reviews, commentaries, or conference abstracts; and (6) studies lacking complete or essential information.

Literature Selection

All studies identified in the search were imported into EndNote (EndNote X20; Clarivate) for deduplication. Two independent reviewers (LM and CLX) screened titles and abstracts according to the inclusion and exclusion criteria and further independently assessed the full text of potentially eligible studies. Disagreements were resolved by discussion, with a third reviewer (XCT) involved when necessary.

Data Extraction

Data extraction was conducted independently by 2 reviewers (LM and CLX). Extracted data included (1) bibliographic details (title, authors, and year of publication); (2) number and sample size of included studies; (3) intervention methods, control interventions, outcome results, 95% CI, I^2 statistics, P values, and study conclusions; and (4) methodological quality assessments of the included studies. Any discrepancies were resolved by discussion with a third reviewer (XCT).

Quality Assessment

Methodological Quality

The included systematic reviews were assessed using the Assessment of Multiple Systematic Reviews-2 (AMSTAR 2) tool [42]. Items 2, 4, 7, 9, 11, 13, and 15 were considered critical domains. Reviews were categorized as “high” quality (no noncompliance on critical items), “moderate” quality (noncompliance on noncritical items only), “low” quality (1 critical item noncompliant), and “very low” quality (more than 1 critical item noncompliant).

In addition, we used the Cochrane Risk-of-Bias tool to reassess the risk of bias in the original RCTs included in the systematic reviews and performed statistical analyses on items with a high risk of bias, such as random sequence generation, allocation concealment, and blinding.

Reporting Quality

PRISMA 2020 [18] was used to evaluate reporting quality. Each of the 27 items was scored as 1 (fully reported), 0.5 (partially reported), or 0 (not reported), for a maximum score of 27. Scores <15 indicated “severely deficient” reporting, 15.5 - 21 “somewhat deficient,” and 21.5 - 27 “relatively complete” [43].

XSL•FO
RenderX

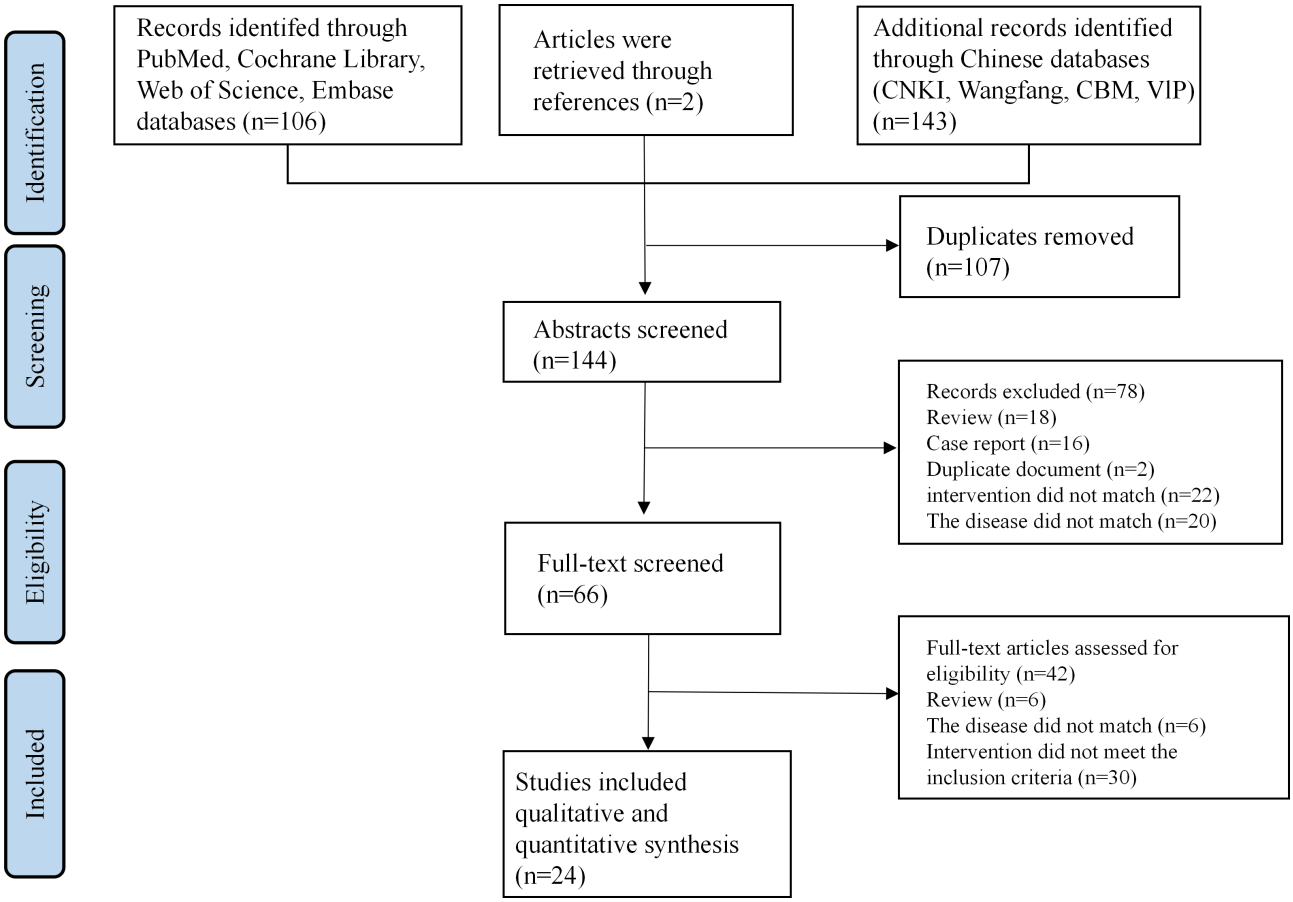
Evidence Quality

The Grading of Recommendations Assessment, Development and Evaluation (GRADE) system [44,45] was used to assess the quality of each outcome. Evidence was categorized as high, moderate, low, or very low, in accordance with Cochrane and contemporary guidelines [46]. Quality assessments were carried out independently by 2 reviewers (LM and XXH), with disagreements resolved through discussion or consultation with a third reviewer (XCT).

Heterogeneity Assessment

Statistical heterogeneity among studies was assessed using the I^2 statistic, quantifying the percentage of variability due to heterogeneity rather than chance [47,48]. I^2 values of 25%, 50%, and 75% were considered low, moderate, and high heterogeneity, respectively [49].

Data Synthesis and Analysis



A narrative synthesis was performed, focusing on study population, sample size, interventions, outcome indicators, relative effect sizes, I^2 statistics, *P* values, and main conclusions. Where possible, results were also summarized in a tabular form. All collected data were entered into Microsoft Excel 2019 for qualitative synthesis. Overlap of primary studies was assessed using the corrected covered area (CCA) method and calculated as follows: CCA (%)=(N-r)/(rc-r), where N is the total number of included observations from all reviews, r is the number of unique primary studies, and c is the number of systematic reviews. Interpretation was categorized as 0% - 5% (slight overlap), 6% - 10% (moderate overlap), 11% - 15% (high overlap), and >15% (very high overlap).

Results

Literature Search Results

A total of 251 records were screened for eligibility. After removing 107 duplicates, 144 articles remained. Upon review of titles and abstracts, 78 articles were excluded, with an additional 42 excluded after full-text assessment. Ultimately, 24 articles [16,19-41] met the inclusion criteria for this overview (Figure 1).

Figure 1. Flow diagram of the search and screening of the studies included in this overview. CBM: Chinese Biomedical Literature Database; CNKI: China National Knowledge Infrastructure.

Study Characteristics

The included studies comprised 24 systematic reviews and meta-analyses, with 11 papers published in English and the remaining in Chinese [20,21,24-26,28,29,31,33,37-39,41] (Table 1). Interventions in the experimental group included acupuncture, electroacupuncture, scalp acupuncture, alone or in combination with Western medicine. Comparator groups received Western medicine, sham acupuncture, placebo, or no treatment. All systematic reviews evaluated the methodological quality of their included studies, with 17 [16,20,23-26,28-30,32,34,35,38-41] using the Cochrane Collaboration Risk of Bias tool, 3 [19,21,33] using the Jadad scale, and 3 [27,31,37] combining both tools. A total of 21

XSL•FO
RenderX

systematic reviews [16,19,21,23-26,28-41] concluded that acupuncture was effective for the treatment of PSD, while 3 [20,22,27] reviews found insufficient evidence to support its benefits. Acupuncture was associated with fewer adverse events than antidepressants.

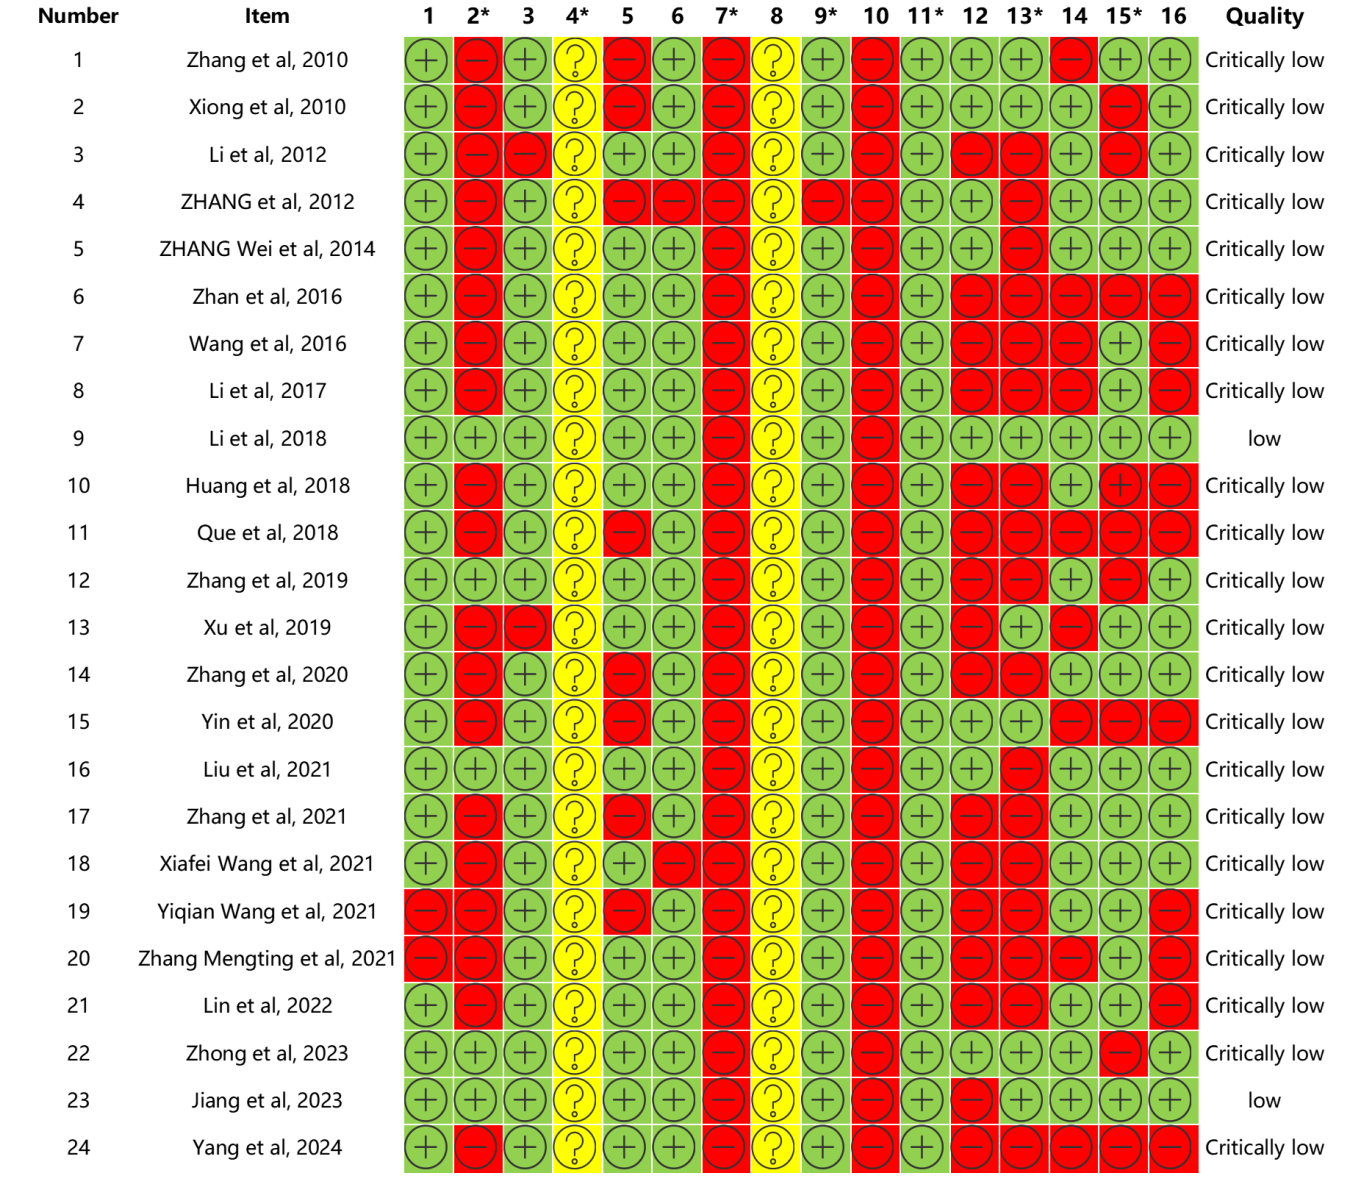
Methodological Appraisal

The methodological quality of the included reviews was assessed using the AMSTAR 2 tool. Every review had at least 1 critical domain rated as "very low" in methodological quality. In particular, major deficiencies were noted in protocol registration (Item 2), provision of excluded studies (Item 7), and comprehensive assessment of publication bias (Item 15; Figure 2). Out of the 24 included studies, 22 [16,19-26,28-39,41] were rated as "critically low" and 2 [27,40] as "low" in methodological quality. Notably, most studies (21/24) reporting positive findings for acupuncture had critically low methodological quality, while all 3 reviews [20,27,29] indicating insufficient evidence also had methodological shortcomings.

Figure 2. Results of the methodological quality evaluation using Assessment of Multiple Systematic Reviews-2 (AMSTAR 2). "+" denotes yes, "–" denotes no, and "?" denotes partial yes.

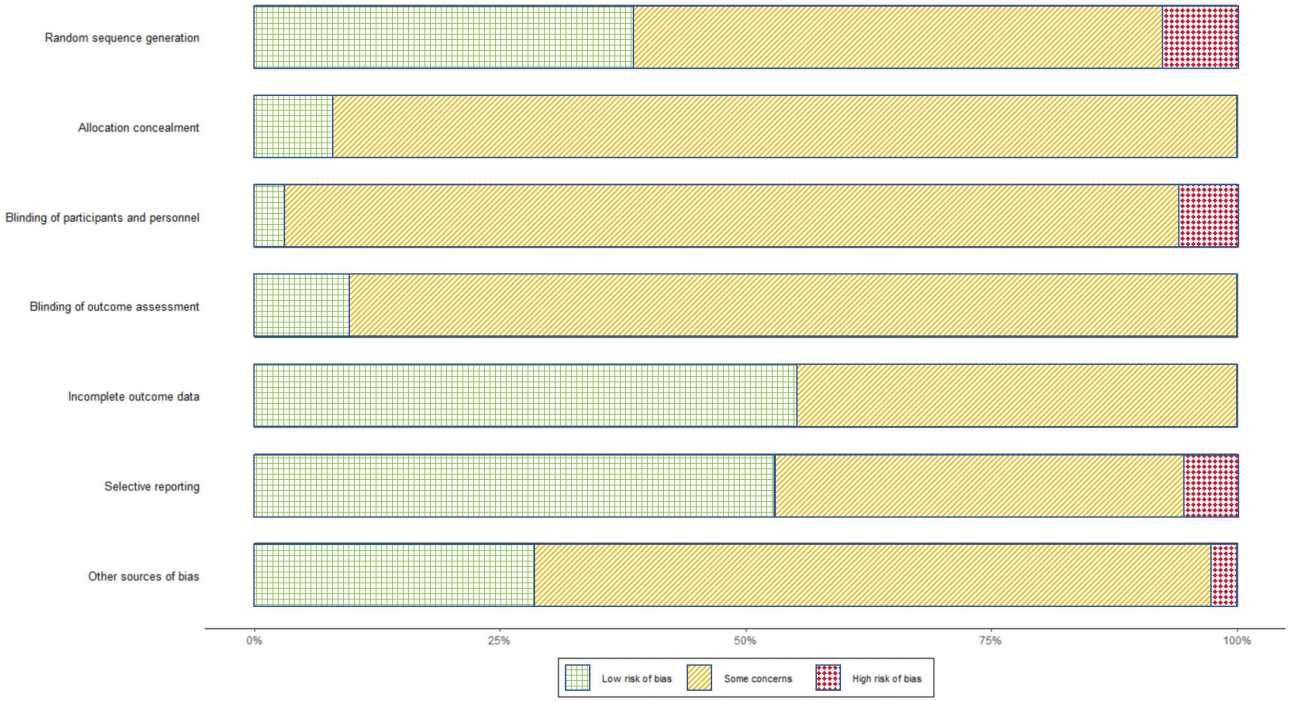


Reporting Quality Appraisal

Reporting quality was evaluated using the PRISMA 2020 checklist. Scores for the 24 studies ranged from 14 to 23. One study [22] was classified as "severely deficient" (score <15), 21 studies [19-21,23-33,35-41] as "somewhat deficient" (score 15 - 21), and 2 studies [34,40] as "relatively complete" (>21). Underreported items included data items (10), methods for evaluating quality of evidence for each outcome (15), presentation of evidence grading (22), registration and protocol (24), competing interests (26), and public information reporting (27) (Figure 3).

XSL•FO
RenderX

Figure 3. Results of the reporting quality evaluation of Preferred Reporting Items for Systematic reviews and Meta-Analyses (PRISMA). "+" denotes yes, "–" denotes no, and "?" denotes partial yes.



Risk of Bias in Original Literature

After deduplication, 222 original studies remained. Of these, 46 articles (20.7%) were classified as high risk of bias, while the remainder were labeled as having "some concern." Among the high-risk domains, random sequence generation constituted 8.6% (19/222), blinding of participants and personnel 7.7% (17/222), selective reporting 4.5% (10/222), and other biases 1.4% (3/222) (Figure 4). Further details can be found in Multimedia Appendix 2. in

XSL•FO
RenderX

Figure 4. Summary chart of bias risks in original literature. Green squares represent low risk, yellow stripes represent some concerns, and red diamonds represent high risk.

Classification of Evidence Quality

The quality of evidence for the outcome indicators, covering 6 different intervention types, ranged from very low to high. Common downgrading factors included high risk of bias, significant heterogeneity, small sample sizes, and inconsistency of results, as outlined in Table 2 [16,19-41].

SDS	B3	0	−1[b]	−1[h]	−2[f]	0	Very low

[a]Asymmetric funnel plots or all positive results may have a large publication bias.

[b]Risk of bias in included studies with respect to randomization, blinding, allocation concealment, completeness of outcome data, or selective reporting risk of bias.

[c]Included in the study 50%≤I^2<75%.

[d]HAMD: Hamilton Depression Rating Scale.

[e]SDS: Self-Rating Depression Scale.

[f]Included in the study 75%≤I^2<100%.

[g]Differences in stroke courses and depression degree exist in the included research.

[h]Inclusion of too small a sample size for the study (sample size for continuous variables <400).

[i]BI: Barthel index.

[j]NIHSS: National Institutes of Health Stroke Scale.

[k]TESS: Treatment Emergent Symptom Scale.

Heterogeneity Assessment

Of the reported outcomes, 25 of 60 (42%) demonstrated no heterogeneity (I^2<25%), 11 of 60 (18%) showed low heterogeneity (25% ≤I^2<50%), 8 of 60 (13%) moderate heterogeneity (50% ≤I^2<75%), and 16 of 60 (27%) high heterogeneity (I^2≥75%). Meta-analyses with high heterogeneity primarily used clinical effective rate and HAMD score as outcomes (Table S2 in Multimedia Appendix 1) [16,19-41].

Overlap of Primary Studies

The primary research indicators we observed were mostly mild to moderate overlap (Table 3). A CCA <10% may suggest incomplete coverage of original studies in the field, with key clinical trials not being adequately included (eg, publication bias of negative results), and a lack of targeted evidence for subgroup populations (eg, different stroke types and severity of depression).

[g]NIHSS: National Institutes of Health Stroke Scale.

Discussion

Main Findings

Acupuncture therapy is increasingly used for PSD in clinical practice, primarily due to its capacity to mitigate depressive symptoms, enhance patients' quality of life, and diminish the adverse side effects typically associated with pharmacological treatments. In recent years, the body of systematic reviews on acupuncture for PSD has grown substantially. This study undertook a comprehensive evaluation of the existing literature, focusing on methodological quality, reporting quality, and evidence quality, to elucidate current weaknesses and provide guidance for future research. Overall, our findings indicate that the included systematic reviews and meta-analyses generally experienced low methodological, reporting, and evidence quality, largely a result of the poor quality of primary studies, especially due to high risks of bias such as inadequate randomization and insufficient allocation concealment. Furthermore, the primary research indices demonstrated mainly mild to moderate overlap, suggesting that coverage of original studies in this field remains incomplete, leaving potentially pivotal clinical trials unincorporated.

Potential Mechanism

The pathogenesis of PSD is multifactorial. Two major hypotheses involve neurotransmitter imbalance and glutamate-mediated excitotoxicity [50]. The monoaminergic mechanism posits that lower levels of monoamines—such as serotonin, norepinephrine, and dopamine—are associated with depressive symptoms [51]. In addition, glutamate, the brain's principal excitatory neurotransmitter, is often elevated in patients with PSD, reflecting a state of excitotoxicity and contributing to depressive pathology [52].

Acupuncture is believed to modulate these neurochemical disturbances. Animal and clinical studies suggest that acupuncture elevates levels of serotonin, norepinephrine, and DA in the brain, normalizes glutamate concentrations, and upregulates key neurotransmitter receptors with fewer desensitization issues compared with pharmacotherapy [53-55]. Beyond neurotransmitter effects, acupuncture exerts anti-inflammatory actions, reducing levels of proinflammatory cytokines and improving immunological balance—processes increasingly recognized as pivotal in PSD progression [56-61]. Furthermore, acupuncture appears to modulate the hypothalamic–pituitary–adrenal axis, helping to normalize neuroendocrine function, and may also reduce neuronal apoptosis, particularly within the hippocampus, which is closely linked to mood regulation [62-65].

Quality Summaries

The methodological quality of the included reviews was evaluated using the AMSTAR 2 system. The methodological strengths of the included reviews were the use of appropriate methods for outcome statistics (24/24, 100%), a satisfactory

XSL•FO
RenderX

assessment of risk of bias (24/24, 100%), and study selection and data extraction in duplicate (15/24, 62.5%). Common methodological weaknesses included the failure to provide preregistered protocols (5/24, 20.8%), explain ROB in individual studies when interpreting results (7/24, 29.2%), provide a full list of excluded studies (0/24, 0%), and extract data on funding sources (0/24, 0%).

The methodological quality of reviews was systematically assessed using AMSTAR 2. All included reviews applied appropriate statistical methods and risk of bias assessments (24/24, 100%) and most performed duplicate selection and data extraction (15/24, 62.5%). However, major shortcomings were evident: only a minority preregistered protocols (5/24, 20.8%), few explained the risk of bias in interpreting results (7/24, 29.2%), none provided a list of excluded studies (0/24), and none extracted funding source data (0/24). The absence of protocol registration and transparency in study selection raises concerns about selective reporting.

According to the GRADE system, although acupuncture appeared more effective than controls for PSD, none of the 60 outcome variables achieved a high-quality evidence rating, and only 8 were rated as moderate quality. Most underlying RCTs were small, single-center studies, with risk of bias, mostly from inadequate blinding, being the most prominent factor for downgrading.

Regarding PRISMA 2020 criteria, the reporting quality was generally suboptimal: only 1 review [22] had major defects, 21 had certain deficiencies, and 2 [16,34] met standards for completeness. Notably, most reviews neglected protocol registration, subgroup or sensitivity analyses for heterogeneity, or evidence grading for outcomes. Several lacked key visualizations such as flow or bias charts, and some failed to report funding or conflicts of interest, compromising the transparency and objectivity of their results.

Outlook and Recommendations

Almost all of the included SRs exhibited low or very low methodological quality, indicating an urgent need to improve the conduct and reporting of these reviews. Acupuncture shows promise as a complementary approach for improving depressive symptoms after stroke. However, these findings highlight a pressing need for large, well-designed, randomized controlled trials and higher-quality systematic reviews. Assessments typically rely on scales such as HAMD, SDS, and the modified Edinburgh-Scandinavian stroke scale, but these are somewhat subjective and may introduce bias. Future research should emphasize blinding (of both patients and outcome assessors), clearer methodology, robust protocol registration, and transparency regarding funding and conflicts of interest, in order to improve the reliability and applicability of the evidence. In addition, the results showed that there was mainly mild to moderate overlap, and key clinical trials may not have been included. Follow-up studies need to increase the coverage of clinical trials and include multiple languages and countries.

Strengths and Limitations

A principal strength of this review lies in its focus on meta-analyses of RCTs, representing the highest tier of evidence, with rigorous eligibility criteria to minimize confounding. Nonetheless, several limitations should be acknowledged: (1) interventions were heterogeneous across studies, precluding quantitative synthesis; (2) the included systematic reviews generally exhibited low methodological, reporting, and evidence quality; (3) the lack of differentiation between different subtypes of PSD and TCM syndromes complicates the interpretation of the evidence for acupuncture in treating PSD; and (4) the subjective nature of AMSTAR 2 and PRISMA assessments could introduce rater bias.

Conclusions

Overall, the preponderance of current systematic reviews suggests a positive effect of acupuncture in the management of PSD. However, the evidence base is undermined by pervasive deficiencies in methodological rigor and quality of reporting. To advance the field and inform clinical decision-making, further high-quality multicenter RCTs and rigorously conducted systematic reviews are imperative.

Acknowledgments

The authors would like to thank the authors of the primary studies, which were used as a source of information to conduct this study. This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.

This study received funding from the Regional Key R&D Program of Ningxia Hui Autonomous Region (grant number 2024BBF01004).

Data Availability

All relevant data generated and analyzed are included in this study.

Authors' Contributions

XCT conceived the study. LM and CLX performed the literature search. LM and CLX performed the parsing of the literature. LM and XXH evaluated the methodological quality, reporting quality, and evidence quality of the literature. LM and CLX performed the writing and prepared the figures. XCT edited and revised the manuscript.

Abstract

Background: Dementia is a global health challenge, particularly in Nigeria, where limited health care infrastructure, cultural stigmas, and poor awareness hinder its care. Telemedicine can improve patient outcomes, increase health care access, and support caregivers. However, challenges such as poor internet connectivity, digital literacy, and a lack of integrated strategies hinder its adoption, particularly in rural areas.

Objective: This scoping review aims to evaluate the adoption of telemedicine for dementia care in Nigeria by highlighting existing interventions, their effectiveness, implementation challenges, and contextual barriers. It also draws on global evidence to propose culturally relevant, sustainable strategies.

Methods: A scoping review was conducted using the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) framework. Peer-reviewed articles were included if they focused on telemedicine or digital health interventions for dementia care in Nigeria or sub-Saharan Africa and published between January 2010 and February 2024. Databases searched included PubMed, Scopus, CINAHL, PsycINFO, Cochrane Library, and Google Scholar. A total of 23 articles met the inclusion criteria.

Results: Among the 23 studies, 10 (43.5%) focused on mobile health apps, 8 (34.8%) on video consultations, and 5 (21.7%) on remote monitoring tools. These interventions improved caregiver support, medication adherence, and access to specialist care. Key barriers included limited digital literacy, poor internet access, and a lack of cohesive national telemedicine policy.

Conclusions: There is an urgent need for an inclusive national telemedicine policy in Nigeria. Interventions such as mobile health, video consultations, and remote monitoring tools show potential to enhance dementia care, reduce caregiver burden, and improve health outcomes.

KEYWORDS

telemedicine; dementia care; Nigeria; mHealth; video consultations; remote monitoring; caregiver support; health care accessibility; national telemedicine strategy; mobile health

Introduction

Overview

Dementia is a progressive neurodegenerative condition marked by declining memory, cognitive abilities, and daily functioning, and it presents a significant global health burden [1]. According to the World Health Organization, more than 55 million people are currently affected worldwide, with nearly 10 million new cases emerging each year. This number is expected to rise to 74.7 million by 2030 and 131.5 million by 2050, underscoring the urgent need for scalable and sustainable models of care. Although the social and health care implications of dementia are increasingly recognized globally, its impact in culturally diverse and resource-limited settings, such as Nigeria, remains insufficiently examined.

Nigeria, Africa's most populous country, is home to more than 250 ethnic groups and more than 500 languages, yet its adult literacy rate is only 62% with significant urban-rural disparities [2]. The education system faces diglossia, as English contrasts with indigenous languages, affecting health care communication and dementia care. Early-onset dementia is rare but tends to progress more rapidly [2]. Clinical presentations of dementia in Nigeria differ from those in developed countries due to cultural interpretations of aging conditions [3]. Behavioral and psychological symptoms are poorly recognized and

XSL•FO
RenderX

underreported due to stigma and lack of awareness in rural areas (Figure 1).

Figure 1. Geographical map highlighting the northeastern Nigerian region for telemedicine dementia care.

Digital literacy worsens these issues: mobile phone adoption has increased in Nigeria, with more than 70% of the population owning at least 1 device [4]. This highlights the need to address awareness gaps for better telemedicine use in dementia care.

The article evaluates Nigeria's telemedicine adoption for dementia care, examining sociocultural, linguistic, and technological contexts, while identifying gaps to improve outcomes [5].

The Role of Telemedicine in Dementia Care

Telemedicine enhances dementia care in Nigeria by providing remote clinical services. According to Louis et al [6], this system includes diagnosis and consultation via mobile phones and computers [7].

Telemedicine allows patients and caregivers to connect with health care professionals, reducing the psychological impacts of distancing [8]. During the pandemic, remote consultations, monitoring, and cognitive assessments eased isolation burdens while strengthening relationships with families and health care professionals, improving well-being and identity [9,10].

Telemedicine use in Nigeria increased during COVID-19, highlighting the need for remote care as face-to-face became limited [11]. Restrictions worsened social isolation and reduced health care access for individuals living with dementia and caregivers [12]. Telemedicine supports diagnosis, caregiver assistance, and community education [10]. In Nigeria, telemedicine provides a viable means to improve dementia care through remote services using computers and mobile phones [13,14].

Dementia remains a global health concern [15]. Increased awareness has emphasized caregiver support, with telemedicine emerging as a key intervention for COVID-19 [15,16].

This review discusses the effectiveness and challenges of telemedicine interventions for dementia care in Nigeria. It also aims to guide future development in resource-poor settings by assessing current usage [17]. Active interventions such as videoconferencing, remote assessment, and mobile apps are prioritized over passive monitoring technologies. According to Haimi [18], research highlights issues such as poor internet connectivity and technological inequality. Despite these issues, telemedicine shows promising potential for improving dementia care in Nigeria and justifies further studies [19].

Conceptual Framework

The conceptual framework shows interactions between caregivers, health care professionals, individuals living with dementia, and technologies to enhance care delivery [13]. Mobile health (mHealth) app video consultations and monitoring devices improve access and integrate stakeholders into a unified system [20]. Caregivers use telemedicine tools for care management, while health care providers use them for diagnosis, treatment, and follow-up. These tools help overcome geographical barriers [21]. Technologies support caregivers in planning routines and seeking advice [22]. Video consultations address and improve specialist access, and monitoring systems

XSL•FO
RenderX

track health for timely intervention [23]. This framework improves health care delivery, reduces caregiver burden, and provides an improved quality of life [24], helping stakeholders identify areas needing improvement.

Digital Literacy

Digital literacy is essential for telemedicine adoption, especially in resource-poor countries such as Nigeria [25]. It remains a challenge in urban and rural areas [26]. Mobile phone penetration is 70%, but rural digital literacy is about 30% compared to 62% in urban areas, highlighting a digital gap affecting telemedicine [23]. Urban caregivers benefit from better infrastructure, while rural caregivers face limited access, education, and training [27]. Low literacy in rural areas hinders the use of telemedicine tools, such as mHealth or video consultations for specialist care [28,29].

Challenges of Telemedicine Adoption in Nigeria

Despite the potential benefits, barriers hinder telemedicine use in Nigeria, especially in rural areas [30]. Technological challenges include infrastructure, internet services, and digital literacy, while nontechnological ones involve ethical concerns and funding issues [31]. This scoping review evaluates the adoption of telemedicine for dementia care in Nigeria, highlighting interventions, effectiveness, challenges, and contextual barriers. It draws on global evidence to propose culturally relevant and sustainable strategies for implementation.

Methods

Study Design

This study used a scoping review methodology, guided by the PRISMA-ScR (Preferred Reporting Items for Systematic reviews and Meta-Analyses extension for Scoping Reviews) framework. The purpose of this work was to explore the adoption of telemedicine for dementia care in Nigeria by identifying current interventions, implementation challenges, and research gaps.

Eligibility Criteria

Peer-reviewed articles were eligible for inclusion if they (1) focused on dementia care in Nigeria or sub-Saharan Africa; (2) included individuals living with dementia, caregivers, or health care professionals; (3) reported on telemedicine or digital health interventions (eg, mHealth apps, video consultations, or remote monitoring); (4) were published in English between January 2010 and March 2024; and (5) applied empirical methods, including qualitative, quantitative, or mixed-methods design. Conversely, studies were excluded if they (1) focused on diseases other than dementia, (2) lacked telemedicine components, (3) were purely theoretical or not empirical, or (4) were not published in English (Table 1).

Table . Inclusion criteria and exclusion criteria for the scoping review.

Criteria	Inclusion	Exclusion
Population	Individual living with dementia, caregiver, or health care professionals	Other diseases than dementia
Interventions	Studies that involve telemedicine interventions or telehealth	Studies that do not involve telemedicine interventions
Study design	Studies that include qualitative, quantitative, and mixed designs	Studies that are purely theoretical
Outcomes measure	The effectiveness of telemedicine on dementia care	No outcomes related to the impact of telemedicine on dementia care
Publication date	Studies published from 2010 to 2024	Studies published before 2010
Language	Studies published in English	Studies published in languages other than English

Information Sources

The following databases were searched: PubMed, Scopus, CINAHL, PsycINFO, Cochrane Library, and Google Scholar. In addition, citation searching involved backward citation tracking from the reference lists of included articles and relevant systematic reviews to identify further relevant studies.

Search Strategy

A comprehensive search strategy was developed using keywords such as “telemedicine,” “dementia care,” “digital health,” “remote care,” “caregiver support,” “Nigeria,” and “Sub-Saharan Africa.” Boolean operators and truncations were used to optimize search results. The full search strategy is available in Multimedia Appendix 1.

Study Selection

Study selection followed a 2-stage screening process in accordance with the PRISMA-ScR framework. In the first stage, 640 records were identified through searches of PubMed, Scopus, CINAHL, PsycINFO, Cochrane Library, and Google Scholar. After removing 220 duplicate records, 420 titles and abstracts were screened independently by 2 reviewers (AA and EO). In the second stage, 100 full-text articles were also independently assessed for eligibility by the same 2 reviewers. At both stages (title or abstract and full-text screening), disagreements were resolved through discussion with a third reviewer (HD).

Data Charting Process

Data were independently extracted by 2 reviewers (AA and EO) using a standardized data charting form, which was piloted and

XSL•FO
RenderX

refined prior to full data extraction. Discrepancies were resolved through discussion, and when necessary, by involving a third reviewer (HD).

Data Items

The following items were extracted from each included study: authorship, publication year, country, study design, target population, type of telemedicine intervention, measured outcomes, and main findings.

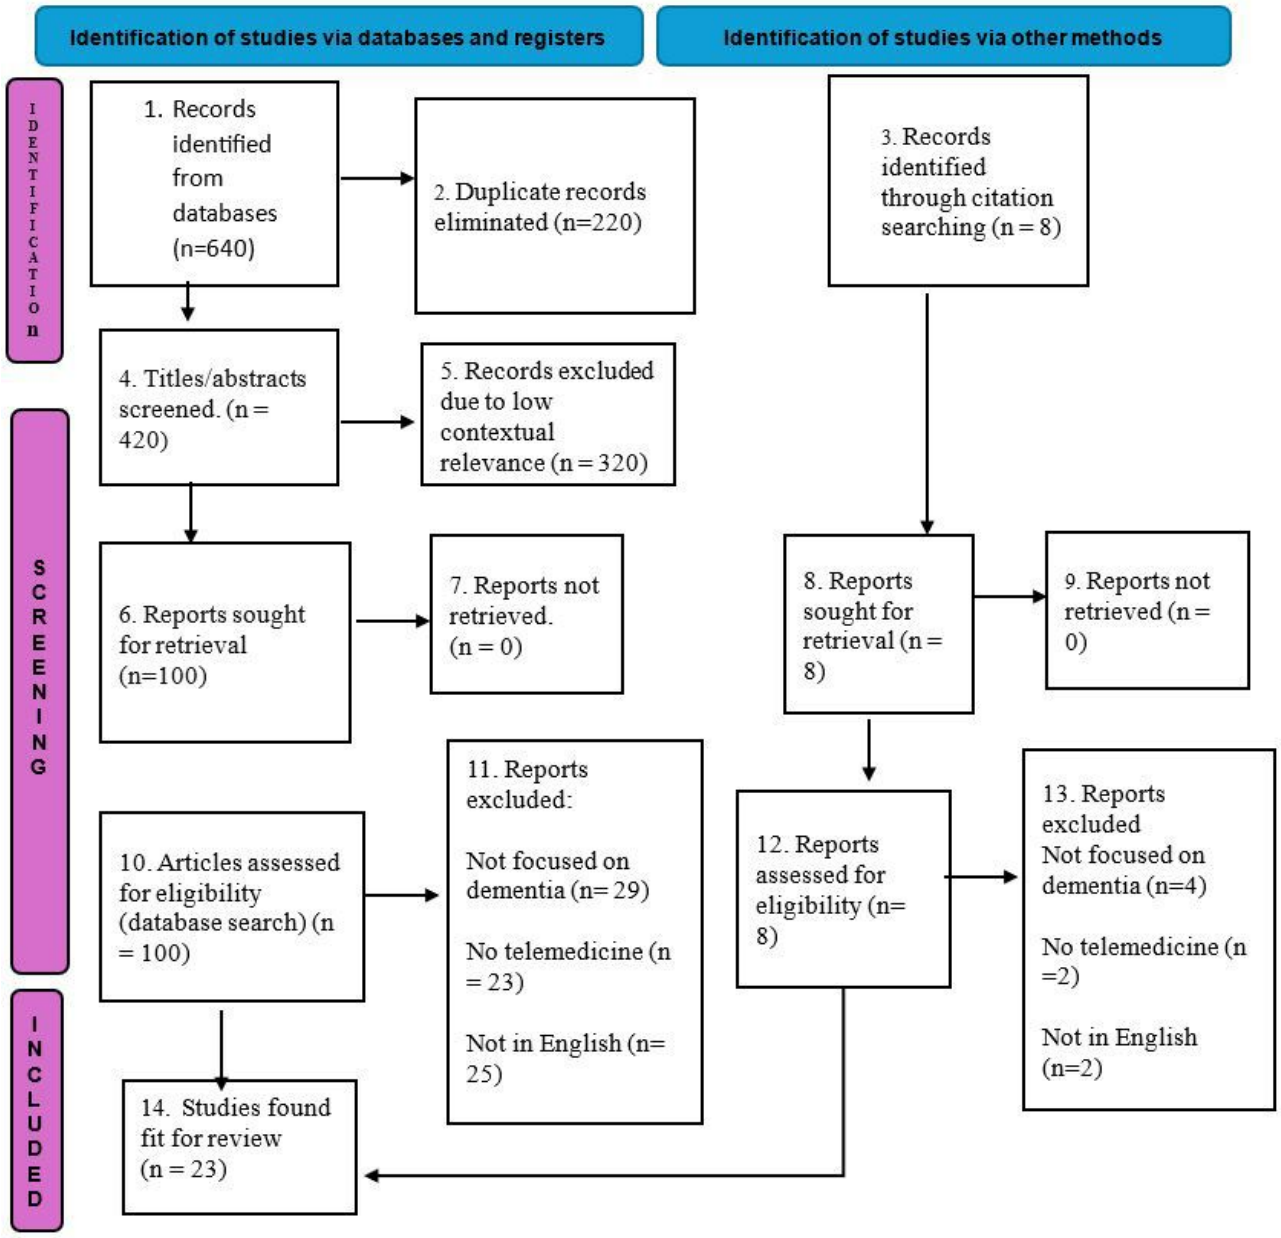
Synthesis of Results

A narrative synthesis was used to categorize the data into 3 main themes: (1) types of telemedicine interventions, (2) barriers to adoption, and (3) facilitating factors. Where applicable, frequencies and percentages were used to summarize the distribution of study characteristics and intervention types.

Data Synthesis by Intervention Type

The extracted data were grouped by type of telemedicine intervention. These included mHealth apps, video consultations, and remote monitoring tools. A narrative synthesis was conducted to identify patterns across studies and categorize findings into key intervention types. The goal was to compare their reported outcomes, implementation contexts, and barriers in dementia care delivery.

Results



Overview

The reviewed studies explored a variety of telemedicine interventions applied to dementia care within Nigerian or sub-Saharan African contexts. These interventions included mHealth apps, video consultations, and remote patient monitoring systems aimed at supporting caregivers, improving access to specialist care, and enhancing patient outcomes. The included studies used diverse methodological approaches, including qualitative interviews, cross-sectional surveys, randomized controlled trials (RCTs), and mixed methods designs. Terms commonly used across the studies included “telemedicine,” “digital health,” “remote care,” “mHealth,” and “eHealth,” reflecting a broad conceptual framing of digital health delivery in dementia care.

The study selection process is outlined in Figure 2 below. Out of 640 initial records, 420 were screened, 40 full-text articles were assessed, and a total of 23 studies met the inclusion criteria and were included in the final review. An additional 8 records were identified through backward citation searching of included studies and relevant systematic reviews. All 8 records were retrieved and assessed for eligibility. However, none met the inclusion criteria due to reasons such as not focusing on dementia (n=4), lack of telemedicine components (n=2), and not being published in English (n=2).

XSL•FO
RenderX

Figure 2. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) flow diagram showing the selection process.

Characteristics of Included Studies

In various regions, the primary characteristics of the studies are outlined in Table 2. A total of 23 studies were conducted mainly in Nigeria (n=7) [1,6,9,11,14,32,33], followed by the United States (n=5) [34-38], the United Kingdom (n=6) [39-44], Hong Kong (n=2) [45,46], Greece (n=1) [13], Germany (n=1) [47], and Spain (n=1) [48]. Study settings varied, individuals' homes (n=6), health care institutions (n=10), and mixed environments (n=7).

[d]mHealth: mobile health.

[e]QoL: quality of life.

[f]QoL-AD: quality of life in Alzheimer disease.

XSL•FO
RenderX

Telemedicine interventions range from remote monitoring, mHealth apps, and video consultations, reflecting differences in health care infrastructure across urban and rural Nigeria. The intervention designs were diverse, highlighting the varied nature of telemedicine adoption.

Three studies were RCTs [46,51,52]. Five studies used quantitative methods, including observational and pretest-posttest designs [6,45,47,53,54]. Six studies used qualitative methods focusing on interviews and observational data to explore feasibility, acceptability, and implementation challenges [13,34,39,48,55,56]. Nine studies used mixed methods, combining quantitative (eg, surveys) and qualitative (eg, interviews) data for comprehensive evaluation [9,11,28,33,35,41,43,49,50]

Sample sizes varied, the largest study involving 250 participants [35] and the smallest only 11 participants [37]. Three studies reported sample sizes over 100 participants [35,45,53], with larger studies using quantitative methods and smaller ones exploring qualitative insights and feasibility. Outcome measure varied, caregiver burden was assessed in 6 studies using self-reported questionnaires [6,11,32,35,39,45]. Four studies used standardized scales to measure quality of life among individuals living with dementia, such as the QoL-AD scale [6,45,46,54]. Studies in rural areas often identified internet access and digital literacy as critical secondary outcomes [6,48]. Two studies addressed behavioral and psychological outcomes, highlighting reductions in agitation and caregiver stress [34,39]. The projected telemedicine growth in Nigeria from 2018 to 2024 shows increased use of mHealth apps, video consultations, and remote monitoring tools across urban and rural areas. Studies show mHealth apps are widely used in Nigeria for telemedicine, supporting caregivers in managing care routines, monitoring individuals living with dementia's health [33].

Common barriers include poor internet connectivity [40], high-cost platforms, devices, and mobile data for health care professionals and caregivers [38]. High mobile phone penetration supports mHealth adoption, particularly in urban areas [49]. This study highlights the challenges and benefits of telemedicine for dementia care in Nigeria, revealing gaps in infrastructure and cultural adaptation. Table 2 summarizes the studies, detailing locations, study design, sample sizes, interventions, and outcomes.

Types of Intervention

Studies (n=23) were grouped according to the type of telemedicine intervention, including mHealth apps (n=10), video-based interventions (n=8), and remote monitoring interventions (n=5).

mHealth-Based Telemedicine Interventions

Ten studies assessed mHealth interventions for dementia care [11,32,36,41,45,47,52,53,55,57]. These included apps for communication, medication reminders, and stress management [45,55], as well as health-tracking tools for cognitive decline and behavior [36,47,58]. Smartphone-based systems improved usability, adherence, and caregiver support [11,32,41,52,53], though barriers such as cost, internet access, and digital literacy persist [11,52].

Video Consultations

Eight studies [9,13,34,35,42,46,53,58] evaluated video consultations linking individuals with dementia and their caregivers to health professionals . These interventions improved specialist care coordination, proved most effective for monitoring and assessments in urban areas, and reduced caregiver travel burden while enhancing access to specialists, although their effectiveness in rural settings was limited by internet connectivity challenges.

Remote Monitoring Tools

Five studies [6,34,39,41,50] investigated remote monitoring tools, including wearable sensors and home-based systems, for assessing cognitive function, daily activity, and sleep patterns. While these technologies demonstrated potential for early detection and improved care management, their adoption was hindered by costs and limited digital literacy, particularly in rural areas.

Caregiver Support Apps

Four studies evaluated apps supporting caregivers [11,36,53,55]. These tools improved communication and reminders, reducing stress [55], enhancing well-being [53], and supporting telehealth and national strategies [11,36].

Remote Health Tracking Apps

Three studies [36,55,58] addressed mHealth apps monitoring cognitive decline and quality of life. Yi et al [36] evaluated medication adherence and cognitive tracking, while Zou et al [57] showed reduced hospital visits, Hengst et al [41] noted improved medication adherence and socialization, while Zhu et al [47] highlighted effective symptom tracking and reduced emergency visits.

Video-Based Interventions

Teleconsultations for Specialist Care

Three studies [7,13,37] found video consultation improved care access without in-person visits. Ruggiero et al [59] reported improved quality of life and cognitive scores, especially in urban areas. Chi and Demiris [44] noted reduced stress and better patient outcomes through checkups.

General Remote Video Visits

Two studies examined routine video consultations for dementia care, which addressed caregiver concerns but produced mixed results [1,46]. While Mulili et al. [1] highlighted that poor connectivity limited adoption in rural areas, Page et al [46] reported reduced caregiver burden through their regular use.

Remote Monitoring Tools

Four studies [11,13,35,53] examined home-based and wearable sensors. Cote et al [39] evaluated wearable sensors tracking daily activities, enabling early interventions. Ojeahere et al [34] highlighted monitoring devices tracking behavioral changes and improving care.

Home-Based Systems

Home systems monitored daily activities, cognitive health, and behaviors, Cote et al [39] noted early detection of health

XSL•FO
RenderX

declines, while Ojeahere et al [34] reported reduced caregiver workload, particularly useful in rural areas.

Wearable Sensors

Wearable sensors improved health tracking accuracy and interventions. Chi and Demiris [44] noted effective monitoring, while Louis et al [6] emphasized cost challenges but potential for scaling in resource-poor settings.

Internet Access

Rezigalla [54] and Ojeahere et al [34] discussed the challenges posed by limited internet connectivity in rural areas, which hindered the implementation of telemedicine tools. These studies suggested infrastructure improvements as a critical step to expanding telemedicine access in such regions.

Digital Literacy

Digital literacy was a major barrier noted by Gately et al [32] and Oyinlola et al [11]. Many caregivers and health care providers lacked the skills to use telemedicine platforms effectively, reducing their uptake. The studies recommended comprehensive training to improve digital competency and telemedicine effectiveness.

Challenges and Feasibility

Several studies highlighted the challenges that remain despite the benefits of remote monitoring. Louis et al [6] reported improvements in urban care management, but clinician readiness, poor internet, device costs, and legal concerns hindered rural adoption. Similar barriers were noted in Germany by Mulili et al [1], where lack of training, financial challenges, and inadequate health care infrastructure limited remote monitoring effectiveness. Travers et al [53] noted that low-resource settings faced technical literacy issues, restricting the scalability of interventions. Other interventions such as telepsychiatry and online support networks were explored [60,61]. Aderinto et al [61] studied telepsychiatry in rural Nigeria, showing potential to address mental health disparities in dementia care. Oyinlola et al [11] evaluated online support groups, noting reduced stress and caregiver burden through resource sharing and social support.

Telemedicine Platforms and Legal Frameworks

The scope of telemedicine platforms and regulatory frameworks affecting dementia care in low-resource settings was examined [14]. In rural areas, regulatory barriers to adoption were identified, indicating the need for supportive legal frameworks. Hamilton and Finley [56] reviewed platforms, noting that effective ones improved patient satisfaction and outcomes but were hindered by cost and accessibility issues.

Gaps in Research

The review identified several gaps in the current research on telemedicine for dementia care in Nigeria. First, lack of large-scale studies: larger studies are needed to assess the long-term impact of telemedicine on dementia care; most studies are small-scale [11]. Second, minimal focus on cultural adaptation: limited research addresses adapting telemedicine tools to meet the cultural needs of caregivers and health care professionals [62]. Third, absence of RCTs: few RCTs have been conducted to strengthen evidence for policy and compare telemedicine with traditional care in Nigeria [63].

Discussion

Summary of the Findings

This scoping review examined telemedicine interventions for dementia care in Nigeria, focusing on video consultations, mHealth, and remote monitoring tools. Video consultations effectively improved specialist access and reduced caregiver burden [11]. mHealth apps are the most used intervention due to high mobile phone penetration [63], while remote monitoring tools face challenges in rural areas due to poor internet connectivity and digital literacy gaps [3]. Key barriers include infrastructural limitations, lack of a cohesive strategy, and cultural barriers [4]. Despite challenges, telemedicine shows potential to enhance patient outcomes, reduce caregiver burden, and improve health care access [56]. The findings align with recent studies demonstrating increased adoption of digital health in low-resource settings [26,37,52]. In addition, successful implementation models, such as remote patient monitoring in dementia care, have been demonstrated in previous studies that reported the successful implementation of remote patient monitoring for dementia care [42,57].

Detailed Discussion of Findings

Video consultations address the shortage of dementia specialists by reducing caregiver travel stress and providing timely health care access [23]. However, poor internet access and inconsistent electricity supply hinder implementation in rural areas, such as other sub-Saharan nations facing infrastructural challenges [5,53]. The extensive use of mHealth apps helps caregivers manage routines and monitor health [4]. High mobile phone penetration supports mHealth adoption, particularly in urban areas, but gaps in digital literacy limit rural use. This issue is consistent with other low- and middle-income countries facing similar telemedicine challenges [64].

Remote monitoring tools, such as wearable sensors and home-based systems, support continuous health monitoring and early detection of cognitive decline, reducing hospital visits [58]. However, affordability, digital literacy, and infrastructure challenges limit their use in Nigeria, reflecting similar issues reported globally [45,58].

Cultural and linguistic diversity also impacts telemedicine adoption. Many older adults and caregivers in rural areas are not fluent in English, the primary language of most platforms [65]. Effective adoption requires multilingual support and culturally appropriate frameworks [66]. This aligns with findings from other multicultural regions emphasizing culturally tailored interventions [65].

Limitations

This review has limitations. The methodological quality of studies varies, with many relying on qualitative data, limiting applicability across Nigeria [18]. The review focused on published literature, overlooking relevant gray literature [52]. Few long-term studies evaluate the lasting impact of telemedicine interventions on dementia care outcomes in

XSL•FO
RenderX

Nigeria, with long-term effects still unknown, despite short-term advantages [13]. Lastly, issues with internet connectivity and digital literacy are commonly noted, but strategies to address them were not comprehensively explored [41].

Conclusions

This review highlights the urgent need for a comprehensive telemedicine policy framework integrating technological solutions within existing dementia care systems. Addressing infrastructural limitations, encouraging caregiver training, and developing culturally adapted tools are essential for broader acceptance. Caregiver-centered solutions can support a sustainable model for dementia care in Nigeria. Policymakers should focus on long-term evaluations, RCTs, and scalable models to bridge the digital divide. These strategies will enhance the quality of life for individuals with dementia and establish Nigeria as a leader in innovative health solutions for resource-limited settings.

Abstract

Background: Digital interventions for obesity have demonstrated efficacy in obesity prevention and management. The emergence of smartphones and ubiquitous apps such as WeChat represents potential modality to enhance the reach, sustainability, and cost-effectiveness of such interventions. By the end of the first quarter of 2024, WeChat had approximately 1.36 billion monthly active users, accounting for 96.5% of China's population. The use of this platform for obesity interventions has been validated in multiple Chinese trials, most published in Chinese language journals.

Objective: We aim to synthesize the existing evidence on obesity interventions delivered through WeChat to generate implications for future intervention design and development, thereby reaching an international audience.

Methods: We conducted a scoping review of PubMed and China National Knowledge Infrastructure using search terms including "WeChat," "obesity," "weight," "BMI," "waist circumference," "hip circumference," "waist-to-hip ratio," "body fat," "skin fold thickness," and these Chinese equivalents "weixin," "feipang," "tizhong," "tizhongzhishu," "yaowei," "tunwei," "yaotunbi," "tizhi," and "pizhehoudu." We included only original research studies, theses, or dissertations with measurable outcomes that used WeChat functions as intervention strategies. Study quality was assessed using the National Institutes of Health Quality Assessment Tool, with specific tools selected based on study design. Descriptive statistics were applied, with categorical variables summarized as frequencies and percentages (n, %) to report study distribution.

Results: Our scoping review based on PubMed and China National Knowledge Infrastructure identified 665 initial records, among which 43 studies met eligibility criteria and were included for data extraction to characterize intervention details. Results indicated effectiveness in 86.0% (37/43) of studies, with WeChat-assisted obesity interventions achieving significant short- and long-term weight loss measured by objective outcomes (body weight, BMI, waist circumference, hip circumference, waist-to-hip ratio, and body fat percentage). However, formative research informing intervention design was insufficient. Common methodological limitations included lack of randomization and blinding (42/43, 97.7%) and unreported intervention compliance metrics (39/43, 92.0%). Functionally, interventions primarily used "WeChat group" and "Official Account"—public accounts that provide health education, diet or physical activity logging, and other features.

Conclusions: Overall, WeChat represents a promising platform for obesity interventions; however, current apps fail to leverage its full features (eg, online payment and live streaming). Key limitations include methodological heterogeneity and cultural specificity, which were addressed through narrative synthesis stratified by study types. Future research should incorporate the formative phase and use more rigorous methodologies such as randomized controlled trials to optimize intervention design and delivery via this modality.

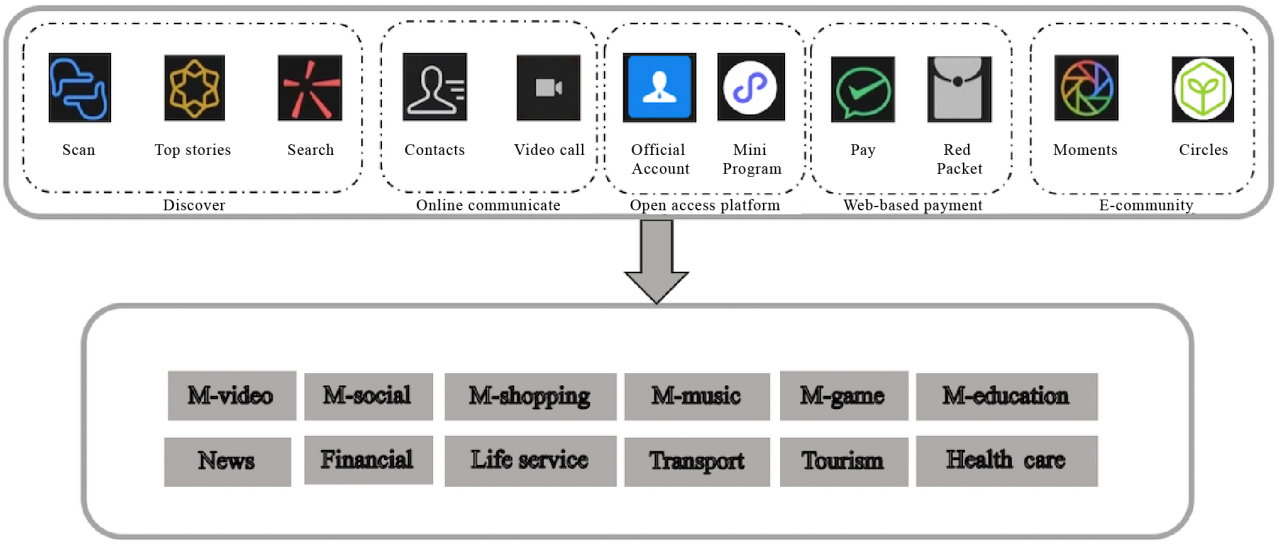
Introduction

Obesity is a global health crisis affecting low- and middle-income as well as high-income countries [1,2]. According to the 2023 Chinese Nutrition and Chronic Diseases Survey, more than 50% of Chinese adults were overweight or obese [3], with prevalence rates of nearly 20% among adolescents and 10% in children younger than 6 years [3]. Obesity is strongly associated with noncommunicable chronic diseases (NCDs), particularly fatty liver, diabetes, hypertension, and dyslipidemia [4]. Furthermore, NCDs accounted for 90.1% (9.6 million) of deaths and 84.9% (324.6 million) of disability-adjusted life years in China in 2019 [5]. Wang et al [6] project that the prevalence of overweight or obesity in Chinese adults will reach 65.3% (790.0 million) by 2030, potentially leading to a 22.0% (more than CNY 400.0 billion [more than US $60 billion]) increase in total medical costs. In response, the Healthy China Action Plan 2019‐2030 established 15 key strategies, including 11 focused on NCDs intervention [7]. Thus, implementing evidence-based obesity interventions is critical for preventing future NCD-related mortality.



Although nearly 90% of countries globally have committed to addressing obesity [8], the efficacy of interventions for sustained weight control remains limited [9,10]. Social media platforms are increasingly used in obesity interventions, particularly for health education delivery [11,12]. Digital health apps can expand geographical reach and overcome barriers to in-person care [13], as demonstrated during the COVID-19 pandemic when obesity interventions rapidly shifted toward mobile health (mHealth) solutions [14]. In the United States, of more than 100,000 available health-related apps, more than 28,000 target weight management [15]. By late 2023, China had 1.09 billion web users (77.5% penetration) [16], with web-based health care users reaching 413.9 million—a 14.2% annual increase [16]. By reducing medical expenses, improving adherence, and promoting communication between researchers and participants [17,18], mHealth enables cost-effective and individualized interventions [19,20]. According to a systematic review about weight management mobile technology, there are a great number of apps designed to facilitate obesity interventions [21]. For example, Oviva's NHS Digital–approved app is a convenient way to track weight, keep a food diary, and deliver dietary guidance [22-25]; Kurbo is an app designed to help teenagers and children aged 8-17 years to lose weight, using the Traffic Light System designed by Stanford University [26-28]; W8Loss2Go (Weight Loss to Go), implementing a 3-phase approach (identifying problem foods, minimizing eating between meals, and gradually reducing portion sizes), is effective for weight loss [29]; Weight Watchers Online is a weight loss app that focuses on food, physical activity (PA), sleep, and mindset [30,31]; and BeHealthy provides education on nutrients, sleep, and yoga [32]. While designed for weight management guidance and monitoring, few apps incorporate health care professional input or rigorous validation [33].

WeChat, a dominant media platform with multiple functions launched by the Tencent Company in China on January 21, 2011, reached 1.359 billion monthly active users in Q1 2024—a 3% increase from March 2023 [34]. Monthly active user, a key metric reflecting monthly engagement with WeChat services, demonstrates its pervasive adoption. Although initially the primary function of WeChat was chatting, with version updates, WeChat has updated more and more features integrating social networking, mobile payment, and enterprise solutions through features such as Official Account for content dissemination, Mini Program for lightweight apps, and WeChat group for real-time group communication (Figure 1). The platform's multifunctional ecosystem facilitates diverse aspects of users' lives (Figure 1), including health education delivery [35] and chronic disease management [36] such as hypertension [37,38] and diabetes [39-42].

Although previous studies have summarized the efficacy of mHealth apps for weight management, none have systematically detailed the functional implementation of WeChat in obesity interventions or established evidence-based frameworks for optimizing these functions in future projects. The goal of this study was to conduct a scoping review of existing obesity intervention studies through the WeChat platform and its potential use in future research. We focused on answering the following questions: (1) What WeChat functions have been used in existing obesity prevention or management intervention studies?; (2) What are the primary methodological limitations in these studies?; (3) How can future WeChat-delivered interventions be optimized?

Figure 1. Functions of the WeChat platform.

Methods

Search Strategy

To identify literature on WeChat-based obesity interventions up to April 14, 2024, we searched PubMed and China National Knowledge Infrastructure (CNKI, the largest academic database, aggregating more than 95% of officially published Chinese scholarly resources), using the following search terms: "WeChat," "obesity," "weight," "BMI," "waist circumference (WC)," "hip circumference (HC)," "waist-to-hip ratio (WHR)," "body fat (BF)," "skin fold thickness," and Chinese equivalent characters: "weixin," "feipang," "tizhong," "tizhongzhishu," "yaowei," "tunwei," "yaotunbi," "tizhi," and "pizhehoudu" (Table S1 in Multimedia Appendix 1).

Study Selection

After eliminating duplicates and off-topic studies, all the papers that described WeChat-based obesity interventions were screened against the following inclusion criteria: (1) full-text original or empirical human research published in peer-reviewed journals (including trials with or without control groups, and blinded or nonblinded designs); (2) WeChat as primary intervention delivery platform (eg, dietary or PA guidance, dietary or PA diary logging, etc); (3) Chinese degree theses or dissertations from the CNKI dataset; and (4) objective anthropometric outcomes including body weight, BMI, WC, HC, WHR, body fat percentage (BFP), or skin fold thickness. The exclusion criteria included (1) studies using WeChat solely for participant recruitment or follow-up; (2) self-reported anthropometric parameters; and (3) study protocols, animal studies, reviews, patents, books, or inaccessible texts. This process was done by 2 authors (YNW and XXZ) who independently screened titles and abstracts and conducted full-text reviews to identify the final set of eligible papers for inclusion. Any conflicts during this process were resolved through team consensus discussions. The flow diagram was adapted from the official PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) template with modifications specific to our search strategy [43].

Data Extraction

The following data were extracted from each study: authors, sample size, presence of control groups, WeChat functions used, interventions duration, outcomes measured, and intervention effectiveness. Intervention effectiveness was categorized as (1) "effective" if all predefined weight-related outcomes (eg, BMI, weight, WC, HC, WHC, BFP, etc) showed statistically significant improvements; (2) "partially effective" if only a subset of predefined outcomes demonstrated significant positive changes; and (3) "not" if none of the predefined outcomes demonstrated significant changes. Themes were synthesized from tile or abstract review followed by full-text review using a blinded, independent dual review process by 2 of the authors (YNW and XXZ). Conflicts were resolved through discussion, with a third author (JG) who would arbitrate unresolved conflicts.

Quality Assessment

A detailed quality assessment was conducted using the Quality Assessment Tool for Controlled Intervention Studies and Before-After (Pre-Post) Studies With No Control Group designed by National Institutes of Health (NIH) [44]. The assessment tool of controlled intervention studies is applicable to those with control group and intervention strategies, containing 14 items to evaluate the research. Before-after studies refer to those without control groups, instead comparing outcomes of baseline and the end. The tool for before-after studies consists of 12 items. All scoring criteria were evaluated as "yes," "no," "not applicable (NA)," or "not reported (NR)." For each item, we assigned 1 point for "yes" and "NA," zero points for "no" and "NR." According to the total score, studies were further rated as "good" (10 for controlled intervention studies; 9 for before-after studies), "fair" (5-9 for controlled intervention studies; 5-8 for before-after studies), and "poor" (zero to 4 for both). Two authors (YNW and XXZ) independently completed the quality assessment for each study. Conflicts were resolved via discussion, with a third author (JG) arbitrating unresolved cases.

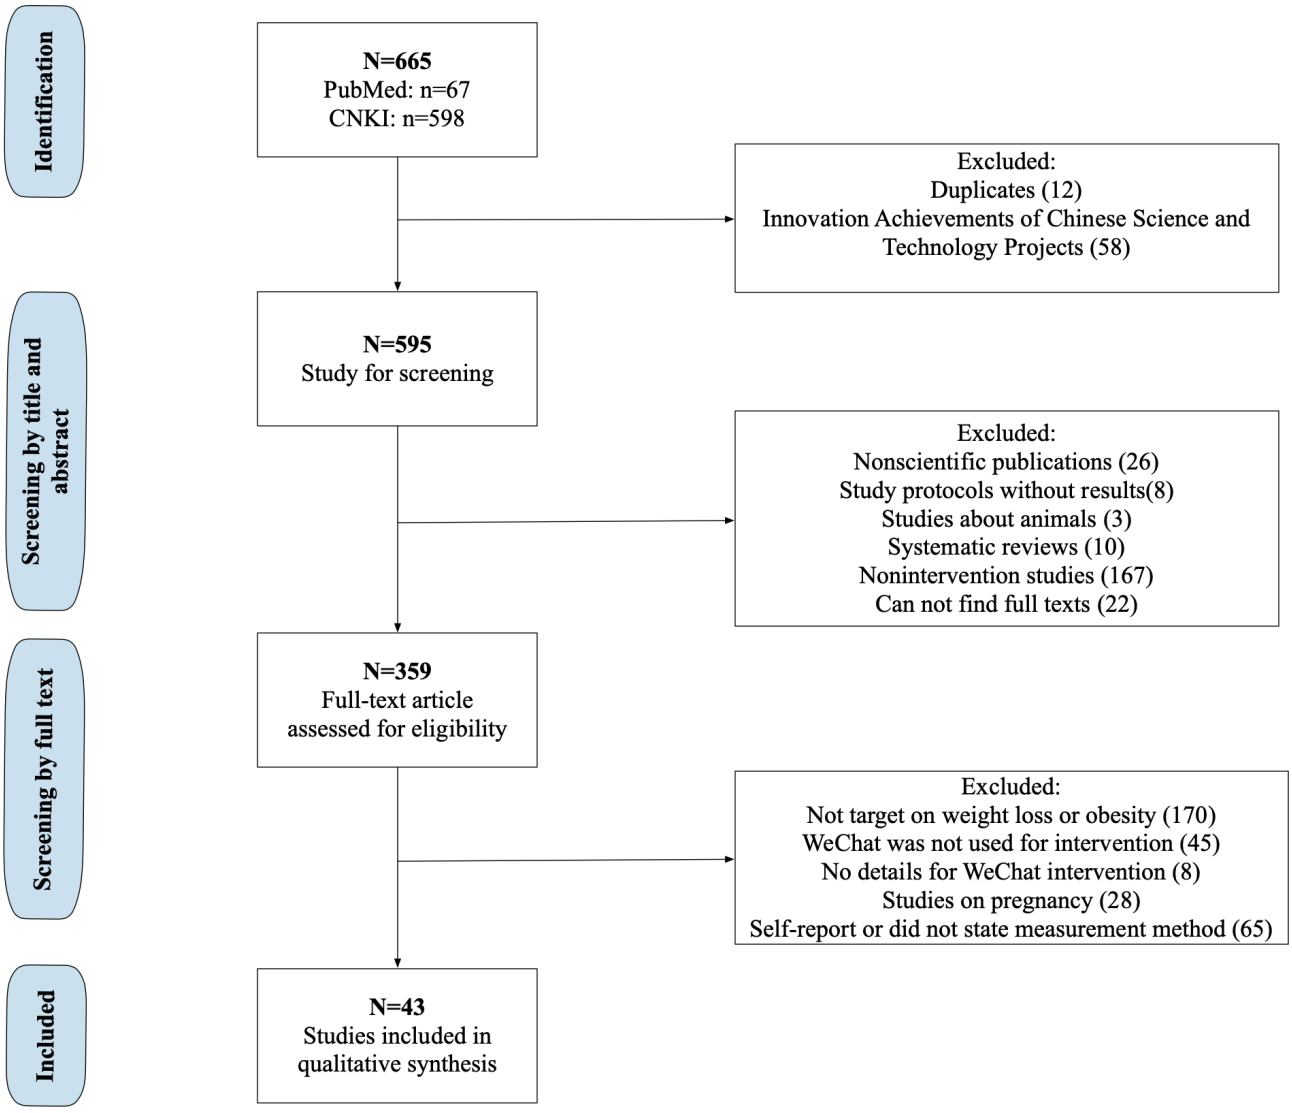
Statistical Analysis



Statistical analyses were performed using GraphPad Prism 8.4.0 (GraphPad). Descriptive statistics were applied, with categorical variables summarized as frequencies and percentages (n, %) to report study distribution across classifications, as well as the quality assessment outcomes of included studies.

Results

Overview

From the initial 665 papers (67 from PubMed and 598 from CNKI), 12 duplicates and 58 Innovation Achievements of Chinese Science and Technology Project designs were excluded. During the first round of title or abstract review, 236 publications were excluded, in which 26 of them were nonscientific publications, 8 study protocols, 3 animal studies, 10 systematic reviews, 167 nonintervention studies, and 22 conference abstracts. Of the 359 studies undergoing full-text review, 315 (87.7%) were excluded due to the following reasons: focus beyond weight loss or obesity (170, 54.0%), WeChat not used for intervention delivery (45, 14.3%), inadequate WeChat intervention strategy details (8, 2.5%), pregnancy-focused studies (28, 8.9%), and self-reported or unverified measures (65, 20.6%). The flow diagram is shown in Figure 2. Eight (18.6%) studies [45-52] were in English with information about study population, control group presence, intervention methods, intervention duration, health outcomes, and intervention effectiveness summarized in Table 1. A total of 35 (35/43, 81.4%) studies [53-87] were in Chinese with study details shown in Table 2. Among the 43 studies finally included, 20 (46.5%) [53,57,59-63,65,70,72,74-76,79,81,83-87] of them were theses or dissertations. All the studies were conducted in mainland China. None of the papers reported using formative research for intervention development. Sample sizes ranged from 20 [64] to 15,310 [46]. Among the 43 papers, 33 (76.7%) [45-47,49-51,56-63,65-67,70-72,74-76,78-87] included a control group, and 26 (60.5%) [45,47,49-51,56-62,65,66,70,72,74,76,78-80,82-86] reported assigning participants randomly. The duration of interventions spanned 4 weeks [51] to 36 months [52].

Table . Summary of studies using WeChat for obesity interventions in English (in order of publication date; n=8).

Authors	Sample	Control group	Intervention related to WeChat	Duration	Outcome	Effective[a] or not
Li et al [49]	42 full-time postgraduate students, Shanghai	Yes (randomized)	WeChat: submit PA[b] diaries WeChat group: connect with other participants for social support	1 month	BW[c], BFP[d], WHR[e], and BMI	Partly effective: BFP
Chen et al [47]	102 women from 2 community health centers in Changsha	Yes (randomized)	WeChat: set up fruit or vegetable intake goals and daily steps, educational modules along with tailored tips and messages, and messages to encourage and reinforce positive behavioral changes	6 months	WC[f] and BMI	Not
Han et al [50]	120 overweight and obese patients with T2DM[g] from a hospital in Nanjing	Yes (randomized)	Official Account: information (video teaching, compulsory course, and Monday paper); function (diet form, resistance or aerobic exercise, body measurement, and homework feedback)	12 months	BMI, WC, HC[h], WHR, and BFP	Partly effective: BMI
Xia et al [45]	343 participants with T2DM	Yes (randomized)	WeChat group: post BG test result, completion of exercises, medication, self-management data WeChat voice call: weekly and monthly summaries to participants	6 months	BW and BMI	Partly effective: BW
Yang et al [52]	977 overweight patients from a hospital in Zhejiang	No (before-after)	WeChat group: report anthropometry (eg, body weight), daily dietary intakes, and PA Mini Program: report body weight WeChat: personal feedback on weight management	36 months	BW	Effective
Ling et al [51]	300 inpatients with primary hypertension in a hospital in Xi'an	Yes (randomized)	Official Account: posthypertension-related knowledge WeChat group: posthypertension-related knowledge; distribute information about educational lectures One-to-one chatting: answer questions	1 month	BMI and WC	Not

XSL•FO
RenderX

Authors	Sample	Control group	Intervention related to WeChat	Duration	Outcome	Effective[a] or not
Liu et al [48]	300 overweight or obese participants in Sichuan	No (before-after)	WeChat: postdinner plates and beverage	3 months	BW, BMI, WC, BFP, and WHR	Effective
He et al [46]	15,310 occupational participants in the Shunyi District of Beijing	Yes (those did not follow the Official Account)	Official Account: Health education including intervention of PA and diet	6 months	BW	Partly effective: males

[a]There were favorable changes in the indices after intervention according to their own reports in the study.

[b]PA: physical activity.

[c]BW: body weight.

[d]BFP: body fat percentage.

[e]WHR: waist-to-hip ratio.

[f]WC: waist circumference.

[g]T2DM: type 2 diabetes mellitus.

[h]HC: hip circumference.

Table . Summary of studies using WeChat for obesity interventions in Chinese (in order of publication date; N=35).

Authors	Sample size	Control group	Intervention related to WeChat	Duration	Outcome	Effective[a] or not
Yinbao[b] [84]	1840 from the 51st Regiment of the Third Division in Xinjiang	Yes (randomized)	Official account: post health knowledge	12 months	BW[c], WC[d], HC[e], and BMI	Partly effective: HC and BMI
Lu[b] [83]	62 patients with coronary heart disease in a hospital in Tangshan	Yes (randomized)	Mini Program: record diets WeChat group: supervise diet, share educational material, and healthy diet competitions WeChat live streaming: educational lectures	3 months	BW, BMI, and WC	Partly effective: BW and BMI
Youxuan[b] [74]	295 people at high risk of hypertension from 15 communities in Haikou	Yes (randomized)	WeChat group: reminding to upload diet and PA[f], upload health education, and health guidance	12 months	BMI, WC, and HC	Effective
Jun[b] [86]	60 patients with prediabetes aged 50 - 70 years from a health management center, Guangzhou	Yes (randomized)	WeChat group: share heart rate data, remind to practice, and communication to promote PA	3 months	BW and BFP[g]	Effective
Linjuan[b] [53]	165 patients with T2DM[h] from a hospital in Inner Mongolia	No (before-after)	Mini Program: record glucose, evaluate diet, daily step recording, nutrition recipe, health knowledge, and remind medicine intake	6 months	BMI	Effective
Tianmeng et al [69]	1292 residents with higher blood pressure in Shandong	No (before-after)	WeChat group: post poster or papers about health knowledge; answer daily questions	3 months (100 days)	WC, HC, BW, BMI, and BFP	Effective
Mengqin[b] [76]	480 patients with essential hypertension aged 18–70 years from 5 towns in rural areas of Shanxi	Yes (randomized)	WeChat group: post health knowledge of posters, papers, and videos	3 months	BMI, WC	Not
Wei et al [78]	200 students with normal blood pressure enrolled in 2017 from a university in Xizang	Yes (randomized)	WeChat group: post health education of essays, cartoon, pictures, videos One-to-one chatting: provide consultancy	6 months	BMI	Effective

XSL•FO
RenderX

Authors	Sample size	Control group	Intervention related to WeChat	Duration	Outcome	Effective[a] or not
Ruixue et ali [73]	63 patients with overweight or obesity from a hospital in Chongqing	No (before-after)	WeChat group: post health knowledge, upload personal PA recording, communications among participants, and upload daily diet recording and evaluated by physicians	3 months	BW, BMI, BFP, and WC	Effective
Lu [83]	152 patients with diabetes from 5 communities in Shenzhen	Yes (randomized)	WeChat group: post health knowledge, discussion, and evaluation on nutrition	3 months	BMI and WC	Effective
Xiaoyuan et al [58]	100 patients with phlegm dampness constitution coronary heart disease from a hospital in Nanning	Yes (randomized)	WeRun: record daily steps WeChat group: supervise daily diet and PA	6 months	BW, WC, and BMI	Effective
Zihao et al [54]	54 overweight or obese people from a hospital in Guizhou	No (before-after)	WeChat group: supervise and provide guidance for daily diets and PA; answer questions of participants	3 months	BW, WC, HC, and BFP	Effective
Weiwei[b] [81]	68 older adult patients with chronic diseases with physical inactivity in 2 communities in Bengbu	Yes (participants from Hubin)	WeChat group: post health education of materials, upload weekly PA recording, and health guidance	6 months	BMI and WHR[i]	Effective
Jinhua[b] [59]	107 older adult patients with hypertension from 4 communities in Changsha	Yes (randomized)	WeChat group: share healthy diet and PA videos, upload healthy knowledge about hypertension, and web-based consultancy	6 months	BMI and WC	Partly effective: BMI
Peijun [65]	120 patients with obesity who underwent physical examination from Sichuan University	Yes (randomized)	WeChat group: post health education materials One-to-one chatting: answer questions Official Account: Traditional Chinese Medicine Health Preservation Special Issue	6 months	BW, BMI, BFP, and WHR	Effective
Jielili[b] [75]	48 cases of obesity from Jinglao Community, Hetian	Yes (obesity and normal weight control)	WeChat group: health education; psychological cognition, and weight management	3 months	BW, WC, and HC	Effective

XSL•FO
RenderX

Authors	Sample size	Control group	Intervention related to WeChat	Duration	Outcome	Effective[a] or not
Ziwei[b] [70]	40 young and middle-aged patients with hypertension from 3 community health care centers in Hengyang	Yes (randomized)	WeChat group: upload health education, share BMI and WC change to encourage each other, supervise daily steps, guidance on smoking and drinking, remind on medicine intake, and share music and videos to relax	6 months	BMI and WC	Partly effective: BMI
Yuepeng[b] [61]	40 patients with hyperuricemia in a Tianjin hospital	Yes (randomized)	Official Account: education on diet, PA, and medication knowledge WeChat group: post health education contents, share videos of PA, and answer questions	6 months	BW, WC, HC, BMI, and WHR	Not
Xi et al [55]	47 employees in an affiliated hospital	No (before-after)	WeChat group: share pictures of daily diets and PA; one-to-one dietary guidance by professional nutritionist (including intervention of PA and diet)	1.5 months	BW, BMI, BF, BFP, and WC	Effective
Jianxin et al [71]	130 older adult hypertensive patients from Chinese PLA Hospital No. 305	Yes (not randomized, grouped by first clinic date)	Mini Program: diagnosis and treatment, medication guidance, and data management	6 months	BW, BMI, WC, WHR, and BFP	Partly effective except BW
Li[b] [62]	100 patients with T2DM from community health service center in Chongqing	Yes (randomized)	Official Account: guidance on personal diet and PAs; upload situation of dietary, PA, glucose, and blood pressure; and supervision and health education	12 months	BW, BMI, WC, HC, and BFP	Effective
Yingming[b] [63]	60 patients with overweight or obesity and polycystic ovary syndrome from 2 hospitals in Hainan	Yes (not randomized, grouped by first clinic date)	WeChat group: experience sharing, life behavior guidance, and supervision	3 months	BW, BMI, WC, HC, and WHR	Partly effective except HC
Lijuan[b] [85]	100 young and middle-aged patients with hypertension from all community health service centers in Fuding	Yes (randomized)	WeChat group: health education, consultancy by a doctor, and remind of changing unhealthy timetable	6 months	BW, WC, HC, and BMI	Not
Jiawei[b] [60]	128 patients with T2DM treated or hospitalized in a hospital, Chengdu	Yes (randomly)	Official Account: post intervention strategies, collect information WeChat group: share intervention strategies	3 months	WHR	Effective

XSL•FO
RenderX

Authors	Sample size	Control group	Intervention related to WeChat	Duration	Outcome	Effective[a] or not
Yuexi et al [66]	60 residents with prediabetes from a hospital in Nanning	Yes (randomly)	WeChat group: upload health knowledge, answer questions	24 months	WC and BW	Effective
Jingxia et al [b] [87]	278 employees from 4 worksites in Yang River Delta	Yes (randomly select 2 worksites)	Official Account: post information about obesity, diet and PA, querying energy of food, querying PAs, web-based competition on daily diet, and PAs with rewards	12 months	BW, BMI, WC, HC, and WHR	Partly effective: BW, BMI, and HC
Rongrong [b] [79]	314 individuals with prediabetes diagnosed by a hospital in Shandong	Yes (randomly)	Official Account: health education WeRun: supervise daily steps WeChat group: health lectures and health educations in voice, words, and pictures	7.5 months	BW, BMI, WC, and HC	Effective
Xujuan et al [77]	36 people with obesity from a physical examination center in Taiyuan	No (before-after)	WeChat group: exercise prescription	2 months	WC, BW, BMI, and BFP	Effective
Xiao and Dafang [68]	301 volunteers	No (before-after)	WeChat group: provide guidance on diet, PAs, and psychology	1 month	BW	Effective
Xiaojuan et al [64]	20 overweight patients with prediabetes from a hospital in Wuxi	No (before-after)	WeChat group: upload health knowledge, share daily food and energy intake, and answer questions	6 months	BW, BMI, and WC	Effective
Bei[b] [57]	262 middle-aged and young patients with primary hypertension from a community health service center in Urumqi	Yes (randomly)	WeChat group: upload health education material weekly, answer questions during intervention, and communicate with other participants	6 months	BMI	Not
Huirong et al [80]	223 patients with chronic noninfectious diseases from a hospital in Xinjiang	Yes (Randomly)	Official Account: Public Health Microworld	3 months	BW, BMI, WC, HC, WHR	Effective
Di [b] [72]	40 obesity children aged 10 - 11 from one of primary school in Beijing	Yes (randomly)	WeChat group: share pictures of 3 meals of children; upload web-based education materials (including PA and diet)	2 months	BW, BMI, WC, HC, and BFP	Partly effective: BW and BMI
Jiangping et al [67]	77 college teachers from 2 universities in Harbin	Yes (1 university)	WeChat group: upload health education and share PAs videos	3 months	BMI and WC	Effective

XSL•FO
RenderX

Authors	Sample size	Control group	Intervention related to WeChat	Duration	Outcome	Effective[a] or not
Dongmei et al [56]	86 coronary heart disease patients from a hospital in Shandong	Yes (Randomly)	WeChat group: upload health education, supervise participants to follow personal treatment, and communicate with others	12 months	BMI	Effective

[a]There were favorable changes in the indices after intervention according to their own reports in the study.

[b]Thesis for degree (master's and PhD).

[c]BW: body weight.

[d]WC: waist circumference.

[e]HC: hip circumference.

[f]PA: physical activity.

[g]BFP: body fat percentage.

[h]T2DM: type 2 diabetes mellitus.

[i]WHR: waist-to-hip ratio.

Methods of Intervention

Among the 43 papers ultimately included, 32 (74.4%) [46-48,50,53-57,59,62-64,66-77,80-82,84-87] used a single WeChat function for interventions, while 11 (25.6%) [45,49,51,52,58,60,61,65,78,79,83] used multiple functions of WeChat to implement their intervention studies. “WeChat group” and “Official Account” were 2 functions used the most, with 33 (76.7%) [45,49,51,52,54-61,63-70,72-79,81-83,85,86] and 11 (25.6%) [46,50,51,60-62,65,79,80,84,87] studies using them, respectively (Table 3). WeChat groups primarily facilitated communication between investigators and participants. Official Accounts were mainly used to deliver dietary or PA education and record daily diets and PA. Four (9.3%) studies [52,53,71,83] used Mini Program in their intervention strategies with similar but expanded functions as Official Account. Three (7.0%) studies [51,65,78] used one-to-one chatting functions enabling confidential consultations. In addition, 2 (4.7%) studies [58,79] used WeRun to conduct interventions. Meanwhile, another 2 used voice call [45] and live streaming [83] separately. A total of 4 (9.3%) studies did not clearly report the specific functions of WeChat they used in their intervention (refer to “Intervention” item in Tables 1 and 2 for more details).

Table . WeChat components used in the interventions.

Function	Definition	Values, n (%)
WeChat Group	Containing up to 500 members; all the members can share information and chat in the group; daily attendance of web-based activities	33 (76.7)
Official Account (accounts that developers or merchants apply for on the WeChat official platform)	The platform uses communication and interaction with specific groups of text, pictures, voice, and video, forming a mainstream online and offline WeChat interactive marketing Way	11 (25.6)
Mini Program	Lightweight apps that run within the WeChat environment; smaller than dedicated apps; no need to download	4 (9.3)
One-to-One Chatting	Sending text messages and voice messages; making video calls and voice calls; sharing pictures or WeChat public press paper; transferring money to WeChat friends	3 (7.0)
WeRun	Recording the number of daily steps taken in walking	2 (4.7)
Voice Call	Free communicating method with your WeChat account followers under network environment	1 (2.3)
WeChat Live Streaming	Directly get access to live streams within WeChat without additional download; providing real-time interaction, content sharing, and more	1 (2.3)
Not specified	Did not mention which specific functions were used for intervention	4 (9.3)

Descriptive Statistics on Intervention Efficacy

In summary, 25 out of 43 (58.1%) studies [48,52-56,58,60,62,64-69,73-75,77-82,86] demonstrated significant improvement across all obesity-related measures. Of the studies remaining, 12 (27.9%) [45,46,49,50,59,63,70-72,83,84,87] showed partial effectiveness on the selected measures and 6 (14.0%) [47,51,57,61,78,85] reported no significant effects with a duration period no longer than 6 months. BMI was the most commonly used outcome measure for obesity, in which 27 (77.1%) [48,50,53,55,56,58,59,62-65,67,69-74,77-84,87] out of 35 [45,47-51,53,55-59,61-65,67,69-74,76-85,87] were significantly decreased after intervention. A total of 28 (65.1%) studies [45,46,48,49,52,54,55,58,61-66,68,69,71-73,75,77,79,80,83-87] assessed body weight, in which 23 (82.1%) [45,46,48,52,54,55,58,62-66,68,69,72,73,75,77,79,80,83,86,87] showed weight loss after intervention. A total of 30 (69.8%) studies [47,48,50,51,54,55,58,59,61-64,66,67,69-77,79,80,82-85,87] assessed WC as outcome, in which 18 (60.0%) [48,54,55,58,62-64,66,67,69,71,73-75,77,79,80,82] of them showed a significant reduction after intervention. For HC, a total of 14 (32.6%) studies [50,54,61-63,69,72,74,75,79,80,84,85,87] were considered it as outcome, in which 9 (64.3%) [54,62,69,74,75,79,80,84,87] showed significant decrease. Similarly, a total of 11 (25.6%) studies [48-50,60,61,63,65,71,80,81,87] assessed WHR as outcome, in which 7 (63.6%) [48,60,63,65,71,80,81] of them showed a significant decrease at the end of the study. Of the 14 (32.6%) studies [48-50,54,55,62,65,69,71-73,77,86] assessing BF, only 1 (7.1%) [55] of them used BF and all others used BFP. BF and BFP were shown to be impacted mostly by interventions compared with other measures in these studies because 12 (85.7%) [48,49,54,55,62,65,69,71,73,77,86] out of 14 [48-50,54,55,62,65,69,71-73,77,86] showed that they were significantly decreased (Tables 1 and 2).

Quality Assessment of Study

Using the NIH Study Quality Assessment Tool, we assessed a total of 33 studies [45-47,49-51,56-63,65-67,70-72,74-76,78-87] that had a control group, with 4 (12.1%) [50,70,76,79] rated as good quality, 25 (75.8%) [45,47,49,51,56-63,65-67,71,74,78,81-87] as fair quality, and 4 (12.1%) [46,72,75,80] as poor (See Table S2 in Multimedia Appendix 1). The number of studies meeting each assessment item is shown in Table 4. Twenty-seven (81.8%) [45,47,49-51,56-63,65,66,70,72,74-76,78,79,82-86] of them were described as randomized, in which 16 (59.3%) [50,51,56-60,62,65,66,70,74,76,79,83,85] reported randomization methods that were regarded as adequate (see Table S2 in Multimedia Appendix 1, item 11 and item 22). Only 2 (6.1%) studies [50,76] reported using a double-blinded randomization process, and only 1 (3.0%) study [50] reported that outcome assessors were blinded. Among all the studies with control groups, 6 (18.2%) [49,72,78,80,82,86] did not report demographic information separately for intervention and control groups, and 4 (12.1%) studies [46,66,75,87] reported significant differences in some demographic or other factors related to the outcome being assessed (see Table S2 in Multimedia Appendix 1, item 6). Two (6.1%) studies [45,87] reported an overall dropout rate exceeding 20%, with exact values of 23.1% [45] and 28.4% [87] separately, and 4 (12.1%) studies [65,67,72,75] provided no information about dropout rate (see Table S2 in Multimedia Appendix 1, item 7). In addition, 3 studies reported high intervention adherence [47,72,86], while 3 others reported low adherence [46,61,87]. Besides, intent-to-treat analysis was used in data analysis in 3 studies to avoid bias caused by dropout [47,50,87].

A total of 10 out of 43 (23.3%) studies [48,52-55,64,68,69,73,77] used a before-after design without a control group. According to the rating, all of them [48,52-55,64,68,69,73,77] were rated as fair quality (Table S3 in Multimedia Appendix 1). The number of studies meeting each assessment item is shown in Table 5. All the before-after studies [48,52-55,64,68,69,73,77] stated research questions or objectives clearly and presented specific inclusion and exclusion criteria. Two (20.0%) studies [48,52] included participants who could represent the population who would be eligible, and 1 (10.0%) study [69] enrolled all the eligible participants meeting the entry criteria. Although some of the studies [48,53,54,64,73] provided information about sample size calculations and power to detect statistical differences, they claimed insufficient power as a limitation. All the studies [48,52-55,64,68,69,73,77] clearly and consistently described intervention strategies and used effective and objective outcome measurements. However, none reported whether blinding was used during intervention implementation or data analysis. All studies [48,52-55,64,68,69,73,77] prespecified outcome measures, which were applied clearly and consistently throughout the study process. Three studies reported a loss to follow-up rate exceeding 20%, with rates of 82.4% [52], 24.3% [53], and 55.5% [73], respectively. All studies [48,52-55,64,68,69,73,77] analyzed changes in outcomes of interest before and after the intervention and presented *P* values, but only 3 studies [52,64,68] measured outcomes multiple times before, during, and after the intervention. None of these studies was conducted at the group level; thus, it was not applicable to account for the use of individual-level data in determining group-level effects in the statistical analysis.

Table . Numbers of studies with control group that met each assessment item.

Assessment item	Values, n (%)
Outcomes valid and reliable	33 (100.0)
Outcome prespecified	33 (100.0)
Dropout rate between groups	29 (87.9)
Randomized controlled trial	27 (81.8)
Overall dropout rate	27 (81.8)
Groups similar	23 (69.7)
Randomization adequate	16 (48.5)
Treatment allocation concealed	15 (45.5)
Sample size enough	11 (33.3)
Other interventions avoided	6 (18.2)
High adherence	3 (9.1)
ITT[a] analysis	3 (9.1)
Participants and providers blinded	2 (6.1)
Analyst blinded	1 (3.0)

[a]ITT: intention-to-treat.

Table . Numbers of studies without a control group that met each assessment item.

Assessment item	Value, n (%)
Objective clearly stated	10 (100.0)
Eligibility criteria clear	10 (100.0)
Intervention clear and consistent	10 (100.0)
Outcomes assessment	10 (100.0)
Analyze changes with *P* value	10 (100.0)
Follow-up rate	5 (50.0)
Outcomes measured multiple times	3 (30.0)
Participants representative	2 (20.0)
All eligible participants enrolled	1 (10.0)

Discussion

Principal Findings

This is the first publication to describe intervention studies focused on weight loss or obesity control conducted via WeChat. We identified gaps in the current design and implementation of these digital intervention studies, such as inadequate tracking options and social support, lack of individualized goals, and absence of health care experts [33]. Overall, the results are promising, suggesting that WeChat may be an effective platform for supporting weight loss or obesity management. However, more rigorous, randomized controlled trials are needed to understand the effectiveness of interventions delivered using this platform, and to determine the best implementation strategies. Our research revealed several important findings.

Deficiency of Current Obesity Interventions via WeChat

None of the studies reported using formative research to design the intervention. Formative research is a process of collecting useful data about the targeted population and context before or during intervention implementation, during which behavioral change strategies are developed and refined to be maximally suitable [88]. This process helps with cultural contextualization and optimizes the impact of intervention strategies [89] by generating more effective interventions tailored to specific populations. For example, formative research on diabetes management and support indicated that intervention strategies for type 1 diabetes should be different from those for type 2 [90]. Thus, to better use WeChat in obesity intervention studies, formative research is imperative for developing further strategies to achieve weight management outcomes. Of the 6 studies [47,51,57,61,78,85] that reported no significant changes in obesity-related measures, all had a duration of less than 6 months. Intervention durations of 6-12 months and higher

XSL•FO
RenderX

contact hours were correlated with more substantial changes [91,92]. Thus, future studies should consider extending intervention duration and enhance contact hours.

According to the assessment of studies using the Quality Assessment Tool designed by NIH [44], most studies had insufficient sample sizes. The intervention studies conducted in Chinese populations also had several common limitations. First, although most studies used randomization to assign participants to groups, blinding was rarely used (more than 95% did not report blinding during the intervention process). Similarly, information about participant adherence to interventions was limited, which impeded evaluation of effectiveness. In addition, our review of the inclusion and exclusion criteria found that most studies did not control for confounding effects caused by simultaneous participation in other intervention studies. These limitations might cast doubt on the generalizability of the findings.

Majority WeChat Functions Used in Current Research

WeChat, one of the most widely used social media platforms in China, has many functions that can facilitate obesity interventions [93,94]. In recent years, more intervention studies have used WeChat as a tool in China [41,93-95] because of its convenience and wide reach. The Official Account and WeChat group were the most common features used in the intervention trials included in this review. Both one-to-one chatting and WeChat groups facilitated immediate communication. Although this type of immediate communication might occupy researchers' time, it can also provide quick assistance to participants, potentially reducing loss to follow-up and increasing adherence to interventions, which may lead to positive outcomes. Official Account and Mini Program are user-friendly ways to disseminate intervention-related information, such as health knowledge and PA courses, as well as to record and evaluate personal data on daily diet and PA. While these functions could help researchers deliver health-related information, they do not ensure that participants actually engage with this information.

Generally, WeChat platform shows promise for obesity interventions; however, its utilization for health promotion still needs to be optimized. For example, although researchers can send intervention materials to participants easily via WeChat, there is no guarantee that they will pay attention to the health messages received [75]. Thus, study coordinators should not only use WeChat to deliver health-related information but also try to improve participant engagement through compelling content and strategies to compete for attention with the vast amount of the information disseminated through digital platforms [75].

Future Directions—Use of WeChat in Future Obesity Intervention Research

Online Payment

To date, no study has incorporated the online payment function of WeChat into existing obesity interventions. A potential strategy could involve offering time-limited discounts on healthy foods (such as vegetables and fruits) to incentivize participants. Financial incentives have been shown to promote participants' adherence and enhance the effectiveness of interventions [96]. Studies targeting obesity or overweight populations for weight loss indicated that financial incentives can motivate healthy behaviors and facilitate weight loss [97-99].

Living Streaming

WeChat's live streaming function could encourage better engagement during health education. Because of the widespread transmission of the COVID-19 pandemic, people were required to quarantine at home and public places, such as parks and gyms, were closed, resulting in physical inactivity [100]. In view of this situation, the Chinese government expressed encouragement and support for live-streaming fitness in its National Fitness Plan (2021 - 2025) [101]. Genghong Liu's (a Taiwanese singer) free live-streamed exercise sessions on Douyin (the Chinese version of TikTok) attracted more than 13.9 billion viewers on April 17, 2022 [102]. This demonstrates the potential opportunity and serves as inspiration for using WeChat's live-streaming function to provide guidance on weight control.

Peer Support

Based on our review of intervention strategies in the included studies, WeChat group function served as a platform on which participants could communicate with each other to exchange experience and thoughts and provide peer support as well as encouragement [49,56,63,73,86]. Group support in a study using Noom, an app for obesity intervention, demonstrated positive impacts of peer support within the group, including enhanced health education acquisition (such as reading and responding to health-themed information) and increased responses to others' posts [103]. Evidence from Noom highlights the importance of social support, especially peer support, for future WeChat intervention studies.

Target Population

Although WeChat users are very diverse, older adults and young people, individuals with low education levels, and those living in poverty-stricken areas, many of whom are nonnetizens, still face difficulties using multiple WeChat functions or even accessing the platform [16]. Thus, implementing WeChat-based interventions among these populations might be limited.

Limitations

Our review has several limitations. First, methodological heterogeneity and variable reporting quality in Chinese language studies limited the direct comparability of outcomes, but we addressed this using narrative synthesis by study type (with or without a control group). Second, while the cultural specificity of WeChat-based interventions limits generalizability, this review lays important groundwork for cross-platform comparisons.

Conclusions

In summary, WeChat is a potential platform for delivering obesity interventions due to its wide use and various functions. Most of the reviewed papers reported effectiveness in terms of weight loss. However, intervention studies conducted via WeChat were limited in design and evaluation rigor. Therefore, future studies should include formative research for intervention development, use a randomized controlled blinded design, and

XSL•FO
RenderX

use objective obesity outcome measures to increase the reliability of their findings. The main features of WeChat used in the included obesity interventions enabled chatting and information sharing without spatial limitation. Thus, further studies should explore multiple functions simultaneously to enhance participant engagement with health education materials, examine the impact of varying exposure levels, and increase participant engagement.

Acknowledgments

The authors attest that there was no use of generative artificial intelligence technology in the generation of text, figures, or other informational content of this manuscript.

Data Availability

No new datasets were created in this scoping review. The manuscript synthesizes data from previously published studies (44-86).

Authors' Contributions

JG was in charge of the investigation process, project administration, and supervision. JG and YW conceptualized the study. YW and XZ worked on the data curation. YW conducted the formal analysis, while JG and YW worked on the design of methodology. YW worked on the visualization and original draft. All the authors contributed to the manuscript review and editing. All authors approved the final version of the manuscript.

Abstract

Background: The increasing prevalence of smart devices has created vast amounts of untapped data, presenting new opportunities for data sharing across various fields, such as environmental sciences, health management, and astrophysics. While a significant portion of the public is willing to donate personal data, we need to better understand how to obtain information about which data assets a person may hold and the risks, benefits, and potential uses of this data exchange mechanism. Developing a trusted data-sharing platform may increase participants' willingness to donate data and researchers' ability to return personalized results from research findings.

Objective: This study aimed to develop a preliminary list of core requirements, which can be used to develop design recommendations for standardizing the return of individual research results to study participants across research disciplines.

Methods: We conducted a narrative literature review of existing platforms used to return research results to study participants. The search strategy included English-language articles published between May 2013 and May 2023. Concepts related to returning, disseminating, and sharing research results were searched for in (1) published research reports on Web of Science and MEDLINE, (2) gray literature, and (3) the bibliographies of included articles. Screening and data extraction were performed by 2 independent reviewers using Covidence. Inclusion criteria required that the study (1) included human participants, (2) returned information based on data collected from or by participants, (3) was published in English, and (4) included a description of a results-sharing system. Articles that met all 4 inclusion criteria were included in the review; articles that met the first 3 were also presented as supplementary articles. Results and requirements were synthesized thematically.

Results: Overall, 6608 abstracts were screened, and 266 articles underwent full-text review to identify 8 articles describing the development and evaluation of 7 different return of results systems. In total, 7 of the 8 articles reported the use of multimodal dissemination methods, including a combination of physical documents, emails, phone calls, and digital platforms to support text and graphical data representations. One article outlined accessibility features to serve the specific participant population. None of the articles described in detail how results were or were not anonymized. A total of 4 studies relied on an expert or clinician to share results on behalf of the research team. Additional educational or contextual materials were included alongside results in four studies, including specific materials designed for follow-up with experts and clinicians. Participants were not hesitant to receive unfavorable results and instead aimed to incorporate such information into their lives via lifestyle changes, clinical intervention, or seeking community.

Conclusions: Return of results systems should support multiple modes of dissemination for text-based results. Additional educational and lay-language materials are helpful for participants to understand and use information gained from receiving results.

Introduction

Background

In 2019, it was estimated that almost 70% of households had a smart device or appliance [1], and as of 2021, 85% of North Americans owned and used a smartphone [2]. This proliferation of smart technology has generated vast amounts of largely untapped data, presenting tremendous new opportunities for open science and knowledge sharing—particularly in areas where citizen scientists [3] want to contribute to academic discovery and applied research. Examples include water quality [4], astrophysics [5], environmental sciences [6], and patient-generated health and activity data [7], which can affect patients' health management by enhancing their ability to convey their health status [8] and improving patient-clinician relationships [9].

As with biobanks, where people can donate samples of tissues or body fluids for targeted or unrestricted use in research and health care [10], there is growing interest in donating personal data in various research areas [11]. Examples include a Swedish activity and physiology data sharing app [12], the ecobee smart thermostat "donate your data" dataset [13], or Tidepool's continuous glucose monitor "Big Data Donation Project" [14]. Increasing public trust may expand the use of this approach.

There is growing support for citizens to be able to donate their data for research. In a United Kingdom survey of 1300 members of the public, 54% of respondents were willing to donate personal data for research [15], motivated by both self-benefit and altruism [15]. However, barriers to data donation include a need to better understand the risks and benefits associated with their data and its potential uses, as well as gain insights into which data assets a person may hold [16,17]. Combined with privacy concerns regarding data-sharing methods, this highlights the need to create trusted data-sharing platforms. Similarly, there may be an enhanced willingness to share data if there is perceived self-benefit, such as the ability to derive insights from one's data or benchmark results against others, which could help their interpretation and provide locally relevant context [18].

Acknowledging these challenges, the National Academies of Sciences, Engineering, and Medicine assembled a committee to develop comprehensive guidance on returning individualized research results from biospecimens [19]. This report outlines 12 key recommendations to support study-specific decision-making, enhance research quality, improve participant understanding, and align with current regulations.

The recommendations emphasize the significance of considering the value of results to participants, evaluating the quality of research laboratories, and engaging community and participant representatives in policy development [19]. They also advocate providing adequate resources for high-quality research, planning for result return in funding applications, and supporting research to broaden the empirical evidence base. In addition, the recommendations call for revising regulations to facilitate the return of individual research results, harmonizing definitions across federal regulations, and ensuring transparency during the consent process. Finally, while the report addresses various factors influencing the feasibility of returning individual results to participants, including the potential burdens that investigators face when doing this for a single study, it does not discuss the systems available for doing so at scale (ie, by establishing infrastructure to be leveraged across multiple studies) or their potential impact on the widespread adoption of practices to return individualized results to study participants.

Existing studies on the return of results have likewise focused on policy, guidance, and best practices [19-22], or the perceptions of both participants and researchers regarding the return of results [23-26]. However, there has not been a formal review of the tools and methods used to return results, as many studies are restricted solely to their relevant discipline and data. This study aims to expand on this discussion.

Some fields have existing context-specific platforms to return research results. Environmental sciences have the digital exposure report-back interface, which returns chemical exposure results, such as lead contamination in drinking water [27], and Gardenroots, which illustrates contaminant levels in water, soil, and plant samples contributed by participants [28]. There are recommendations for returning environmental health-related data results [29], but other fields have less well-defined mechanisms [30].

Objective

This study aimed to develop a preliminary list of core requirements, which can be used to develop design recommendations for the standardizing of the return of individual research results to study participants across research disciplines.

Methods

Study Design

We conducted a narrative review of the published literature for reports of existing platforms used to return research results to study participants. The protocol was registered at the Center for Open Sciences' registry on May 24, 2023 [31]. A narrative review was chosen because the breadth and heterogeneity of this topic made a systematic review impractical. Systematic reviews are ideal for narrowly focused questions and structured data synthesis. In contrast, narrative reviews allow for broader interpretation and integration of diverse sources, which was essential for our research aims [32]. We followed the registered protocol for article selection but extended it to present a larger set of articles that met a limited set of our inclusion criteria as supplementary material.

Literature Search Strategy

Terms related to research results, result dissemination, and sharing of individual data from studies were used to search the literature. The search method combined search terms using proximity searching to identify key phrases related to the methods and process of returning research results. This approach was chosen instead of traditional keyword searching as the terms describing the method of returning research results to participants were often not specific enough to avoid large

XSL•FO
RenderX

quantities of extraneous articles. These included cases of "research" being used as an adjective alongside "data" or "results," while similarly, the term "results" tended to include headers and titles within abstracts rather than methods. An initial search strategy was created with the guidance of a research librarian to identify key phrases to search in abstracts, titles, and keywords (Multimedia Appendix 1).

A search was performed on Web of Science (Appendix A) and MEDLINE (Ovid; Appendix B). All searches were limited to articles published between May 2013 and May 2023. Gray literature was also searched by including the first 100 results with the search term "returning research results to participants" on Google Scholar. IEEE Xplore was also searched using this phrase and others, as multiple proximity operators are not supported within the same search. Finally, the reference lists of all identified reports and articles were iteratively searched for additional studies until no more relevant articles were identified.

All articles were uploaded into Covidence (Veritas Health Innovation, Melbourne, Australia), and duplicates were removed.

Article Selection Process

Two reviewers (RC and VC) independently completed an initial screening based on the article titles and abstracts to identify which articles would be included in the full-text review. The inclusion criteria were: (1) the reported study included human participants (members of the public or nonexperts) receiving information on their study results; (2) the information returned to participants was based on data previously collected from or by participants and included at least one variable with a description of the variable (ie, what was being measured) and domain context (ie, the meaning of this measurement in the context in which the study was conducted); (3) the article was published in English; (4) the article must include a description of a system or design (implemented as a pilot, at least) for sharing research results. Articles that met all 4 inclusion criteria were included in the full review, while articles that met the first 3 inclusion criteria but not the fourth were included as supplementary articles.

Two reviewers (RC and VC) then independently performed a full-text screening of the selected articles. Disagreements were resolved through discussion; if there was no resolution, additional reviewers were added to achieve consensus. Articles meeting criteria (1), (2), and (3), but not (4), formed a larger pool of supplementary articles of secondary interest. Articles that met all 4 inclusion criteria, including the additional system criteria, were selected to undergo full data extraction.

Data Extraction

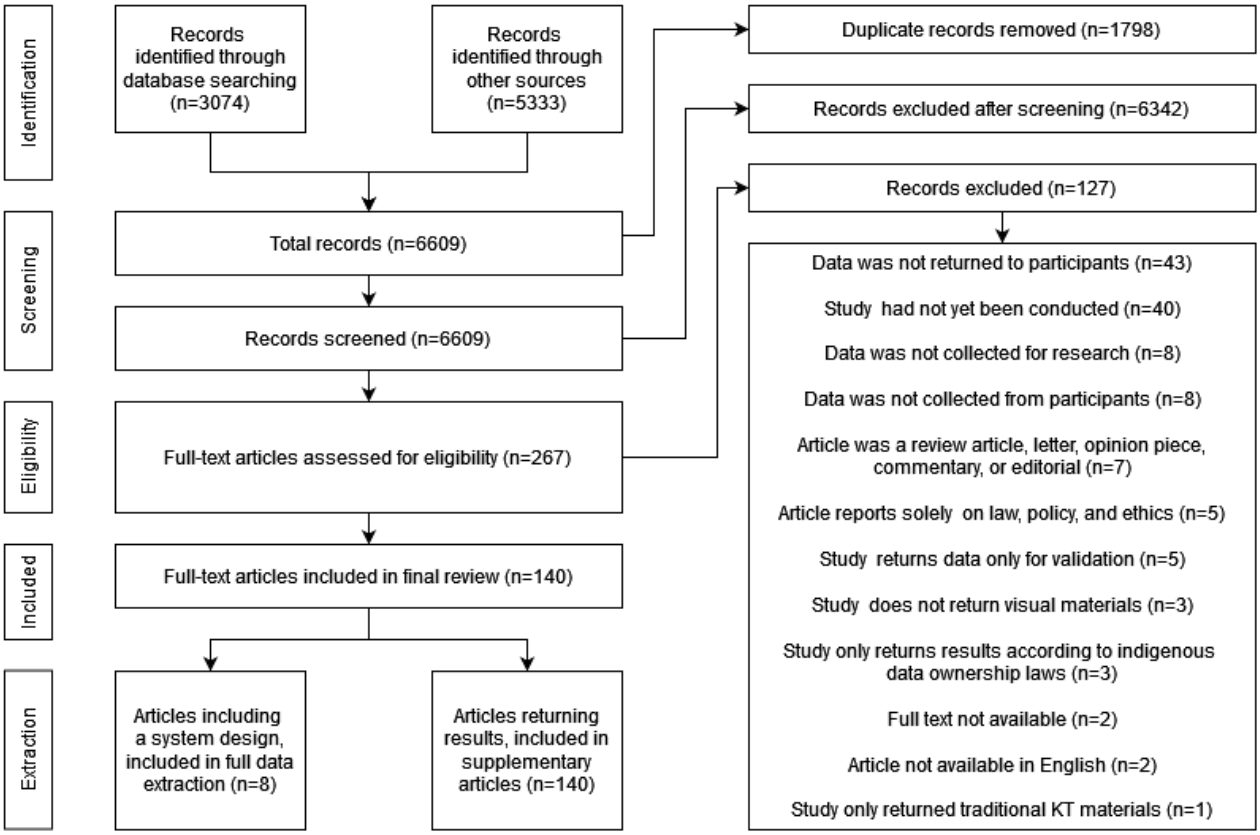
Two independent reviewers (RC and VC) used a standardized data extraction form in Covidence to extract data from each selected article (Multimedia Appendix 2). The following information was extracted into the template: study details, study characteristics, population characteristics, data sharing methodology, and data characteristics.

Risk of Bias and Quality Assessment

Two researchers (RC and VC) independently rated the quality of each study using the Authority, Accuracy, Coverage, Objectivity, Date, Significance checklist [33], as none of the included articles included randomized control trials, which was a prerequisite for using other tools.

Data Analysis

Data collected were analyzed and synthesized by 2 researchers (RC and VC) using thematic analysis [34]. Open coding was initially used to identify key segments in the data, after which themes were developed inductively through an iterative process. These themes were then organized into a hierarchy to form key findings. The findings include summarized information on study characteristics, variables measured, data presentation, delivery mechanism, results contextualization, whether the data shared are personalized, and system design requirements.



Results

Study Selection

After removing duplicates, 6609 articles were identified from the literature search and bibliographies of iteratively included papers. After reviewing the titles and abstracts, 267 articles were selected for full-text review. The total number of articles included in the supplementary list was 140 (Multimedia Appendix 3). From this, 8 articles [27,35-41] met all 4 inclusion criteria; however, 2 articles described a single study, discussing its design criteria in 1 article [27] and its implementation in another article [40], which were combined, resulting in a total of 7 studies (Figure 1).

XSL•FO
RenderX

Figure 1. Study selection and inclusion flow chart using Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) categories. All articles included in the full data extraction are also included in the supplementary articles, as they meet the inclusion criteria for both groups.

Study Characteristics

The eight included articles (Table 1) were published between 2017 and 2023, with 5 articles from the health care domain [35-39] and 3 (describing 2 studies) from the environmental health domain [27,40,41]. In total, 4 studies were based in the US [27,35,38,40,41], 1 in the Netherlands [39], 1 in the UK [37], and 1 in Japan [36]. The total number of study participants varied from 20 up to 24,163, with 1 study including 7 researchers as additional participants to provide feedback on system usability [41].

In total, 5 of the 7 studies involved vulnerable groups, including children [27,40,41], infants and mothers [38], retinal disease patients with significant vision loss [37], and cancer survivors [39]. In 2 studies, participants were identified and recruited from previously collected data (previous genetic testing or whole genome sequencing) [35,36]. In total, 4 studies included recruitment directly through a health care provider (HCP) or hospital setting [35,37-39], with 1 of these studies being a company recruiting via local HCPs [37]. In 1 study, the primary participants were researchers [41], and in 1 study, participants were recruited through community engagement or door-to-door soliciting [27,40]. Financial compensation was provided for participation in some study activities in 1 study [38].

XSL•FO

Table . Study characteristics of the seven studies including system design.

Study	Study domain	Participant characteristics	Sample size	Country or region
Boronow 2017 [27]; Perovich, 2018 [40]	Environmental health	Children with doctor-diagnosed asthma	10 participants completed feedback interview	US; Metro-Boston (Lowell, Lawrence, Old Colony, Castle Square) and Cincinnati
Cope, 2023 [38]	Health care	Babies of birthing parents at least 11 years of age	1823 participants completed feedback survey, 24 participants completed feedback interview	North Carolina
Gilbert, 2022 [37]	Health care	Patients with inherited retina disease	20 participants attended initial focus groups, 30 participants attended technology workshops, 50 participants attended user research focus groups	UK; London
Ohneda, 2022 [36]	Health care	Population-based genome cohort	161 participants completed questionnaire survey before receiving results, 150 participants completed questionnaire survey after receiving results	Japan
Polka, 2021 [41]	Environmental health	Homes in two environmental justice communities, children in areas with manganese in their local drinking water	7 researchers interviewed	US; Massachusetts
van de Poll-Franse, 2022 [39]	Health care	Cancer patients or survivors	N/A[a] (population registry)	Netherlands
Savatt, 2018 [35]	Health care	Anyone who has had genetic testing regardless of genetic test results or diagnosis	1601 participants enrolled in GenomeConnect	US

[a]not applicable.

Risk of Bias and Quality Assessment

Based on the Authority, Accuracy, Coverage, Objectivity, Date, Significance checklist (Multimedia Appendix 4), none of the seven studies had a strong indication of bias, with 3 having minor concerns.

Method of Dissemination

Several modalities of returning results were reported, with seven articles describing the use of 2 or more methods. Results were returned as a physical report through traditional mail in 2 studies [36,40], and 1 also returned results at an in-person community meeting [40]. A total of 4 studies used an online web-based portal [35,36,38,39], and 1 used a dedicated mobile application with specific accessibility features for people with vision loss [37]. Finally, 1 study used an online portal that required a clinician to deliver specific results (such as positive screening results) by phone [36] or an unspecified mechanism [38]. In total, 2 studies required clinicians to review before dissemination, though the clinicians did not disseminate results directly [35,37]. Emails were used by 2 studies to notify participants that their results were available [35,38] or that changes had been made (such as a new interpretation of previously collected data) [35].

Data Format

Out of 7 studies, 6 studies returned at least part of the participants' results in a text format (written word) [27,35-38,40,41] (Table 2), with 1 article not specifying the data format used [39]. Visuals were also included in 4 studies as charts or graphs [27,40,41], image data (such as retinal scans) [37], or graphics (non-data images used for aesthetic purposes) [36]. A total of 3 studies created their own results report for their participants [27,36,40,41], 1 returned standard medical laboratory reports [38], and 1 created a specific "physician report" alongside the participant report for sharing with their HCP [36].

In addition, 1 study also included nontraditional results in the form of personalized t-shirts for participants that included the number of chemical values measured in their homes and aggregate results in the form of data physicalization [42], which participants could observe at a community meeting organized by researchers [40].

XSL•FO
RenderX

Table . Data characteristics of the seven studies including system design.

Study	Presentation of information	Mechanism of delivery	Contextualization of results	Identifiable	Education of results
Boronow 2018 [27]; Perovich, 2017 [40]	Two report-back packets designed with the DERBI system containing personalized graphs and text summaries, personalized data shirt, and data physicalization (physical objects that display data in the real world instead of on paper or a screen)	The two report-back packets were delivered in person during a home visit and a community meeting. Personalized data shirts and data physicalization were available to participants who could attend the community meetings. Participants who could not attend were mailed their report-back packets.	In addition to personalized results, participants received aggregate results of chemical levels in the homes of other participants in the study cohort.	Personalized	Yes
Cope, 2023 [38]	Portal results page explains the meaning of a normal result, accuracy of the screening test, and information about the diseases that were screened. CLIA-certified laboratory report provided.	Participants with normal results were notified via email when results were available on the portal. Participants with positive screening results were notified by the study genetic counselor.	No context	Personalized	Yes
Gilbert, 2022 [37]	Not reported	MyEyeSite patient application	Not reported	Personalized	
Ohneda, 2022 [36]	Participants received information about generic and brand names of drugs considered as potential risks, along with their indication, medicinal effects, and individual predicted genotyped-based response to the drug. Health professionals of patients were given a single sheet containing all three genes, medication, and dosage recommendations based on the genomic results	Mail and genetic counseling through telephone	No context	Personalized	Yes
Polka, 2021 [41]	Numerical, text, and graphical representations of participant's results	Not reported	Population and study cohort	Personalized	Yes
van de Poll-Franse, 2022 [39]	Not reported	Not reported	Population; age- and sex-matched normative population with cancer	Personalized	Yes
Savatt, 2018 [35]	Notification with general statement that genetic test results have been updated and suggestion to contact the ordering healthcare provider or genetics provider in their area	Email	Match with other participants with similar characteristics (eg, gene, disease, U.S. state)	Not reported	Not reported

XSL•FO

Contextualization, Education, Recommendations, and Results Literacy

In 4 studies, additional details were provided alongside returned results to contextualize the information and provide recommendations [27,36,38,40,41]. One article (which described 2 pilot studies) described the return of individual in-home air concentrations of common contaminants, accompanied by general information on common pollutant sources and population averages for comparison [41]; the second pilot study returned individual tap water manganese levels, including general information and "group-level information," likely aggregated data from the study population, but which was not specified [41]. Another study included additional information on diseases for which participants had been screened in the results [38]. Other studies included recommendations about "improving" one's results (lowering exposure to specific chemicals) [40] or recommendations for avoiding specific drugs based on one's pharmacogenetic results within the results [36].

Expert Intervention, Follow-Up, and Community Engagement

Experts, primarily clinicians such as genetic counselors, were involved in 4 studies at various stages [35-38]. In 2 studies, clinicians reviewed results before dissemination [35,37], and 2 required a clinician to deliver specific results [36,38]. Genetic counseling was mandated for participants with specific results in one study [36]. Finally, 1 study, which allowed participants to upload data directly to the application, would automatically notify an HCP if data exceeded predefined thresholds so that an intervention could occur [37].

Follow-up with experts outside of the study team was also common: 2 studies nudged their participants to follow up with their primary HCP [35,36], one of which had prepared and included tailored results for this purpose [36]. Participants also expressed their plans to share their results with their HCPs [37,38,40]. However, this motivation was sometimes mediated by the results, as participants in 1 study did not feel the need to report "normal" results to experts [38].

When participants were not directly engaging with experts, one platform also provided methods to engage with additional research opportunities and clinical trials [37]. In contrast, another study looked at creating or maintaining a community involved in the research through community events and engagement sessions [40]. One platform also allowed participants to view relevant products to purchase [37].

Identifiability and Anonymity

The extent to which data or results were identifiable was not clearly stated in all 8 articles. Researchers in 1 study used participant IDs in the internal database that were only accessible by researchers to avoid linking identifiers [36]. Another system only made information accessible to researchers that could not be easily identifiable (such as unlabeled images or appointment schedules) [37]. The methods were unspecified in one article, though data were described as "anonymous" [35] and 2 articles did not specify any level of inherent anonymization unless researchers deliberately did this using outside tools or methods [27,41]. Finally, 1 article did not mention privacy or anonymity, but the registry was tied to the local government and health authorities [39].

Participant Perceptions

Participant perceptions of results were positive, with sentiments of increased trust, autonomy, and knowledge being key factors [27,37,39,40] (Table 3). In 1 study, participants did not experience worry or anxiety associated with receiving results [27,40]. Negative perceptions included a lack of adequate education materials or appropriate language [36,38], inadequate anonymization and options to opt-out of communications [37], or not having the option to receive additional results if they became available [35].

XSL•FO
RenderX

Table . Feedback and conclusions of the seven studies including system design.

Study	Positive participant opinions	Negative participant opinions	Researcher opinions
Boronow 2018 [27]; Perovich, 2017 [40]	Motivated to join because participants are able to access information that wouldn't be available otherwise. Participants felt like they were able to build trust with researchers. Results did not cause excess worry/anxiety/distress to participants. Participants made specific positive changes and brought study results to medical resources.	Participants recommend creating report-back materials for different audiences.	Digital exposure report-back interface is good for large studies where personalization is very important.
Cope, 2023 [38]	Calling participants with positive screening results ensures that participants with significant implications for their health are aware. The portal was rated easy to use and helpful for understanding individual research results. But literature indicates that online portals may be only acceptable to some participants.	Avoid technical terms and use plain language as much as possible.	Returning individual research results online was a time-efficient method that reduced burden on study staff.
Gilbert, 2022 [37]	Participants reported increased agency and being empowered to manage their own conditions. Information should be expressed in lay terms.	Patients who lack experience with digital tools rely on others for assistance. Data needs to be anonymized, and there should be easy opt-in/opt-out options for research studies and receiving notifications for eligible studies and findings from studies	—[a]
Ohneda, 2022 [36]	Participants' knowledge of PGx testing improved after receiving results	Even though the basic information of PGx had been given several times, some participants felt that the PGx concepts and terminology were difficult to fully understand	—
Polka, 2021 [41]	—	—	Manual report-back allows researchers to become familiar with participants' results, but the process is time-intensive, which limits individualization and creativity and presents challenges of data accuracy
van de Poll-Franse, 2022 [39]	Return of individual results not only empowers patients but can also be an incentive for cohort retention. Comparison to an age- and sex-matched normative population is helpful in the interpretation of findings	—	—
Savatt, 2018 [35]	—	Registry participants want to receive information about potential updates to their genetic testing results (ie, if the interpretation has changed)	—

[a]not applicable.

Researcher Perceptions

There was 1 study that included interviews with the researchers who were tasked with creating and disseminating the results. Even with a dedicated system, researchers report that the process was time-consuming, particularly for individual results [41]. Another study that included interviews with the research team as well as the participants who received the results reported that researchers were concerned about the generalizability of the participants' results and that participants would have poor reactions to receiving "bad" results [40].

Supplementary Articles

There were 140 supplementary articles (Multimedia Appendix 3), including the 8 articles identified in the primary search. The inclusion of these articles illustrates the return of results more broadly beyond digital systems.

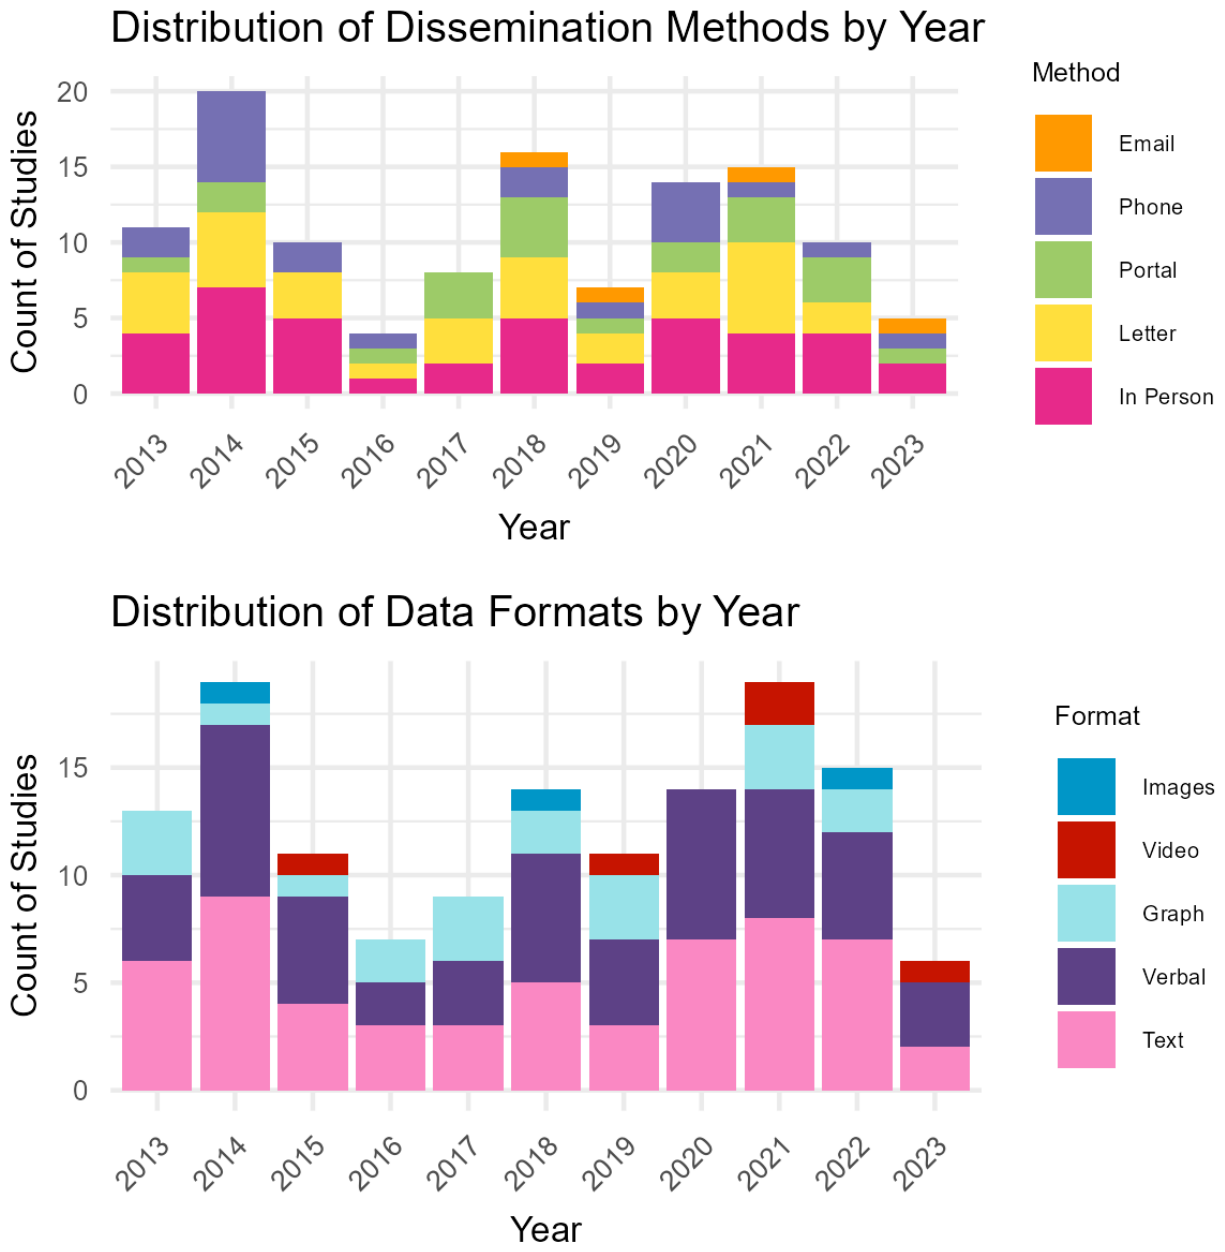
In total, 98 articles reported genetics studies, with 27 relating specifically to *BRCA*1 and *BRCA2*. A total of 20 articles came

XSL•FO
RenderX

from environmental health, mostly related to chemical exposure, and 16 articles came from the general health domain. One study was related to staff retention, and another to family studies.

The return of aggregate results was described in 36 articles, the return of personalized results in 114 articles, and the return of nonidentifiable results in 3 articles. Additional education materials were included alongside results in 104 studies, while 11 articles did not report on this.

Of the possible methods for disseminating results either fully or partially (in cases where multiple methods were used), 56 studies delivered results via an in-person interaction, 48 used letters through traditional mail, 35 used phone calls, 25 used an online portal or application, 5 used emails for disseminating their results, 4 used other non-traditional methods, and in 32 articles the method used was unspecified. Digital methods, such as email and online portals, have become more common in recent years (Figure 2).



The data format also varied with many studies using multiple modalities: 85 studies returned results verbally, 73 in text format, and eight in video format (including YouTube videos or "relaxation tapes"). Some additional extraneous formats included t-shirts, folders, infographics, booklets, colour-in posters and comics, and various presentations, including conferences with an unspecified audience. More diverse methods have become more common in recent years (Figure 2).

In total, 29 studies included charts or graphs in their returned results (6 included graphics, images, or other visuals, including "visual aids," and 26 did not specify the format used).

A total of 85 studies involved experts to return results: 79 studies involved clinicians, with 62 including genetic counselors. Experts used to return results in other studies included a medical geneticist, an oncologist, physicians, nurses, and other HCPs. Other nonclinician experts included health educators, licensed social workers, laboratories, community health workers, community leaders, public health authorities, and decision-makers.

XSL•FO
RenderX

Figure 2. (Top) Distribution of dissemination methods of returned results (if reported) per publication year. (Bottom) Distribution of data formats of returned results (if reported) per publication year.

Discussion

Principal Findings

This review identified 8 articles that described and evaluated 7 systems for returning results to study participants and a total of 140 studies in which results were returned to participants, with or without using a specifically designed system. Among the 8 articles, 4 studies had dedicated digital platforms [35,37-39] to create results, share results, or both, while 139 of the total 140 studies used less scalable and costly methods, such as in-person meetings and phone calls, to return some or all results to participants.

Many researchers and research ethics boards are concerned about providing adequate participant privacy [27], and this concern is particularly relevant when participants receive personalized results. Typically, including personal information is required for the information to be valuable to the participant (such as receiving personal genetic results instead of study-level results), yet some researchers opted to preserve participant privacy at the cost of the relevancy of the results [43]. There may be a mismatch between the privacy risk participants perceive versus the privacy risk researchers believe participants perceive, as researchers tend to self-censor when considering research methods, including the return of results [37,44-46]. For example, while many researchers would likely consider t-shirts with individual data for participants [40] to be a blatant misuse of private data and put participants at risk, such personalized tokens were well received by the participants in that study as it aided in them forming a community, not only with the researchers but amongst themselves [40]. Such non-traditional options may be permissible by ethical research

XSL•FO
RenderX

frameworks but might not be considered due to researcher uncertainty around what is permitted and misconceptions of what may be beneficial to participants (such as the opportunity for peer support). While specific privacy and security measures are crucial, such as password-protected portals [38] or anonymizing data where possible [36], community benefits may be another factor to consider.

Dissemination modes constrain potential data formats. For example, returning graphical data over a phone call is impossible. The COVID-19 pandemic required a switch in modalities for all research fields [39,47-49], and more recent studies often required genetic counseling to be conducted over the phone rather than in person, where physical documents could be exchanged [36].

The accessibility of dissemination modalities should also be a consideration. Returning results in physical formats (such as physical documents, phone calls, or in-person meetings) often limits the ability to return results at scale due to resource limitations. However, transitioning to a fully digital system is not equitable for all participants for reasons including age, race, socioeconomic status, location, and language proficiency [50,51]. The ability to provide results in different formats facilitates the opportunity for participants to make use of the information for themselves [27,36,40]. This accessibility becomes even more crucial with participants from vulnerable populations, as they often have unique accessibility concerns [37], but also have increased incentives for getting information from research projects [37,38,40].

An additional consideration for creating accessible results is including adequate language and educational or contextual materials alongside results. While some participants may be well-versed in the research context due to previous research experience, most are laypeople. Therefore, considerations must be made regarding literacy and education [52]. Even when attempts were made to contextualize or explain complex concepts by providing additional educational materials, many participants still struggled to understand their results and what to do with the information [36-38]. While improving lay formats will always be valuable [53], additional prestudy or preresults educational materials may help bridge the gap.

Key Requirements of a Results-Sharing System

First, it is crucial to support multiple dissemination methods, such as supplying physical documents alongside digital text [27,36,38,40]. Digital systems, such as secure portals, may require considerable development effort but offer easy-to-use and scalable solutions [35,38,41]. However, additional physical formats like mailed documents should be available to participants as an option for the few who require them [27,40]. This ensures that participants who lack digital access or prefer nondigital interactions can still receive their results [40]. Participants who have different accessibility needs may be able to make use of existing digital adaptive technology [37] unless the researcher offers methods that support this intrinsically.

Secondly, text results may be adequate, though including relevant graphs, charts, and images can relay information more effectively [27,35,37,38,40,41,54]. Importantly, these must be in appropriate lay language, and educational materials must be provided to contextualize the results for participants [35,54,]. While participants are willing to receive favorable, neutral, and unfavorable results [37,38,40], excessive jargon or lack of clear directions of what can be done with the information impedes its use [36,38]. In many cases, participants will not act on neutral or positive information (such as clear screening results or standard contaminant levels) [38]. However, those who receive unfavorable information (such as indication of illness or other concern) express a clear desire to act on it and must be informed of who they can contact regarding their results, whether a research team member, their own personal HCP, or another expert for further information when results are unclear [36,38,40].

Thirdly, participants preferred receiving personalized information, while expecting many systems used methods to still maintain their privacy [35-37]. Articles emphasized the importance of deidentification whenever possible, which can involve using participant IDs or removing identifiers when storing and handling data up until the point of result dissemination, which can be further blinded from researchers by the system. This approach ensures that researchers do not have access to identifiable information during the result-creation process. Identifiers should only be used at the dissemination point to accurately link the results back to the participants, preserving their privacy and minimizing potential misuse of personalized data [35-37].

Strengths and Limitations

This review surveyed articles across various research disciplines using a registered protocol. A reference librarian aided in developing and validating a comprehensive search strategy and methodology to avoid bias toward a specific research discipline.

However, there are also several limitations. Returning results is rarely the primary focus of research articles and is a method, not an intervention. As there is no scalable method for screening the body text of published work, this review was limited to articles where the method of returning results was reported in the abstract or title of the article. Similarly, the return of results is referred to using different terminology between research disciplines, so it is possible that instances of returning results were missed as the specific terminology was not included in the search strategy; this may bias our results, due to the authors' greater familiarity with the terminology in some research fields rather than others. This may have also resulted in over-representing particular disciplines, primarily through iterative bibliography screening. In addition, this review did not consider any non-English language publications or publications after May 2023, which may have missed global or more contemporary research.

Future Work

Future research should explore returning results to healthy participants or less vulnerable groups to explore the influence of altruism and the benefit to all research participants rather than only those who have a clear benefit to participating.

A generalizable results-sharing system should have a discipline-independent design available to all researchers. Many

XSL•FO
RenderX

systems are highly tailored to a specific data and discipline type and, therefore, are unavailable to other researchers [27,35,37-40]. While this may contradict the requirement to provide educational and contextualizing materials, current solutions are too context-specific to be broadly adopted by other disciplines where participants could also benefit from receiving results. Consequently, this impedes their ability to scale and generalize, which can be addressed in future system design.

In addition, while most studies describe the methods used to return results, few include evaluation data to assess their effectiveness. Future research should incorporate evaluation components to determine whether these methods achieve their intended goals, such as increasing participant knowledge, reducing anxiety, or improving engagement with research findings. Moreover, none of the included studies compared different modalities for returning results, as they each focused on a single system design. Future work should explore participant preferences for different return methods to inform more user-centred approaches.

Conclusions

This review identified 7 systems used to return individual results to research participants. While the return of results systems and methods are often tailored to the needs of the participants and the research discipline, some factors are universal. There is a clear need to support multiple dissemination methods, such as providing results digitally via a portal and (if requested) in physical form to allow equal opportunity for participants to receive and share their results. The inclusion of additional educational materials is crucial. Text is the most standard data format for results, though other, more creative formats can be well received by participants when applicable. Future work should include the development and testing of a discipline-independent research results sharing system.

Acknowledgments

The authors thank Colleen Pawliuk (librarian at the University of British Columbia) for her feedback on the search strategy development and Alex Stolz, Jenna Ramji, and Sasha Sokolov for their help in screening articles for the review.

Generative artificial intelligence tools were not used in this manuscript's development, writing, or editing. The study was supported by an NSERC Discovery Grant (RGPIN-2021 - 02833 to MG). MG holds a Michael Smith Health Research BC scholar award (SCH-2020 - 0494).

Authors' Contributions

RC and MG were responsible for the conceptualization and methodology of the study. Investigation and data curation were conducted by RC and VC. The original draft was prepared by RC, and all authors critically reviewed the manuscript. Resources and supervision were provided by MG.

Abstract

Background: Health care systems around the world face numerous challenges. Recent advances in artificial intelligence (AI) have offered promising solutions, particularly in diagnostic imaging.

Objective: This systematic review focused on evaluating the economic feasibility of AI in real-world diagnostic imaging scenarios, specifically for dermatological, neurological, and pulmonary diseases. The central question was whether the use of AI in these diagnostic assessments improves economic outcomes and promotes equity in health care systems.

Methods: This systematic review has 2 main components, economic evaluation and equity assessment. We used the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) tool to ensure adherence to best practices in systematic reviews. The protocol was registered with PROSPERO (International Prospective Register of Systematic Reviews), and we followed the PRISMA-E (Preferred Reporting Items for Systematic Reviews and Meta-Analyses - Equity Extension) guidelines for equity. Scientific articles reporting on economic evaluations or equity considerations related to the use of AI-based tools in diagnostic imaging in dermatology, neurology, or pulmonology were included in the study. The search was conducted in the PubMed, Embase, Scopus, and Web of Science databases. Methodological quality was assessed using the following checklists, CHEC (Consensus on Health Economic Criteria) for economic evaluations, EPHPP (Effective Public Health Practice Project) for equity evaluation studies, and Welte for transferability.

Results: The systematic review identified 9 publications within the scope of the research question, with sample sizes ranging from 122 to over 1.3 million participants. The majority of studies addressed economic evaluation (88.9%), with most studies addressing pulmonary diseases (n=6; 66.6%), followed by neurological diseases (n=2; 22.3%), and only 1 (11.1%) study addressing dermatological diseases. These studies had an average quality access of 87.5% on the CHEC checklist. Only 2 studies were found to be transferable to Brazil and other countries with a similar health context. The economic evaluation revealed that 87.5% of studies highlighted the benefits of using AI in dermatology, neurology, and pulmonology, highlighting significant cost-effectiveness outcomes, with the most advantageous being a negative cost-effectiveness ratio of –US $27,580 per QALY (quality-adjusted life year) for melanoma diagnosis, indicating substantial cost savings in this scenario. The only study assessing equity, based on 129,819 radiographic images, identified AI-assisted underdiagnosis, particularly in certain subgroups defined by gender, ethnicity, and socioeconomic status.

Conclusions: This review underscores the importance of transparency in the description of AI tools and the representativeness of population subgroups to mitigate health disparities. As AI is rapidly being integrated into health care, detailed assessments are essential to ensure that benefits reach all patients, regardless of sociodemographic factors.

Introduction

Background

Health care systems globally face numerous challenges, including geographical and economic disparities, uneven access to services, and unequal distribution of health care professionals. Patient diversity, influenced by factors such as skin color, ethnicity, and socioeconomic status, adds an extra layer of complexity [1]. However, over the last several years, technological advances in artificial intelligence (AI) have offered promising solutions [2,3]. AI, an interdisciplinary field, aims to develop systems capable of performing tasks that typically require human reasoning [4]. Machine learning, a subfield of AI, creates algorithms capable of learning and improving from experience without explicit programming [5,6]. In health care, AI algorithms have been developed to improve medical image analysis, offering benefits such as automatic recognition of abnormalities and disease prediction, ultimately leading to optimized clinical decision-making, cost reduction, and error prevention [7,8]. Despite these advances, gaps remain in evaluating the economic feasibility and equity implications of AI tools in real-world applications, as highlighted by previous studies [9]. Some critical issues must be addressed to maximize the clinical potential of AI. Methodological limitations, including insufficient validation studies and the lack of transparency in the AI decision-making process, threaten the broader adoption and effectiveness of AI systems in clinical settings [10,11].

Moreover, an emerging issue is bias in the real-world use of AI algorithms, particularly with respect to the populations used to train and validate AI models, potentially leading to skewed results that favor certain ethnic or demographic groups [12]. This bias can result in less effective or misleading results when applied to underrepresented populations, perpetuating existing health care inequalities [13,14]. Voets et al [9] emphasized these disparities, noting the critical need for research that not only evaluates the cost-effectiveness of AI but also addresses how these technologies can reduce inequities in health care access.

Equity in health care advocates for equal access to quality care regardless of personal characteristics such as ethnicity, gender, or socioeconomic status [15]. The inclusion of equity-related data into AI requires careful interpretation to avoid unintended biases [16-19]. Though the relationship between economic evaluation and equity lies in the distributional impact of costs and benefits. By identifying cost-effective strategies, economic evaluations can help allocate resources more equitably, ensuring that underserved populations gain access to innovative diagnostic technologies. For instance, reducing diagnostic costs through AI could enhance access for low-income or remote populations, addressing disparities in health care delivery[18].

Brazil, an upper-middle–income country with many social inequalities, has the largest free public health care system in the world, on which the majority of its population relies [20]. However, socioeconomic barriers create challenges in providing diagnoses, especially in impoverished and remote areas. Digital health initiatives, including AI-powered clinical decision support systems, have proven effective in reducing health disparities and improving access to health services [21]. To tackle these challenges, the Brazilian Ministry of Health's Support Program for the Institutional Development of the Unified Health System (in Portuguese, "Programa de Apoio ao Desenvolvimento Institucional do Sistema Único de Saúde," known as PROADI-SUS) supports a collaborative project named "Banco de Imagens" (Bank of Images) to create a nationwide cloud-based repository of medical images, as well as to develop and validate AI algorithms to assist in disease diagnosis.

The selection of dermatological, neurological, and pulmonary diseases was guided by the Brazilian Ministry of Health, which sponsors this study, as these conditions are considered national health priorities. Dermatological diseases, particularly melanoma, were included due to the critical need for early diagnosis and the shortage of specialists. Neurological diseases rely heavily on imaging for diagnosis, where timely intervention is essential; yet, specialist availability remains limited. Pulmonary diseases, particularly tuberculosis (TB), continue to pose significant public health challenges, especially in low-resource settings. The Ministry of Health identified these 3 disease areas as key targets where AI could enhance screening and diagnosis. Given this strategic priority, we conducted a single study encompassing all 3 disease groups.

Objectives

This systematic review investigates the economic performance and viability of the use of AI in diagnostic imaging examinations in real-world scenarios, particularly for dermatological, neurological, and pulmonary diseases. This review will also assess the potential impact of this intervention on equity in health care systems. The research question guiding this investigation is as follows: "To what extent does the use of AI in imaging examinations for the diagnosis of dermatological, neurological, and pulmonary diseases result in improved economic outcomes, and does it promote equity in health care systems?"

Methods

Overview

This study was conducted as a systematic review with two main components. The first component focused on economic evaluations, while the second focused on equity considerations. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) tool [22] was used to ensure adherence to best practices in systematic reviews (the PRISMA checklist is provided in Checklist 1). A protocol for this systematic review was registered in the PROSPERO (International Prospective Register of Systematic Reviews)

XSL•FO
RenderX

database under registration number CRD42023407755. No deviations from the registered protocol occurred during the study. We have published a detailed version of the protocol [23]. In addition, we followed the PRISMA-E (Preferred Reporting Items for Systematic Reviews and Meta-Analyses - Equity Extension) guidelines for systematic reviews with a focus on equity [24]. To structure our research question, we followed the PICO (Population, Intervention, Comparison, and Outcome) framework, as shown in Table 1.

Table . Population, Intervention, Comparison, and Outcome structure for the systematic review of global economic evaluations and equity studies on the use of artificial intelligence in medical diagnosis in people with dermatological, neurological, and pulmonary diseases.

Acronym	Description	Criteria
P	Population	Patients examined for pulmonary, neurological, and dermatological diseases, considering the entire world population, regardless of income and development of the respective country
I	Intervention	Use of artificial intelligence to support diagnostic decisions in any type of medical imaging
C	Comparison	Conventional or human-based diagnostic methods
O	Outcomes	Full economic evaluation studies, such as cost-effectiveness, cost-utility, cost-benefit, or cost-minimization. We also assessed changes in patient outcomes related to health care access and demographic factors such as age, gender, race, and income, with a focus on equity.

Eligibility Criteria

Scientific articles reporting on economic evaluations or equity considerations related to the use of AI-based tools in diagnostic imaging. These include (1) dermatology, specifically melanoma and carcinoma; (2) neurology, focusing on conditions with notable radiological findings such as microcephaly, brain atrophy, and hydrocephalus; and (3) pulmonology, focusing on conditions such as TB, lung consolidation, pleural effusion, atelectasis, pneumothorax, mediastinal widening, lung edema, lung opacity, lung lesion, lung cancer, other pleural diseases, and lung nodules. Detailed inclusion and exclusion criteria, including language and year of publication, can be found in Table 2.

Table . Inclusion and exclusion criteria for the systematic review of global economic evaluations and equity studies on the use of artificial intelligence (AI) in medical diagnosis in people with dermatological, neurological, and pulmonary diseases.

Criteria	Inclusion	Exclusion
Article types	Original articles reporting economic or equity evaluations. Cost-effectiveness, cost-utility, cost-benefit, and cost-minimization analyses were considered. Regarding equity, the authors analyzed reported improvements or declines in patient outcomes based on access to health care and demographic indicators such as age, gender, race, and income.	Articles that were not complete economic evaluations, such as cost analyses, cost description studies, and cost outcome descriptions, were excluded. The exclusion was based on the need to include only studies that provided a complete assessment of both costs and outcomes, allowing for a comprehensive understanding of the economic impact of AI interventions. This approach ensures that the review addresses studies that evaluate both the financial and health-related consequences of AI technologies. Regarding equity, we excluded studies that did not account for diverse samples reflective of the broader population.
Study focus	The use of artificial intelligence-based tools in diagnostic imaging in dermatological, pulmonary, and neurological fields.	Studies focused on other medical areas, such as heart disease, breast cancer, and diabetes. AI clinical validation and studies to predict risks were also excluded.
Language	No restrictions based on language.	No restrictions based on language.
Year of publication	No restrictions based on the year of publication	No restrictions based on the year of publication

Information Sources

Searches were conducted in the PubMed, Embase, Scopus, and Web of Science databases in March 2023, with no restrictions on publication date. Additional searches were performed to identify the references cited in the retrieved articles.

XSL•FO
RenderX

Search Strategy

A customized search strategy was defined for each database, using terms related to AI, relevant health conditions or diseases according to eligibility criteria, economic evaluations, and equity. A separate search was conducted for each topic area, as well as a general search without a specific area. The final search terms are provided in the Multimedia Appendices 1-4.

Data Management

An Excel (Microsoft Corp) spreadsheet was used to manage and organize the records during data extraction and synthesis.

Selection Process

First, all records retrieved by the search terms in different databases were exported to EndNote software (version X9.3.3; Clarivate), a reference management software. Then, the articles were exported to the Rayyan platform (Qatar Computing Research Institute), which was used to remove duplicates and select articles for screening by reading titles and abstracts.

The selection process consisted of 2 phases. In the first phase, 2 researchers independently assessed and selected articles. Researchers GOS and RML evaluated titles and abstracts from the fields of pulmonology and neurology, while researchers GOS and BCRS evaluated titles and abstracts from the field of dermatology. Researchers GOS and RMC also assessed an additional search related to the use of AI in medical images in general, without a specific field. All disagreements were resolved by a third researcher (LRC).

In the second phase, the selected articles from the first phase underwent full-text review. Researchers GOS and RMC assessed the full texts for all fields and searches. All disagreements were resolved by a third researcher (LRC).

Data Extraction Process

After selecting the articles, 2 researchers (GOS and RMC) collected the variables of interest for the systematic review from each publication with available data. The following information was prioritized for collection: publication title, year of publication, journal, authors, URL, study type, language, study location, time horizon, corresponding author contact, summary, objectives, methodology, study population, participant demographics, health indicators, access to health care services, equity indicators such as odds ratios and relative risks, study perspective, sample size, statistical significance, applied AI, incremental cost-effectiveness ratio (ICER), cost-benefit or equity of results, quality-adjusted life years (QALY), direction of effect (favorable or not), model applied, sensitivity analysis, initial assessment of methodological quality, conflicts of interest, funding, and transferability of results.

We adopted the World Bank's 2023 classification of countries by income level [25], which categorizes groups by gross national income per capita calculated using the World Bank's Atlas method. The groups are low income, US $1135 or less; lower-middle income, US $1136 - $4465; upper-middle income, US $4466 - $13,845; high income, US $13,845 or more.

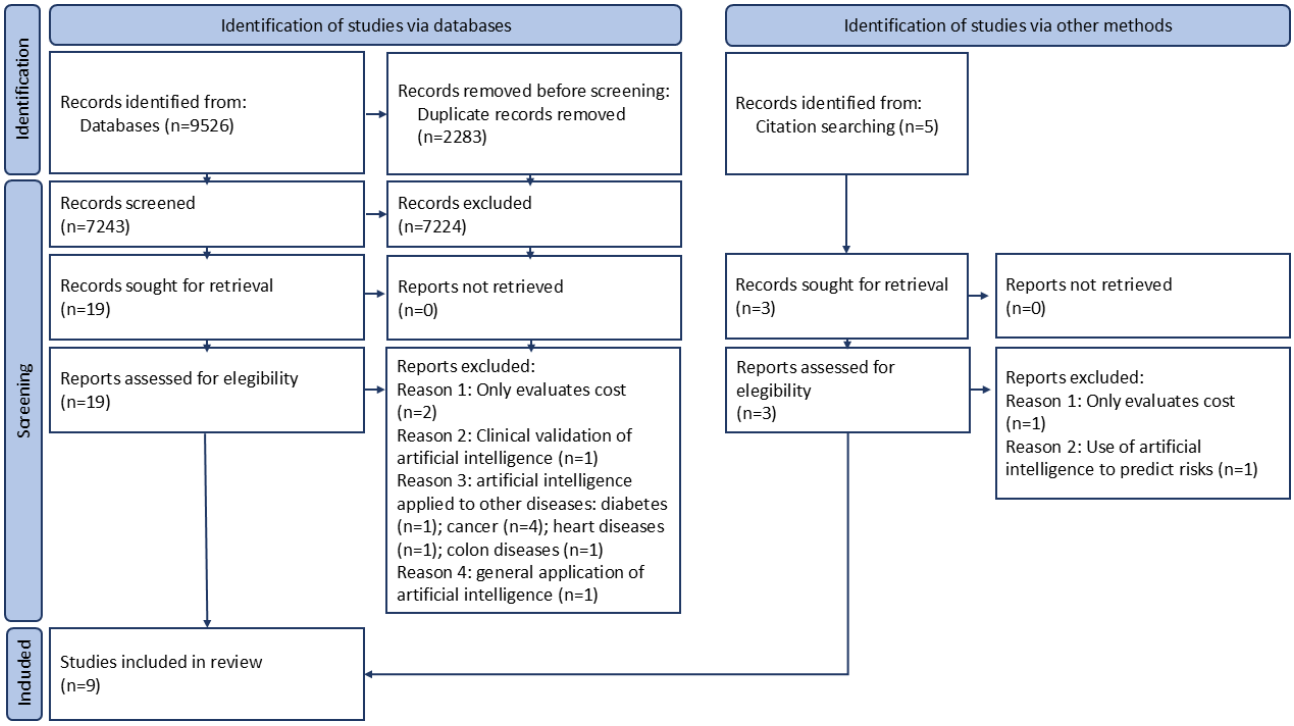
Risk of Bias in Individual Studies and Transferability

Three tools were used to assess the methodological quality of the selected studies: (1) the CHEC (Consensus on Health Economic Criteria Checklist) economic evaluation checklist [26]; (i2) the EPHPP (Effective Public Health Practice Project) quality assessment tool for quantitative studies that are not economic evaluations but were selected for their equity results [27]; and (3) the Welte checklist to assess the transferability of technologies used in the selected studies between different countries [26,28]. The methodological quality assessment of the studies was conducted independently by 2 researchers (GOS and RMC). Any discrepancies were resolved through discussion with a third researcher (LGNP).

For the CHEC checklist, points were awarded for each criterion met, so that a maximum of 20 points were available for the evaluation. No points were awarded if the criterion was not fully met. A percentage score was calculated by dividing the number of points awarded by the total number of points on the checklist and multiplying by 100.

For the EPHPP tool, each section was scored 1 (strong) if it met the criteria, 2 (moderate) if at least 1 section was rated as weak, and 3 (weak) if 2 or more sections were rated as weak. Finally, a global score was calculated based on the scores for each section.

For the Welte checklist, points were assigned based on the following criteria: perspective (2 points); discount rate (2 points); medical cost approach (2 points); absolute and relative prices in health care (1 point); practice variation (1 point); incidence and prevalence (1 point); case mix (1 point); life expectancy (1 point); productivity and lost work time (1 point), for a total of 12 points. Studies that scored 10 points or more were considered transferable.



Results

Search Results

The database searches identified a total of 9526 entries, of which 2283 (23.9%) were excluded as duplicates. Of the remaining sample of 7243 articles, 7224 (99.7%) were excluded after screening of titles and abstracts. A total of 19 articles proceeded to the eligibility stage, of which 11 (57.9%) were excluded as they did not meet the inclusion and exclusion criteria. In addition, by reading the references of the selected articles, 3 further articles were identified for full-text reading, of which only 1 (33.3%) was selected for the study. A schematic representation delineating the process of record identification, screening, and exclusion is depicted in Figure 1.

XSL•FO
RenderX

Figure 1. Flowchart illustrating the selection of articles included in the study, based on database searches and additional sources.

Overview of the Included Studies

An overview of the included studies is presented in Table 3 and Multimedia Appendix 5. Most of these studies were published in 2021 (n=5, 55.5%), the others in 2022 (n=3, 33.4%) and 2020 (n=1, 11.1%). They focused primarily on pulmonary diseases (n=6, 66.6%; [29-34]), followed by neurological diseases (n=2, 22.3%; [35,36]), and only 1 [37] study (11.1%) focused on dermatological diseases. Of the selected studies, 8 [29-32,34-37] (88.9%) were economic evaluation studies and only 1 (11.1%) [33] addressed equity. The majority of studies (n=5, 55.5%) [29,33-35,37] were conducted in high-income countries, and 3 [30-32] of the 4 (75.0%) studies were conducted in low- to middle-income countries in partnership with institutions located in high-income countries. Notably, 5 [29,31,32,35,37] out of 9 studies (55.5%) reported a conflict of interest. Only 3 [31,32,37] out of 9 studies (33.3%) reported funding, none of which was private.

Table . General characteristics of the articles selected for the study and the results of the checklists applied for quality assessment.

ID	First author and year of publication	Study type	Place of study	Conflict of interest	Funding
Dermatology, Dentistry, and Ophthalmology					
1	Gomez Rossi et al [37]	Cost-effectiveness analysis	United States, Germany, and Brazil	Yes	Yes, public
Neurology					
2	Leeuwen et al [35]	Cost-effectiveness analysis	United Kingdom	Yes	No
3	Mansour et al [36]	Cost-effectiveness analysis	Egypt	No	Not mentioned
Pulmonology					
4	Adams et al [29]	Cost-minimization analysis	United States	Yes	No
5	Bashir et al [30]	Cost-minimization analysis	Pakistan	No	No
6	MacPherson et al [31]	Cost-effectiveness analysis	Malawi	Yes	Yes, philanthropic institution
7	Nsengiyumva et al [32]	Cost-effectiveness analysis	Pakistan	Yes	Yes, public
8	Seyyed-Kalantari et al [33]	Equity	United States	No	No
9	Ziegelmayer et al [34]	Cost-effectiveness analysis	United States	No	No

Methodological Quality Assessment

The methodological quality of the studies was assessed using the CHEC checklist, with scores calculated based on the percentage of criteria met (Tables 4 and 5). Scores ranged from 55.0% to 100.0%, with an average of 85.6%.

Table . Scores for the checklists applied for quality assessment.

ID	CHEC (Consensus Health Economic Criteria) score, (%)	EPHPP (Effective Public Health Practice Project) score	Welte score
1	95%	N/A[a]	10 points (transferable)
2	90%	N/A	10 points (transferable)
3	55%	N/A	6 points (nontransferable)
4	80%	N/A	9 points (nontransferable)
5	75%	N/A	8 points (nontransferable)
6	100%	N/A	7 points (nontransferable)
7	95%	N/A	8 points (nontransferable)
8	N/A	Strong (no weak sections)	N/A
9	95%	N/A	8 points (nontransferable)

Table . Results of the checklists applied for quality assessment.

ID	Replaced clinical practice	Description and use of AI[a] application	Study population	Sample size
1	Diagnosis of melanoma (dermatology) and diabetic retinopathy (ophthalmology) performed solely by clinicians without AI assistance	Convolutional Neural Network (CNN)[b]. Use: decision support for the diagnosis of melanoma, caries, and diabetes	General population (age 50 y), children (age 12 y), people with diabetes (over 40 y), respectively	N/A[c]
2	Detection of intracranial large vessel occlusions in stroke cases performed solely by clinicians without AI support	Not mentioned. Use: computed angiography for stroke detection	People diagnosed with stroke (age 66 y)	71,840
3	Manual ASPECTS assessment for ischemic stroke diagnosis using computed tomography images sent via WhatsApp (Meta)	RAPID ASPECTS by iSchemaView. Use: automated cerebrovascular analysis in computed tomography images for stroke detection	Patients with ischemic stroke who received intravenous thrombolysis (average age 59 y)	122
4	The exclusive use of Lung-RADS classification by radiologists for risk stratification of lung nodules in baseline lung cancer screening	Not mentioned. Use: automated digital chest radiography for lung cancer detection	General population (63% men; average age 61 y; 93% White)	3197
5	The use of radiologists for reading chest x-rays in tuberculosis (TB) screening and triage	CAD4TB (Delft Imaging, Netherlands), Lunit INSIGHT CXR (Lunit, South Korea), qXR (Qure.ai, India), and InferRead DR Chest (Infervision, China). Use: automated digital chest radiography for TB detection	General population (no detailed information)	1.378 million
6	Standard of care tuberculosis (TB) and HIV screening without systematic digital chest x-ray and computer-aided detection (CAD)[e]	CAD4TBv5 Use: automated digital chest radiography for TB detection	Adults (>18 years) with cough symptoms (44% men; average age 33.8 y)	1462
7	Direct microbiological testing (smear microscopy or GeneXpert) for all individuals with presumptive TB, without previous triage	CAD4TBv6 and qXRv2 Use: automated digital chest radiography for TB detection	People with symptoms suggestive of TB (52% men; age 15 y and older, average 33 y)	N/A
8	Traditional radiologist interpretation of chest x-rays for pathology classification	Not mentioned. Use: automated digital chest radiography for pulmonary disease detection	General population (55% men, all ages, 36% [40-60] years, 34% [60-80] years)	129,819
9	Traditional radiologist interpretation of baseline low-dose CT[f] scans for lung cancer screening	Not mentioned. Use: automated digital chest radiography for lung cancer detection	General population (age 60 y)	N/A

[a]AI: artificial intelligence.

[b]Convolutional neural network (CNN), a type of machine learning model designed to analyze visual data, such as images, by automatically identifying patterns and features.

[c]N/A: not applicable.

[d]ASPECTS: Alberta stroke program early CT score.

[e]Computer-aided detection (CAD) refers to the use of computer algorithms to assist in the identification and diagnosis of medical conditions; CAD systems help health care professionals by highlighting potential areas of concern, improving diagnostic accuracy and efficiency.

[f]CT: computed tomography.

XSL•FO
RenderX

All studies explicitly stated the context of the study and the main question in the introduction. Moreover, they described a study design suitable for their objectives. However, the information on the populations studied was limited. Two studies [30,35] (25.0%) provided no further information, 3 [31,34,37] (37.5%) provided information on the age of participants, 3 [29,32,36] (37.5%) mentioned age and gender, and only 1 study [33] (12.5%) provided information on age, gender, and race or ethnicity. Regarding the use of AI, most studies referred to the technology's name (n=5, 62.5%). These technologies were mainly used to detect TB (n=3, 37.5%) [30-32], followed by applications in lung cancer [29,34] (n=2, 25.0%), stroke [35,36] (n=2, 25.0%), and 1 study [37] (12.5%) that focused on assisting in melanoma diagnosis.

Transferability Results

In terms of transferability, only 2 studies [35,37] (25%) were considered transferable to Brazil and other countries with a similar health context. Five studies [29-31,35,36] did not meet the discount rate criterion (62.5%), 1 study [36] did not address medical costs (12.5%), and the majority (75%) [30-32,34,36,37] did not meet the case mix criterion (Tables 4 and 5).

Equity Assessment

For the equity study, we used the EPHPP checklist and analyzed the study exhibited robust findings, with no sections identified as weak (Tables 4 and 5). The comprehensive selection of databases bolstered the representativeness of the study's population. The study design was also deemed appropriate for the methodology used. While the study could not analyze race or ethnicity and health insurance confounders for 2 of the 3 databases, it was able to assess gender and age in all cases. The data sources used were appropriately referenced by the authors and were considered reliable. The statistical methods used were deemed appropriate.

Economic Evaluation

Among the 8 economic evaluation studies identified, the majority (75%, N=6) focused on cost-effectiveness. A cost-effectiveness study evaluates the correlation between the financial resources invested and the benefits obtained, offering an essential analysis for enhancing the economic efficiency of an intervention, project, or program. However, 2 of the studies [29,30] (25.0%) were cost-minimization studies, which focus on identifying the most economical option among alternatives that yield similar outcomes, aiming to minimize expenses while delivering comparable results. Out of the 6 cost-effectiveness studies [31,32,34-37], 2 [34,35] (33.3%) examined the societal perspective, another 2 [31,32] (33.3%) considered the viewpoint of health care providers, and the remaining 2 [36,37] (33.3%) analyzed a combined perspective that encompasses both the health care system and society. Regarding the cost-minimization studies, one [29] adopted the health care system's perspective, while the other [30] took a combined approach involving both the health care system and society.

The results varied as the studies examined different scenarios with different methods. Nevertheless, the majority of the studies [29,31,32,34-37] (7 out of 8, 87.5%) showed positive results regarding the use of AI in the diagnosis of disease in dermatology, neurology, and pulmonology. The sole study presenting an unfavorable view pertained to the AI's efficacy in enhancing TB detection [30]. This singular negative outcome may be ascribed to several factors, one of which involves the economic implications of subsequent diagnostic tests required to validate the screening results, which were conducted in 61% of the study's participants. A summary of the methodological details of these economic evaluation studies is provided in Table 6.

XSL•FO
RenderX

Table . Details of the economic or equity evaluation of the studies.

ID	Model type	Perspective	Outcome measure	Direction of effect
1	Markov	Patient and health care system	The ICER[a] for dermatology and ophthalmology was –US $27,580 and –US $38,848 per QALY[b], respectively. The dominance in favor of AI[c] depended on small differences in the fee-for-service and assumed postdiagnosis treatment.	Favorable
2	Markov	Society	Over a lifetime horizon, AI resulted in cost savings of US $156 (0.23%) and an incremental gain of 0.01 QALYs per patient with suspected ischemic stroke. For each annual patient cohort, this translates to a total cost savings of US $11 million and a gain of 682 QALYs.	Favorable
3	Decision tree	Health care system and society	The incremental cost of ASPECTS[d] interpretation with WhatsApp support compared to automated ASPECTS interpretation was US $220.94. The estimated treatment decision cost was US $618.28 over a 90-day period[e].	Favorable
4	NA[f]	Health care system	Net cost savings from the AI-based management strategy of US $72 per screened patient in the first year after screening.	Favorable
5	NA	Health care system and society	The cost per screening for two CAD (computer-aided detection) software was lower than that of a radiologist (US $0.70-$0.93) for the high-yield scenarios studied. Projecting nationwide implementation, the additional cost of deploying CAD software was US $2.65 to US $19.3 million compared to US $23.97 million for human readers over a 4-year period.	Favorable
6	Not mentioned	Health care service provider	AI-assisted HIV and tuberculosis detection had an ICER of US $4620.47 per QALY, above Malawi's cost-effectiveness threshold, making it cost-ineffective compared to conventional screening within the 56-day trial period.	Unfavorable

XSL•FO
RenderX

ID	Model type	Perspective	Outcome measure	Direction of effect
7	Decision tree	Health care service provider	Screening strategies using AI-based chest radiographs compared to initial smear microscopy and GeneXpert projected cost savings of US $23,233 and US $34,346 per 1000 people, respectively, and prevented 3% - 4% and 4% of DALYs[g] over a 1-year time horizon.	Favorable
8	NA	NA	The algorithms showed underdiagnosis bias in three large public datasets based on gender, ethnicity or race, age, socioeconomic status, and intersectional subgroups.	Unfavorable
9	Markov	Society	At a willingness to pay of US $100,000 per QALY over a twenty-year analysis period, AI support for initial screening is cost-effective up to a cost of US $1240 per patient, and the ICER remains negative up to a threshold of US $68.	Favorable

[a]ICER: Incremental Cost-Effectiveness Ratio.

[b]QALY: Quality-Adjusted Life Years.

[c]AI: artificial intelligence.

[d]ASPECTS: Alberta stroke program early CT score.

[e]*: considering that £1 was equivalent to US $0.06349 on May 1, 2020 [36].

[f]NA: not applicable.

[g]DALY: disability-adjusted life years.

Equity Evaluation

Only a single study focusing on equity evaluation was identified. This study used extensive datasets containing images from over 129,000 patients. The demographics of these patients displayed an almost equal distribution across genders, with the majority aged between 40 years and 80 years. The authors developed various AI models for detecting anomalies in chest x-rays. The findings from the equity evaluation indicated signs of underdiagnosis in AI-based interpretations of these imaging examinations, especially within specific subpopulations. For a comprehensive summary of the methodological details of this equity evaluation study, refer to Table 6, under study ID: 8.

Discussion

Principal Findings

This study presents a novel systematic review that examines the economic and equity implications of AI in medical diagnostic imaging across dermatology, neurology, and pulmonology. It stands out from previous research [9] by incorporating equity considerations and expanding the scope of medical specialties beyond those traditionally studied. The findings of this systematic review suggest that AI integration could provide economic benefits to health care systems, as the majority of included studies indicate that the technology is cost-effective. However, only 1 study assessed AI from an equity perspective, highlighting the issue of underdiagnosis, particularly among subgroups defined by gender, ethnicity, and socioeconomic status. This underscores the need for further research to ensure AI models are both cost-effective and equitable in clinical practice.

An important observation from this review is the notable scarcity of studies dedicated to exploring the economic and equity impacts of AI in the diagnostic imaging of dermatological, neurological, and pulmonary diseases. The bulk of the research has centered on pulmonology, tackling conditions like TB and lung cancer, followed by neurology. Dermatology emerged as the least studied field despite the availability of numerous open datasets for training models on skin lesions. The generalizability of AI algorithms and their practical application in clinical settings remains an unresolved issue. There is a necessity for real-life clinical trials using AI algorithms to broaden their applicability in routine medical practice. Dermatology, in particular, poses a unique challenge due to the diversity of skin tones, which requires a varied dataset for effective algorithm training [38].

Moreover, this review has also underscored a remarkable deficiency in studies investigating the aspect of equity in AI

XSL•FO
RenderX

applications. This observation highlights the necessity for more inclusive research focused on equity-related issues. Furthermore, it is critical to acknowledge the potential influence of publication bias, where studies yielding positive outcomes are more likely to be published, thereby shaping the literature landscape [39].

A significant proportion of the studies included were conducted in high-income countries. Even studies involving low-income countries often collaborated with institutions from high-income countries. This trend raises important questions about the applicability of these findings in health care settings with limited resources. Some authors argue that the adoption of AI in low- and middle-income countries should follow a distinct path, rather than in high-income countries due to differences in staff, clinical experience, disease profiles, demographics, digital infrastructure, and available medical equipment. Health care facilities facing resource constraints require an integrated approach that encompasses clinical training, infrastructure enhancement, and a gradual introduction of AI technologies [40].

A key concern highlighted in this review is the insufficient detail provided about the AI tools used in the studies. Many articles did not disclose critical details such as the technology's specific name, architectural framework, training and validation datasets, manufacturer, availability, and licensing details. These omissions limit result reproducibility and hinder health care professionals' ability to implement AI technologies in clinical practice [41]. To address this gap, we emphasize the need for studies to follow established AI reporting guidelines, such as the MINIMAR (Minimum Information for Medical AI Reporting) framework, which advocates for transparency in AI model development and validation [42]. Furthermore, future studies should include standardized performance metrics, report biases in training data, and disclose the impact of image acquisition parameters, particularly in public health settings where data variability is significant. Establishing clear reporting standards and regulatory expectations will be crucial in ensuring AI models are both clinically applicable and equitably implemented.

On the other hand, the descriptions of the study populations often lacked essential demographic details, such as age, gender, and race, despite large sample sizes. This paucity of data on the study populations might impede the extrapolation of results across various demographic groups, especially when evaluating the impact of AI from an equity standpoint [41,43]. To address potential biases in AI, it is crucial for future studies to incorporate detailed demographic information and ensure training datasets are diverse across race, gender, socioeconomic status, and geographic regions. In addition, AI models should undergo fairness testing and be adjusted using bias-mitigation techniques, such as reweighting algorithms and adversarial debiasing. Policy makers should establish guidelines for transparent reporting of model performance across subpopulations and encourage collaborations between AI developers and public health institutions to ensure AI applications are equitable and contextually appropriate for diverse health care settings.

This review also identified a gap in the information regarding the timeframes during which the medical images were collected and analyzed. Understanding the timing of data collection and analysis is crucial for contextualizing the relevance of the findings. The dynamic nature of this field is reflected in the recent publication dates of the studies, indicating an evolving landscape where new technologies may emerge and existing ones may advance. Singh et al [44], 2021 reported a significant growth in the interest in medical applications of AI from 1998 to 2019, with a marked increase starting in 2015. Our systematic review, including articles regardless of publication date, found all relevant articles published post 2020, signifying a recent spike in scientific interest in evaluating AI technologies for potential health care integration.

The transferability of these technologies to Brazil's public health system presented significant challenges. Only 2 of the studies were considered relevant to the Brazilian context, a finding that resonates with similar observations in the global research community. This highlights the potential for applying these findings to other countries with comparable demographics and health care circumstances. Numerous studies from various countries have also reported challenges in adapting AI technologies to their unique health care systems. This situation underscores the necessity for crafting tailored strategies to facilitate the effective international transfer of medical technologies. To make AI interventions more effective and globally relevant, it is necessary to promote region-specific research that accounts for demographic, socioeconomic, cultural, and infrastructure variations [41].

In dermatology, real-world clinical trials are particularly critical due to the diversity of skin tones, environmental exposures, and disease presentations across populations. Data collection should be standardized and consider cultural and socioeconomic variables that may impact model performance. This can be achieved using mixed-methods research designs, including qualitative interviews and focus groups to identify context-specific factors, followed by quantitative observational studies (eg, cross-sectional and longitudinal cohort studies) to assess data quality and variable distribution. Pilot studies and feasibility trials are also valuable to test recruitment strategies, data collection workflows, and model deployment logistics in diverse settings. Data analysis should involve appropriate statistical methods, such as stratified analyses and interaction testing, to validate the model's effectiveness across different populations and clinical contexts. These methodological steps are essential for informing the design of robust, equitable clinical trials that evaluate AI-based interventions. In summary, future research should prioritize external validation of AI models on datasets that reflect social determinants of health to ensure equitable performance. In addition, partnerships between research institutions in low- and middle-income countries and international organizations could facilitate the adaptation and implementation of AI solutions, while also ensuring that developed models are more representative of the populations served. Incorporating standardized evaluation frameworks and transparency in AI reporting will further support the safe and effective deployment of dermatology-focused AI in diverse health care environments.

The only economic evaluation study reporting a disadvantageous outcome for AI use compared to standard care established a

XSL•FO
RenderX

cost-effectiveness threshold of up to US $1200 per QALY [31]. This threshold, variable across nations, is influenced by factors like per capita income, public preferences, resource availability, and health policy, yet has inherent limitations. For example, in Brazil, the threshold is set at US $7914 per QALY (considering that US $1 was equivalent to BRL R$5.05 on October 20, 2023), increasing to US $23,744 per QALY for severe and rare diseases [45]. In the United Kingdom, the range is between US $24,335 and US $36,502 per QALY gained (considering that US $1 was equivalent to GBP 0.82 on October 20, 2023) [46]. To better contextualize AI cost-effectiveness, it is essential to examine cost thresholds across different health care systems. Given the economic disparities between high-, middle-, and low-income countries, AI adoption must be evaluated within country-specific willingness-to-pay thresholds. In low- to middle-income countries, where health care budgets are more constrained, AI solutions must demonstrate cost savings that justify their implementation, particularly when compared to existing diagnostic methods. Policy makers should consider not only the direct costs of AI but also its long-term benefits, such as improved diagnostic accuracy, reduced hospitalizations, and enhanced workforce efficiency. Future research should explore region-specific economic models to determine realistic AI pricing structures that optimize health care accessibility and sustainability.

The studies in this review imply AI's potential to enhance cost-effectiveness, efficiency, and quality of life in health care, aligning with other research demonstrating AI as a cost-saving diagnostic tool. AI's acceleration of diagnosis, reduction of subjectivity, and facilitation of treatment allow health care systems to allocate resources more efficiently, yielding tangible benefits and cost reductions. Hence, AI applications are emerging as an innovative strategy potentially beneficial to patient care, with prospects for widespread adoption and long-term cost minimization [47].

However, in terms of equity, the sole study meeting the criteria indicated unfavorable outcomes, highlighting underdiagnosis in specific subgroups. This is significant as health equity is a core principle in health care, and AI should not perpetuate or intensify existing disparities. Other studies have also shown that, despite accuracy in some AI models, racial disparities can persist [18]. To ensure equity, it is recommended that AI models incorporate indicators of social determinants, such as environmental, occupational, and income exposures. Efforts should be made to integrate the full etiological "context" of a patient's health and optimize these models [43].

This study has limitations, including the potential bias of the chosen databases towards North American and European studies, possibly omitting relevant research from other regions, particularly Asia. Furthermore, the exclusion of gray literature, such as articles in open repositories like arXiv, might have constrained the scope of our review. Another significant challenge was the variability in study designs, data sources, and methodological approaches across the reviewed articles. This diversity made it difficult to synthesize the results comprehensively, rendering a meta-analysis unfeasible. Finally, the focus of this study on three specific medical fields—dermatology, neurology, and pulmonology—meant dealing with a limited number of available primary studies. This focus inherently excluded a vast array of studies in other medical areas, potentially overlooking relevant findings and insights that could be applicable to the broader discussion of AI in health care.

In summary, this systematic review emphasizes the imperative for a more robust and inclusive approach to using AI in medical imaging diagnostics, with particular attention to equity. Although the reviewed studies showcase AI's potential in enhancing medical diagnostics, it's crucial to ensure that such technologies do not deepen or perpetuate existing health disparities. Transparency in the depiction of AI tools and ensuring that study populations are representative are essential factors for consideration in future research endeavors. With AI rapidly integrating into health care, its comprehensive evaluation is necessary to guarantee that its benefits are accessible to all patients, irrespective of race, age, gender, or socioeconomic background. In addition, it is important to recognize that technologies developed within specific contexts, such as in high-income countries or for predominantly white populations, might not seamlessly transfer to other contexts or nations.

Conclusion

This review underscores the importance of transparency in the description of AI tools and representativeness of population subgroups to mitigate health disparities. As AI is rapidly being integrated into health care, detailed assessments are essential to ensure that benefits reach all patients, regardless of sociodemographic factors.

Acknowledgments

The authors would like to thank the people who contributed significantly to this project, including Pedro Vieira Santana Netto and the PROADI-SUS *Banco de Imagens* team; Leandro Seiti Anazawa, Tayna Gomes de Souza Bandeira, Renato Tanjoni, and their team; as well as the Edna Terezinha Rother's library team and the team from the Department of Science and Technology (SCTIE/DECIT) of the Brazilian Ministry of Health.

This project received funding from the Brazilian Ministry of Health, in collaboration with the Hospital Israelita Albert Einstein, under the *Programa de Apoio ao Desenvolvimento Institucional do Sistema Único de Saúde* (PROADI-SUS, NUP 25000.161106/2020 - 61).

Data Availability

All data generated or analyzed during this study are included in this published article and its supplementary information files.

Authors' Contributions

GOS, LRC, and JPQP contributed to the conceptualization of the study. Data curation was performed by GOS, LRC, RMC, RML, and BCRS. Formal analysis was conducted by GOS, RMC, and LGNP. ETR provided the necessary resources. LRC supervised the project. The original draft of the manuscript was written by RMC and GOS. All authors contributed to reviewing and editing the manuscript.

Conflicts of Interest

The authors are involved in the PROADI-SUS *Banco de Imagens* project. This project represents a joint effort between the Brazilian Ministry of Health and Hospital Israelita Albert Einstein, aiming to improve public health in Brazil. The initiative's primary focus is on establishing a nationwide, cloud-based medical image repository and developing AI algorithms to support disease diagnosis.

Abstract

Background: Body dissatisfaction is a condition where individuals are dissatisfied with their physical appearance. It has become a global issue, especially among children and emerging adults. A growing number of digital interventions have been developed to address body dissatisfaction in children and emerging adults; however, controversies remain regarding their efficacy, underscoring the need for a comprehensive synthesis of current evidence.

Objective: This systematic review aimed to explore the effectiveness of digital interventions in improving body image–related outcomes among children and emerging adults.

Methods: From inception to April 24, 2024, a literature search was performed across 7 databases—PubMed, Web of Science, MEDLINE, EBSCO (Elton B Stephens Company), Cochrane Library, CNKI (China National Knowledge Infrastructure), and WANFANG—to identify randomized controlled trials (RCTs) with a predefined set of inclusion criteria. This systematic review was reported in line with PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-analyses) guidelines. Study selection, data extraction, and risk of bias assessment using the Cochrane Risk-of-Bias Tool 2.0 were conducted independently by 2 researchers. Standardized mean differences (SMDs) and 95% CIs from the included RCTs were calculated for the meta-analysis. Heterogeneity was assessed with I^2 values. A fixed-effects model was used when $I^2 \leq 50\%$, and a random-effects model was selected when $I^2 > 50\%$.

Results: Twenty RCTs with 5251 participants (2610 in intervention groups and 2641 in control groups) met the inclusion criteria. Digital interventions included web pages, mobile apps, computer-based videos, computer-based sessions, internet-based sessions, internet games, chatbots, podcasts, and social media. Our results indicate that digital interventions could significantly improve body dissatisfaction (SMD=0.38, 95% CI −0.63 to −0.13; I^2=55%; P=.003), physical appearance comparison (SMD=−0.24, 95% CI −0.45 to −0.03; I^2=0%; P=.003), thin-ideal internalization (SMD=−0.28, 95% CI −0.36 to −0.2; I^2=41%; P<.001), self-esteem (SMD=0.14, 95% CI 0.07-0.21; I^2=21%; P<.001), self-compassion (SMD=0.55, 95% CI 0.33-0.78; I^2=35%; P<.001), and depression (SMD=−0.59, 95% CI −0.97 to −0.21; I^2=0%; P=.002), with small to medium effect sizes.

Conclusions: While digital interventions improved body dissatisfaction among children and emerging adults, additional well-designed, rigorous, and large-scale RCTs are needed to decisively provide estimates of the effectiveness of digital interventions on body dissatisfaction.

Introduction

Prevalence and Impacts of Body Dissatisfaction

Body image encompasses an individual's cognition, emotional attitudes, and behavioral regulation regarding their body, and is a multidimensional concept [1]. Dissatisfaction with one's body's appearance, including its shape, weight, and other features, is known as body dissatisfaction [2]. Body dissatisfaction has a pervasive hold on children and emerging adults, and the phenomenon has been described as "normative discontent" [3]. Studies showed the prevalence of body dissatisfaction ranged from 42.2% to 80.9% among children and emerging adults across the world [4-7]. Females, those with higher BMI, and those from minority groups were reported to experience greater body dissatisfaction [8]. Body dissatisfaction can lead to a range of physiological issues, such as low self-esteem [9], anxiety [10], and depression [11], as well as behavioral burdens, such as eating disorders [12], extreme weight loss behaviors [13], alcohol, drug abuse [14], and excessive pursuit of cosmetic procedures [15]. The direct economic costs of body dissatisfaction were estimated to be US $84 billion in the United States [16].

Existing Face-to-Face Interventions and Limitations

Existing face-to-face interventions, such as cognitive behavioral therapy (CBT) and behavior interventions and supports (BIS), demonstrated small to moderate efficacy in reducing body dissatisfaction. For instance, CBT helps reframe maladaptive thoughts about body image [17], while dissonance-based interventions like the EVERYbody Project reduced thin-ideal internalization and eating disorder symptoms in college students [18]. A systematic review revealed that behavior interventions and supports improved disordered eating, body dissatisfaction, and extreme weight control behaviors in girls, but not boys [19]. However, the face-to-face interventions are sometimes constrained by accessibility, the costly nature of the format, a global shortage of mental health professionals, or stigma [20].

Efficacy of Digital Interventions

Digital technologies offered cost-effective alternatives in body dissatisfaction interventions [21]. Although studies identified that social media engagement was associated with higher body dissatisfaction and restricting food [22], digital interventions could offer especially critical support in adolescents [23]. A systematic review assessed the effectiveness of universal body image interventions delivered through a digital platform among young women. Most articles indicated that these interventions were effective in improving at least one body image outcome [24]. However, findings in other studies remained inconsistent. A study involving 127 girls aged 10-13 years, using videos developed by the Dove Self-Esteem Project, revealed that after intervention, there was no significant difference between the intervention group and the control group on body satisfaction [25]. This highlights the need for a comprehensive synthesis of current evidence.

Gaps in Current Evidence

There was no systematic review to explore the effectiveness of digital interventions on body dissatisfaction in children and emerging adults through quantitative synthesis. In this regard, this study aimed to fill this identified gap in the literature through a meta-analysis and to synthesize the effectiveness of various digital interventions on children and emerging adults with body dissatisfaction. By providing meta-analyses of currently available randomized controlled trials in children and emerging adults, this paper aimed to consolidate evidence on the use of digital interventions to treat body dissatisfaction.

Methods

Search Strategy

This systematic review was reported in line with PRISMA (Preferred Reporting Items for Systematic Review and Meta-analysis) guidelines [26] (the PRISMA checklist is provided in Checklist 1). PubMed, Web of Science, MEDLINE, EBSCO (Elton B Stephens Company), Cochrane Library, the Chinese databases CNKI (China National Knowledge Infrastructure) and WANFANG were searched from inception to April 24, 2024. This process was carried out independently by 2 researchers (LL & JNY). The PICOS (population, intervention, comparison, outcome, and study design) formula was used:

- Population (#1): youth OR young* OR child* OR adolescent OR teen* OR juvenile OR junior OR girl OR boy OR adult or students;
- Intervention (#2): remote OR website OR digital OR online OR network OR phone OR internet OR eHealth OR mHealth OR app OR multimedia OR social media OR zoom OR Facebook OR Instagram OR telephone OR (virtual reality);
- Comparison (#3): "usual care";
- Outcomes (#4): (body image) OR (body shape) OR (body dissatisfaction) OR (body weight) OR (physical appearance);
- Study design (#5): randomized controlled trials.

The final search strategy is #1 AND #2 AND #3, with #4 (Type of Study: randomized controlled trial) applied as a filter. Reference lists of publications were also searched for potentially relevant studies (see Multimedia Appendix 1).

Inclusion and Exclusion Criteria

Design

Any randomized controlled trial (RCT) in English or Chinese that explored the effects of digital interventions on body dissatisfaction among children or emerging adults was included, including randomized waitlist-controlled trials and crossover RCTs.

Participants

Children (<18 years [27]) or emerging adults (18 - 25 years [28]) with body dissatisfaction were included. Some special groups of children or emerging adults were excluded, including but not limited to those who were pregnant, postpartum women, new mothers, children, or emerging adults with amputation, patients with cancer, models, or cosmetic surgery sequelae. Only children's data were extracted if parents and children had been involved in the RCTs as participants.

XSL•FO
RenderX

Intervention

Intervention methods were based on Internet or smartphone technologies, including apps, web pages, virtual reality, telemedicine, Zoom (Zoom Video Communications), Facebook (Meta Platforms), Instagram (Meta Platforms), and other social media.

Outcomes

Outcomes of interest include at least one of the following measures, primary outcomes: body image satisfaction or dissatisfaction, such as body dissatisfaction, body appreciation, shape and weight concerns, and physical appearance comparisons; secondary outcomes: internalized outcomes, such as self-esteem, self-compassion, thin-ideal internalization, and self-objectification; negative affect, such as depression and anxiety symptoms, and negative affect; and eating behaviors, such as eating disorder and eating restraint. These secondary outcomes were selected based on the Tripartite Influence Model [29], which presents that family, peers, and media influence an individual's body dissatisfaction via appearance-related social comparisons and thin-ideal internalization. Thin-ideal internalization serves as a predictor of body dissatisfaction [30], while studies showed that body dissatisfaction acted as a risk factor for negative affect [31] and eating disorder pathology [32].

Study Selection

The reference manager EndNote 21 (Clarivate) was used to manage studies and remove duplicates. The remaining records were screened by 2 independent reviewers (LL and JNY) based on the titles and the abstracts. The full text of studies that either reviewer identified as potentially eligible continued to be read and screened by the 2 independent reviewers (LL and JNY) based on the inclusion and exclusion criteria. Any discrepancies were resolved with the third reviewer (XLZ) until consensus was reached.

Quality Assessment

The risk of bias in eligible RCTs was independently assessed by the 2 reviewers (LL and JNY) according to 7 domains of the Cochrane risk-of-bias tool for randomized trials [33]: (1) random sequence generation, (2) allocation concealment, (3) blinding of participants and personnel, (4) blinding of outcome assessment, (5) incomplete outcome data, (6) selective reporting, and (7) other potential sources of bias. For each domain, the risk of bias was classified as low, high, or unclear. Discrepancies were adjudicated by the third reviewer (XLZ) until a consensus was achieved. Studies were considered low risk of bias if all 7 domains were assessed as low risk, or only one domain was assessed as high risk or unclear. If 2 domains were assessed as high risk or unclear, the studies were determined to have some concerns. If more than 2 domains were assessed as high risk or unclear, the study was rated a high risk of bias [34].

Data Extraction

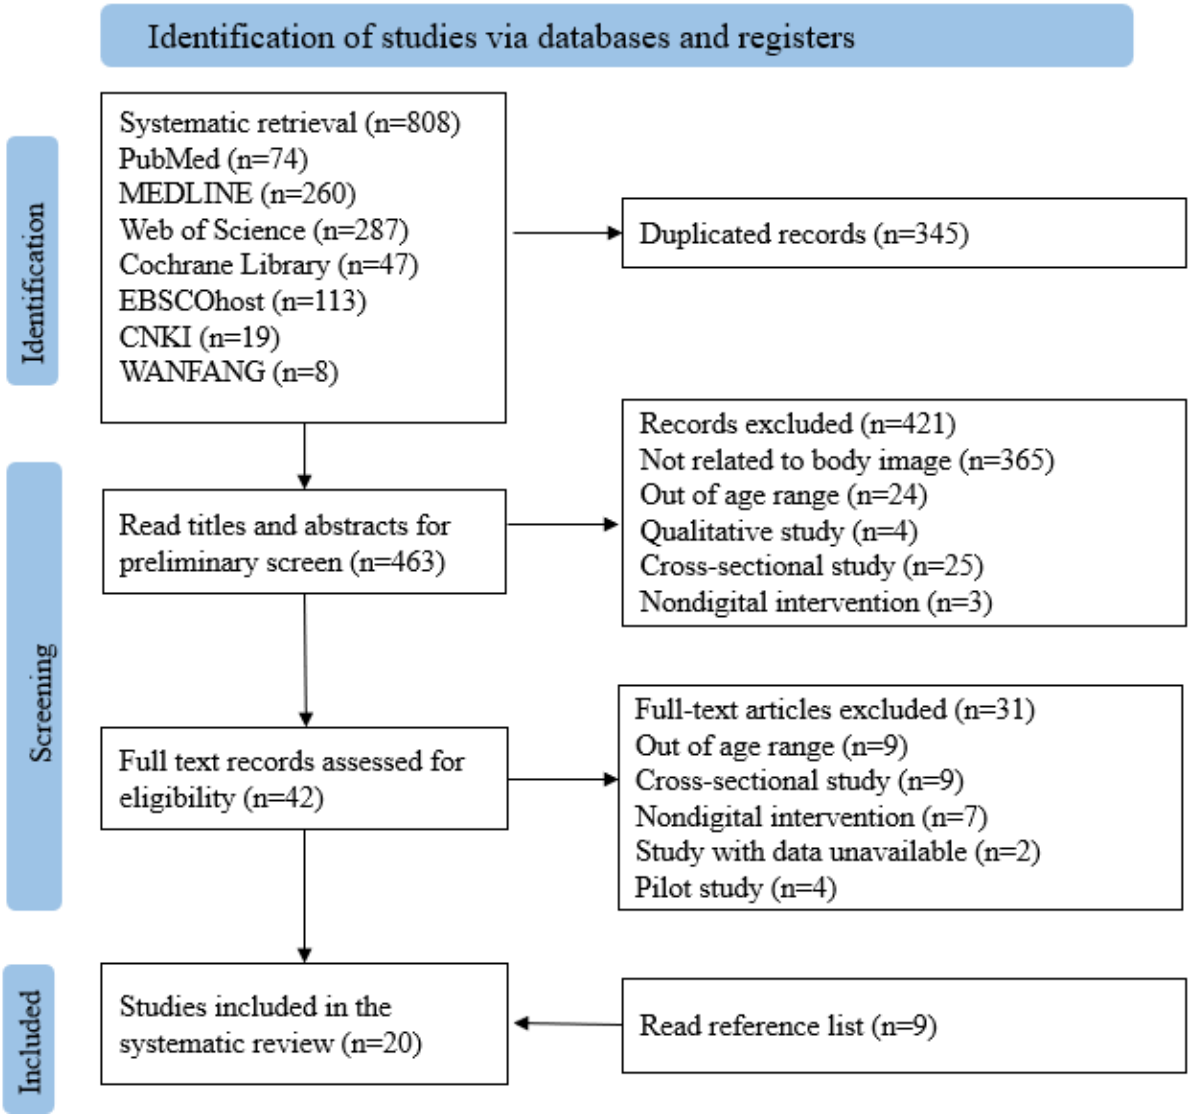
A standardized data extraction form was used to extract data from each study, which included the following details: (1) first author, the year of publication, and country; (2) inclusion and exclusion criteria; (3) sample size of the experimental and control groups; (4) intervention characteristics (contents of intervention and comparison, follow-up); and (5) outcomes and main results. Data were extracted by LL and JNY and verified by XLZ. Only the data in the first period were extracted in the randomized waitlist-controlled trials. Only the data in the digital intervention groups and the control groups were extracted when participants were divided into more than 2 groups.

Data Analysis

Review Manager v5.4.1 (Cochrane Collaboration) was used for data synthesis. The findings that could not be synthesized were narratively described based on the outcomes of interest. For the continuous variables, standardized mean difference (SMD) and 95% CIs were calculated through random or fixed-effects models when the studies assessed the same outcome. SMD values of 0.2 - 0.5 represented a small effect size, 0.5 - 0.8 was considered medium, and values greater than 0.8 were interpreted as large [35]. The effect size of individual studies was mainly combined using the random effects model because of the different scales involved in assessing the same outcomes. The I^2 statistic was used to assess the heterogeneity across studies. I^2 values of 25%, 50%, and 75% were considered as low, moderate, and high heterogeneity [36]. When $I^2 \leq 50\%$, a fixed-effects model was selected; otherwise, a random-effects model was used [37]. Strategies for addressing heterogeneity included choosing a random or fixed effect model, excluding studies, or conducting subgroup analysis. The test level was $\alpha=.05$, and $P<.05$ was considered to indicate statistical significance.

Ethical Considerations

This systematic review is based on the synthesis of previously published studies and does not involve the collection of primary data directly from human participants. As such, formal ethical approval, including an institutional review board approval number, informed consent, and compensation, was not applicable. However, we have adhered to the ethical principles of research, including the accurate and transparent reporting of study findings. We have also ensured that all included studies were conducted in accordance with relevant ethical guidelines and regulations.



Results

Search Results

A total of 808 records were identified from the initial literature search. After removing the duplicates, titles and abstracts were screened, and 42 studies were further reviewed in full text. Finally, 20 studies [25,38-56] met the inclusion criteria, including 9 [41-43,49,50,53-56] studies identified from reference lists. The study selection flow chart is shown in Figure 1.

XSL•FO
RenderX

Figure 1. Preferred Reporting Items for Systematic Reviews and Meta-Analyses flow diagram.

Study Characteristics

All the studies included were RCTs, including randomized waitlist-controlled trials (n=7). Only the data in the first phase were extracted in the randomized crossover and waitlist trials. Of the included studies, 20 RCTs with 5251 participants were included, including 2610 participants in the intervention groups and 2641 participants in the control groups. The studies were published between 2000 and 2023 and were conducted in the United States (n=10), Australia (n=3), the United Kingdom (n=3), China (n=1), Indonesia (n=1), Italy (n=1), and Brazil (n=1). Five studies [38-42] had mixed-gender samples, 15 [25,42-56] with only females. Sample sizes of the included studies ranged from 53 to 2000. All studies reported postintervention effects, whereas short-term and long-term follow-up data were reported in 11 [38,42,43,45,49,51-56] and 3 [39-41] studies, respectively. Participants and study characteristics are summarized in Table 1.

The digital interventions mainly included web page (n=6), computer-based sessions (n=1), internet-based sessions (n=2), computer-based videos (n=2), social media–based video (n=1), social media (n=3), such as Facebook and podcasts, mobile apps (n=2), internet games (n=1), animated films (n=1), and chatbot (n=1). Among the included studies, the interventions varied in length from 1 minute to 2 hours per session and in duration, ranging from a single day up to 8 weeks.

Risk of Bias in Studies

Of the 20 included studies, only 4 (20%) were assessed as low risk of bias, while 13 (65%) demonstrated high risk of bias, and 3 (15%) were categorized as moderate risk of bias (see Multimedia Appendix 2).

Random Sequence Generation

This domain assesses whether the method used to generate the random sequence was adequate to prevent selection bias. Although all studies were reported to be RCTs, only 11 studies were assessed as having a low risk of bias in random sequence generation. Computer-generated random numbers were reported in 1 study [46], and a random number table was reported in 3 studies [25,39,42]. Cluster or block randomization was reported in 4 studies [38,41,53,55]. Minimization functions in Qualtrics were reported in 2 studies [40,56]. It was reported in 1 study [54] that whole timeslots were randomly allocated to a condition to avoid cross-contamination in an open computer laboratory, which was assessed as low risk of bias. However, 1 study [44] was assessed as having a high risk of bias in random sequence generation because students were assigned to a group based on class schedule rather than randomization. The remaining 8 studies [43,45,47-52], which did not mention a specific method used to generate the random sequence, were assessed as unclear bias.

Allocation Concealment

This domain evaluates whether the process of assigning participants to groups was concealed. Participants were reported to be randomly allocated to the intervention or control groups in all studies. Only 4 studies [39,41,49,53] reported the use of email to complete allocation concealment, which was assessed as a low risk of bias. In one study [55] reported participants and researchers were not concealed from the randomized arm, which was assessed as a high risk of bias. Due to a lack of further details about allocation concealment, 15 studies [25,38,40,42-48,50-52,54,56] were considered as an unclear risk of bias.

Blinding of Participants and Personnel

This domain assesses whether participants and researchers were blinded to group allocation. It was hard to achieve the blinding of participants or personnel because digital interventions were conducted in intervention groups and nondigital interventions were conducted in control groups in most studies involved. Internet-based or social media assessments and interventions were used in 6 studies [45,46,51,53-55], which may be interpreted as blinding of participants and personnel. Among the 6 studies, 1 study [45] reported that participants used a pseudonym. One study [54] reported that all assessments were self-reported anonymously via computer. One study [39] reported that assessments were housed on a survey software, and the procedure was identical for participants in both the intervention and control groups. Two studies [25,44] mentioned that participants were instructed not to discuss the study with other students to reduce potential cross-contamination, which might be seen as blinding participants and personnel. Four studies [40,42,47,49] were assessed as high risk of bias for their failure to blind participants. Seven studies [38,42,44,46,48,53,56] were assessed as unclear risk of bias due to a lack of further details being reported.

Blinding of Outcome Assessment

This domain evaluates whether the outcome assessors were blinded to the intervention group assignments. Twelve studies were assessed as having a low risk of bias in the blinding of outcome assessment. One [42] of these studies used dummy codes instead of participants' names for outcome assessment. The outcome assessors in another 2 studies [48,55] were unaware of group allocation. Although assessors were not blinded, questionnaires were completed via website, social media, or application by participants in 6 studies [38,39,41,46,53,54]. Another 3 studies [47,49,56] were assessed as having a low risk of bias because questionnaires were sent by e-mail. Eight studies [25,38-40,46-48,50] were assessed as unclear due to the lack of clear information on whether the outcome assessors were blinded to the intervention group assignments. No study was evaluated as having a high risk of bias.

Incomplete Outcome Data

This domain assesses whether there was any missing data and how it was handled. Fourteen studies were assessed to have a low risk of bias. Three [25,41,53] of these studies reported that no missing data emerged. One study [45] reported the usage of baseline measures in place of missing posttreatment or follow-up data. One study [46] claimed that its missing item values were replaced with the mean value of that participant's scale scores. Another 9 studies [38-40,43,47,48,51,54,55] reported low attrition rates with balanced numbers across groups. Four studies [42,44,49,56] were assessed as high risk of bias because of high attrition rates after being randomized. Two studies [50,52] did not report any information about the attrition rate, which was assessed to be at unclear risk of bias.

Selective Reporting

This domain evaluates whether the study reported all the outcomes that were planned at the outset. One study [49] was assessed to be at high risk of bias, as it mentioned that nonsignificant results were not reported. A total of 19 studies [25,38-48,50-56] were assessed as having a low risk of bias.

Other Potential Sources of Bias

This domain assesses other potential biases not covered by the previous domains. Seven studies [25,39,40,42,52,54,55] with microinterventions lasting less than a week were assessed as unclear risk of bias. The rest appeared to be free of other biases (Figure 2) [25,38-45,47-56]. A funnel plot of SE against SMD was generated for 2 outcomes with at least 10 studies: thin-ideal internalization and body dissatisfaction. A visual inspection of the plot for the 2 funnel plots revealed the presence of publication bias (Multimedia Appendix 3).

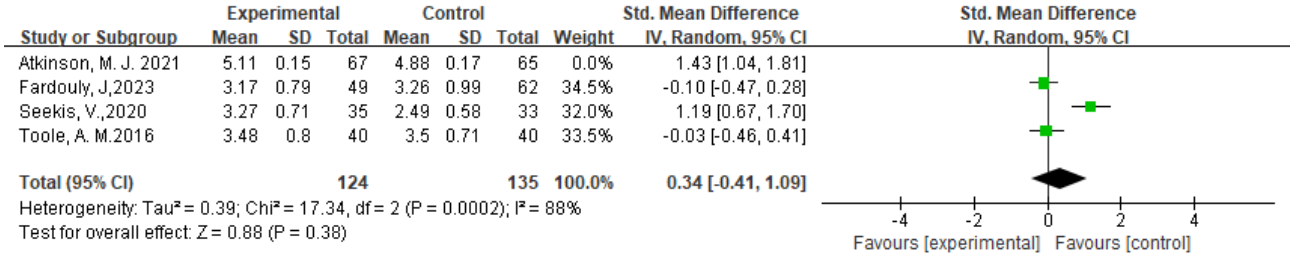
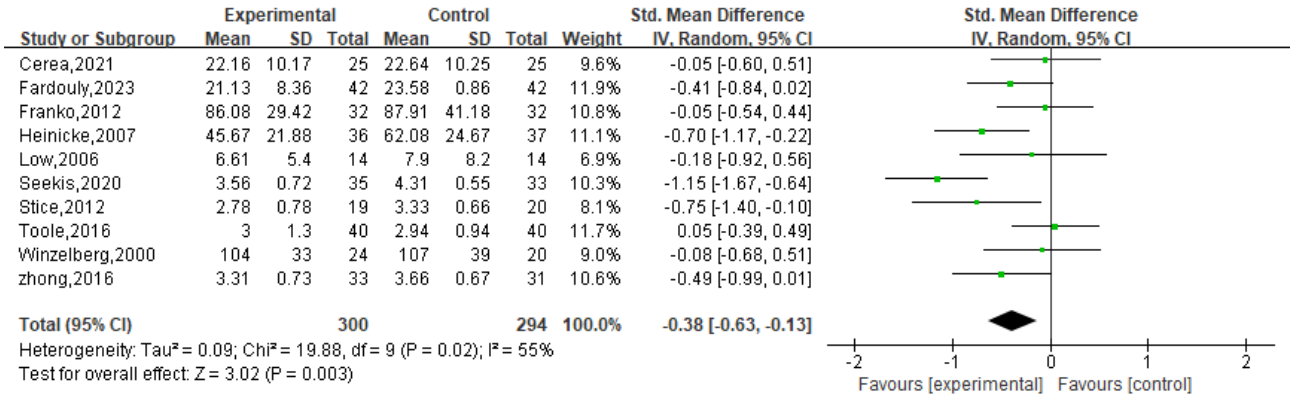
Results of Syntheses

The Effect of Digital Interventions on Body Image Satisfaction or Dissatisfaction



Three studies [40,42,54] reported the original data of body satisfaction among 1157 children and emerging adults by using the body satisfaction subscale of Visual Analogue Scale (VAS), and the higher scores indicated higher body satisfaction. The effect of digital interventions on body satisfaction was shown to be nonsignificant in the random-effect model (SMD=0.86, 95% CI −0.17 to 1.89) with a high level of heterogeneity across studies (I^2=98%; P=.10). This may be due to a diverse rating system, that is, one study used the mean score for each item, while another two studies used a summed score. While the heterogeneity reduced (I^2=53%) after one study [40] was excluded, and the result was a statistically significant conclusion with a small effect size (SMD=0.29, 95% CI 0.04 to 0.55; P=.02; Figure 3 [40,42,54]).

Figure 3. The effect of digital interventions on body satisfaction [40,42,54].

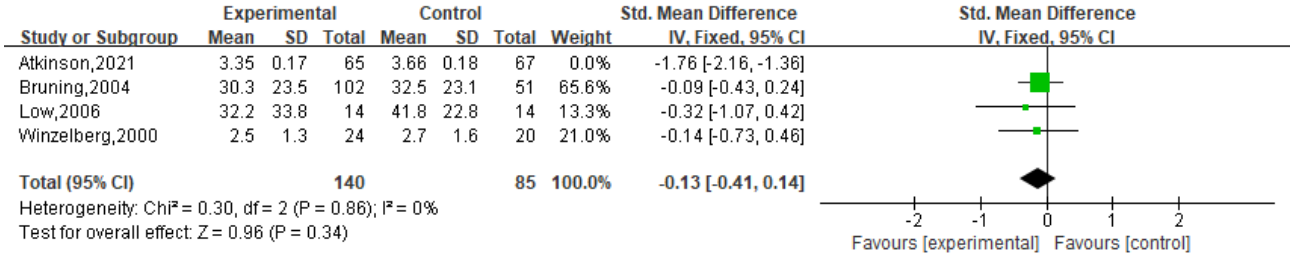


Four studies [51,53,54,56] assessed the effect of digital interventions on body appreciation among 391 children and emerging adults. The pooled analysis showed a nonsignificant improvement in body appreciation between groups in the random-effects model with a high level of heterogeneity (SMD=0.62, 95% CI −0.19 to 1.43; I^2=93%; P=.13). When excluding the study [54] with the outlying effect size, the overall effect did not change (SMD=0.34, 95% CI −0.41 to 1.09; P=.038; Figure 4 [51,53,54,56]), and the heterogeneity remained high (I^2=88%).

Figure 4. The effect of digital interventions on body appreciation [51,53,54,56].

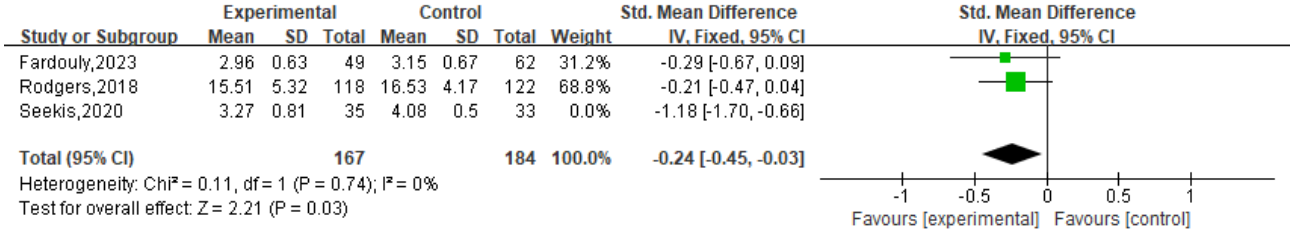
Ten RCTs [41,43,45-48,50,51,53,56] assessed the effect of digital interventions on body dissatisfaction among 594 participants, and the higher scores of the scales used in these studies indicated higher body dissatisfaction. The effect of digital interventions on body dissatisfaction was shown to be statistically significant with a small effect size in the random-effect model (SMD=−0.38, 95% CI: −0.63 to −0.13; I^2=55%; P=.003; Figure 5 [41,43,45-48,50,51,53,56]).

Figure 5. The effect of digital interventions on body dissatisfaction [41,43,45-48,50,51,53,56].



Four RCTs [43-45,54], including 357 participants, reported the effectiveness of digital interventions on the shape and weight concerns. Shape and weight concern is a facet of negative body image, and higher scores on the scales in the included studies reflected greater body dissatisfaction and less body image satisfaction. The pooled analysis showed non-significant improvement (SMD=−0.59, 95% CI −1.5 to 0.32) in shape and weight concern with high heterogeneity (I^2=93%; P=.21). There was no heterogeneity (I^2=0%) after one study [54] was excluded

XSL•FO
RenderX



(SMD=−0.13, 95% CI −0.41 to 0.14; *P*=.34; Figure 6 [43-45,54]). However, the result was not significantly different between groups.

Figure 6. The effect of digital interventions on shape and weight concerns [43-45,54].

Three RCTs [39,53,56] measured the effects of digital interventions on physical appearance comparison among 419 participants. The higher the scores of the scales included in the studies, the more severe the physical appearance comparison among the participants. The result showed a statistically significant conclusion with high heterogeneity (SMD=−0.52, 95% CI −1.02 to −0.01; I^2=82%; *P*=.004). The heterogeneity decreased to low with a small effect size (SMD=−0.24, 95% CI −0.45 to −0.03; I^2=0%; *P*=.03; Figure 7 [39,53,56]) when one study [53] was excluded.

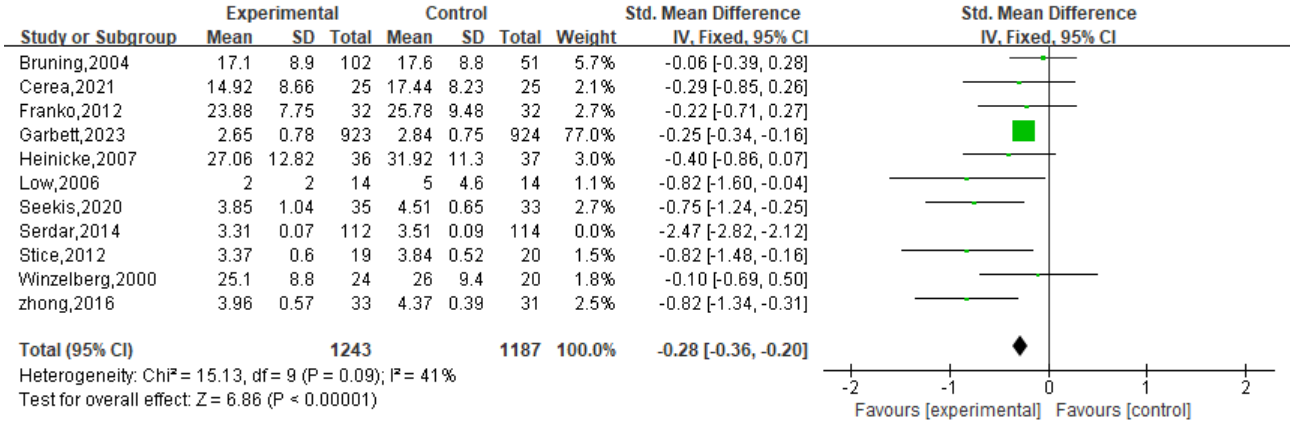


Figure 7. The effect of digital interventions on physical appearance comparison [39,53,56].

Effect of Digital Interventions on Internalized Outcomes

Eleven RCTs [41,43-50,53,55] measured the effect of digital interventions on thin-ideal internalization among 3362 participants. The higher the scores of thin-ideal internalization, the stronger the desire to be thinner, not objectively thin. The pooled analysis showed a significant improvement in thin-ideal internalization in the random-effect model (SMD=−0.64, 95% CI −1.09 to −0.18) with high heterogeneity (I^2=94; *P*<.001). The heterogeneity reduced to moderate (I^2=41%) when one study [49] was excluded, while the result remained a small and significant effect size (SMD=−0.28, 95% CI −0.36 to −0.20; *P*=.001; Figure 8 [41,43-50,53,55]).

Figure 8. The effect of digital interventions on thin-ideal internalization [41,43-50,53,55].

Six RCTs [25,38,39,42,49,55] measured the effectiveness of digital interventions on self-esteem among 3632 participants. Higher scores for self-esteem indicate higher body image satisfaction. The result depicted self-esteem in the experimental group was significantly better than the control group with high heterogeneity (SMD=0.28, 95% CI 0.08-0.47; I^2=81%; *P*=.005). When excluding the study [49], the intervention effect on self-esteem remained significant with a small effect size (SMD=0.14, 95% CI 0.07-0.21) with low heterogeneity (I^2=21%, *P*<.001; Multimedia Appendix 4).

Meta-analysis results on 3 studies [39,51,53] with 385 participants showed that self-compassion in the experimental group was significantly better than the control group with a high level of heterogeneity (SMD=0.73, 95% CI 0.25-1.2; I^2=76%; *P*=.003). The heterogeneity reduced to moderate (I^2=35%) after excluding the study [53], and the intervention effect on

XSL•FO
RenderX

self-compassion remained significant with a medium effect size (SMD=0.55, 95% CI 0.33-0.78; *P*=.001; Multimedia Appendix 5).

Two RCTs [52,56] assessed the effect of digital interventions on self-objectification among 191 participants. Self-objectification refers to conceptualizing one's own body as objects to be scrutinized by others, and higher levels of self-objectification indicate greater body dissatisfaction. The pooled analysis showed that self-objectification in the experimental groups was not significantly different from the control groups (SMD=−0.05, 95% CI −0.33 to 0.24; I^2=0%; *P*=.75; Multimedia Appendix 6).

Effect of Digital Interventions on Negative Affect

Four RCTs [39,42,55,56] assessed the effect of digital interventions on negative affect among 2981 participants. The negative effects include afraid, upset, shame, hostility, and misery, and higher scores of negative affect indicate higher body dissatisfaction. The pooled analysis showed that the negative affect in the experimental groups was not superior to the control groups (SMD=−0.07, 95% CI −0.14 to 0.00; I^2=0%; *P*=.05; Multimedia Appendix 7).

Four RCTs reported the effect of digital interventions on depression, anxiety, and stress among 342 participants by using the Beck Depression Inventory (BDI) [46,48], the Depression Anxiety Stress Scale-21 (DASS-21) [41], and the Social Appearance Anxiety Scale (SAAS) [53]. The higher scores in the 3 scales indicate higher depression, anxiety, and stress. Owing to the assessment of different psychological outcomes, the data could not be synthesized in the 2 studies [41,53], and there was no statistically significant improvement found in the 2 studies, separately. However, the pooled analysis of the BDI group showed a significant improvement in depression in the fixed-effects model with a medium effect size (SMD=−0.59, 95% CI −0.97 to −0.21; I^2=0%; *P*=.002; Multimedia Appendix 8).

Effect of Digital Interventions on Eating Behaviors

Four RCTs [41,44,45,49] assessed the effect of digital interventions on eating disorders among 457 participants. The pooled analysis of eating disorders showed there was no statistically significant difference between groups (SMD=−0.37, 95% CI −1.36 to 0.6) with high heterogeneity (I^2=95%; *P*=.45). The heterogeneity decreased to low (I^2=0%) after one study [49] was excluded, and the result remained no significant difference between groups (SMD=−0.04, 95% CI −0.31 to 0.22; *P*=.75; Multimedia Appendix 9).

Two RCTs [46,48] assessed the effect of digital interventions on eating restraint among 203 participants. Higher scores of eating restraint are indicative of greater use of extreme weight loss behaviors. The pooled analysis of eating restraint showed that there was no statistically significant difference between groups (SMD=−0.36, 95% CI −0.71 to 0.00; I^2=31%; *P*=.05; Multimedia Appendix 10).

Discussion

Principal Findings

This systematic review and meta-analysis synthesized evidence from 20 RCTs involving 5251 participants to evaluate the effectiveness of digital interventions (eg, web pages, mobile apps, and social media) on body dissatisfaction and related outcomes. Key findings indicated that digital interventions significantly improved body dissatisfaction, physical appearance comparison, thin-ideal internalization, self-esteem, self-compassion, and depression, with small to medium effect sizes. However, there was substantial heterogeneity across studies, and potential publication bias was detected. Digital interventions did not significantly improve negative affect (including depression and anxiety) and eating behaviors.

Study Characteristics

All the included studies have been conducted in the last 2 decades, but only 2 studies have been done in developing countries. This indicates that high-quality RCTs need to be conducted further in this area, especially to explore their effectiveness on body dissatisfaction in different ethnic and cultural backgrounds in developing countries [57]. Ten out of twenty included studies selected different theories or models to motivate participants to reduce the pursuit of thin-ideal internalization, to improve emotional regulation, such as self-compassion, and to develop coping strategies with the involvement of parents, peers, and the media. The cognitive dissonance theory, cognitive behavioral theory, and sociocultural theory were recognized as the most widely mentioned theories to reduce body dissatisfaction in the studies. The average sample size was high 200s, but most studies included participants of less than 100. This would result from the narrow age range and the diagnosis of anorexia nervosa and other eating or psychiatric disorders among children and emerging adults in the inclusion criteria. The participants' ages ranged from 7 to 25 years old, and 6 studies included those younger than 14 years old in private or public schools as participants. Nearly 80% of participants were females in this review, and 9 studies only included female college students or undergraduates as participants, which accounted for 16.7% of the total participants. This can indicate that females would be more likely to experience body dissatisfaction, like other studies [58].

Comparison to Previous Work

The meta-analysis revealed that digital interventions showed a small to medium effect across most outcomes in body satisfaction and internalized outcomes, and the result was similar to another systematic review [24]. In the systematic review, although there was no quantitative synthesis, body dissatisfaction, body esteem, body appreciation, and other body image outcomes were also included in the review to explore the effectiveness of digital interventions in emerging adults and emerging adults. The results showed 8 out of 15 studies reported digital interventions were effective in improving at least one body image outcome from pre-post interventions with mostly small to medium effect sizes. This means digital interventions are superior to some traditional interventions, such as brochures, documentaries, newspapers, or magazines. It may result from

XSL•FO
RenderX

the advantages of digital interventions, such as real-time feedback and motivation enhancement [59], and anonymity of platforms [60], which could reduce the shame and social anxiety emerging adults face when dealing with body image-related issues. However, given that effect sizes were small to medium, it would be caused by the following reasons. First, the intervention duration of this meta-analysis was 6 weeks on average. Second, digital intervention had its limitations, such as being incapable of genuinely caring about one's feelings during the intervention process. This indicated that digital interventions with an in-person element would be associated with greater effectiveness in body image [61].

Digital interventions did not significantly reduce the negative affect (including depression and anxiety) and eating behaviors. However, another 2 systematic reviews [61,62] found a significant effect of digital interventions on depression and anxiety among emerging adults and emerging adults. This would result from the contents of the digital interventions. The digital interventions of the 2 systematic reviews specifically targeted mental health disorders, including depression and anxiety. However, this meta-analysis mainly targeted improving body dissatisfaction with depression and anxiety as secondary outcomes in some studies included. Furthermore, it indicated that digital psychotherapy did not significantly reduce both eating disorders and restrained eating in this meta-analysis. This would be caused by the following reasons. First, no more than 4 RCTs were included in this meta-analysis to explore the effects of digital interventions on eating disorders or restraint eating. Second, the age of participants in this meta-analysis ranged from 7 to 25 years. Especially for the emerging adults who were predominant participants, who have already established eating behavior habits, which would be so ingrained and resistant to change through short-term digital psychological therapy. According to the Transtheoretical Model [63], the process of behavior change is complicated with 6 different stages, and it would not be easy to change eating behaviors. In addition, the digital interventions in the 20 included RCTs were aimed at addressing body dissatisfaction rather than specific eating disorder symptoms, which might account for the insignificant outcome in changing eating behaviors.

Implications for Clinical Practice

The findings suggest that digital interventions can serve as scalable and cost-effective supplementary tools to improve body dissatisfaction in children and emerging adults. Clinicians may recommend digital interventions as adjuncts to traditional face-to-face therapies, particularly for individuals with limited access to in-person mental health services due to cost, stigma, or geographic barriers. Body dissatisfaction, thin-ideal internalization, eating disorders, and negative affect should be addressed simultaneously in a single intervention to verify the effectiveness of digital interventions in the future. Future studies should be conducted in Asia and some other low-income countries, as this review found that studies in these regions are lacking. Furthermore, the quality of included studies held room for improvement.

Limitations

This systematic review has several limitations. First, the high heterogeneity in meta-analysis may result from the use of different scales to assess the same outcomes, even using different versions or varying score systems (eg, summed versus mean scores) of the same scales. However, the SMD was selected to express the size of the intervention effect, instead of the mean difference. Second, confidence in the meta-analysis was limited because waitlist groups were set in 7 studies, and assessment-only control (receive no intervention) groups were set in another 4 studies, rather than active control groups. Third, there was insufficient data on long‐term follow‐up and a potential gap that future RCTs can look to fill. Specific tactics could be analyzed to maintain engagement in body image interventions for children and emerging adults, such as integrating digital interventions into existing curricula. Fourth, the quality of included studies held room for improvement, with most of the RCTs included being rated as "unclear risk" for bias. Fifth, publication bias may have influenced the results, particularly for outcomes with small sample sizes, highlighting the need for larger, registered RCTs.

Conclusion

Digital interventions could help children and emerging adults improve body satisfaction or dissatisfaction, physical appearance comparison, thin-ideal internalization, self-esteem, self-compassion, and depression. Because of the limitations, the results should be generalized with caution. In the future, high-quality RCTs with longer intervention duration and long-term follow-up should be conducted, especially in different races and cultures in transitional countries.

Abstract

Background: Patents are an early sign of innovation, yet their role in horizon scanning for health care remains unclear.

Objective: This study investigates the role of, and methods for, patent analysis in advancing health care technology innovation in a sector that is characterized by diverse health care technologies and significant research investment. Patents are critical early indicators of innovation, supporting horizon scanning and weak signal detection. The study aimed to identify intellectual property sources, evaluate methods for patent retrieval and analysis, and outline objectives for using patent data to anticipate trends and inform health care strategies.

Methods: A rapid scoping review was conducted following Cochrane Rapid Review Methods recommendations and PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, with a preregistered protocol on the Open Science Framework. Searches in Embase, IEEE Xplore, and Web of Science targeted records published 2020 onward to capture the most recent sources, methods, and tools. Three independent reviewers screened studies using Rayyan (Qatar Computing Research Institute). We included any study type published since 2020 that provided patent sources data, methods, and tools applied to the study of health care technologies. Our data extraction included bibliographic details, study characteristics, and methodological information. Risk of bias assessments were not undertaken. Narrative and tabular methods, supplemented by visual charts, were used to synthesize findings.

Results: Our searches identified 1741 studies, of which 124 were included after title, abstract, and full-text screening, with 54% being original research, 43.5% reviews, and the remainder being conference abstracts (2.5%). Most studies (68%) relied solely on patent databases, while others searched the gray and published literature. Research objectives of the included studies were grouped into 10 themes, with trend analysis (50%) and the provision of recommendations for future research, policy, and strategy development (20%) being the most common. Our review identified up to 47 patent databases, with 27% of studies using multiple sources. Whenever time limits were reported, the mean time horizon for patent searches was 24.6 years, ranging from 1900 to 2019. Automated approaches, used in 33% (n=43) of studies, frequently used tools such as Gephi (Gephi Consortium) for network visualization. Disease mapping based on National Institute for Health and Care Excellence classification indicated that cancer (19%) and respiratory conditions (16%), particularly COVID-19, were key areas.

Conclusions: Patent data are valuable for identifying technological trends and informing policy and research strategies. While patents provide crucial insights into emerging technologies, inconsistent deduplication practices across studies pose the risk of data inflation, accentuating the need for transparency and rigor. Finally, this review emphasized the importance of data transformation and visualization in detecting emerging trends, with Python and R being the most commonly used programming languages for developing custom tools.

Introduction

According to the World Intellectual Property Office, a patent is an exclusive right granted for an invention [1]. From the moment a patent is filed, a full disclosure of the invention to a patent office would have occurred [1]. This information will be made available to the public in due course and often prior to the patent being granted [2]. In the health care technology context, patented innovations may include new pharmaceuticals, diagnostics, and medical devices. Often, inventors will apply for patents before clinical trials are initiated to protect the intellectual property of the innovative technology in the trial. However, in the case of low-risk medical devices, where clinical trials are not always conducted, patents may be one of the few indications of a new innovative product before it is introduced to the market. Therefore, patents may be considered as one of the first signs of innovation and are often searched in horizon scanning studies alone or in combination with other sources of weak signal detection [3].

However, with the complexity of some types of health care technologies such as medical devices, as well as the advent of artificial intelligence and its integration into health care technologies, it is quite difficult to identify early signs of innovation in a timely manner. Some digital applications, for instance, evolve rather rapidly, while most class 1 (low risk) medical devices do not undergo clinical trials. Yet, these technologies serve as a primary source of weak signal detection for emerging health care technologies used by the Innovation Observatory (IO), the UK national horizon scanning and research intelligence body, funded by the National Institute for Health and Care Research [4].

Furthermore, a thorough understanding of the health care technology development pathway from ideation to market is imperative to support early warning and alert systems which will, in turn, help inform strategic decision-making, the formulation of health policy, the allocation of research and development funds, and play a vital role in anticipating regulatory challenges associated with emerging technologies. Despite previous horizon scanning and forecast studies conducted in the context of the UK health care horizon scanning needs, it remains unclear how patent analysis methods are being used in forecasting technology emergence globally and how and whether current horizon scanning methods can be enhanced by the regular use of patent analysis studies [5].

Anticipating health care technology innovation before market entry is a key challenge for horizon scanning activities. However, the role of patent landscape analysis within existing horizon scanning methods remains underexplored. For instance, could routine patent analysis help identify emerging MedTech opportunities earlier, thereby enabling more proactive innovation support? Might it also inform the development of regulatory frameworks to reduce delays in technology adoption? To assess the potential of integrating patent analysis into existing horizon scanning practices, we reviewed recent literature on patent studies related to health care technologies. The study had 3 main aims: to identify key intellectual property sources, such as patent databases; to examine methods used for patent retrieval and analysis; and to determine the primary purposes for using patent analysis in this context. The findings aim to support the standardization of weak signal detection and offer a methodological foundation for integrating patent landscape analysis [6] into horizon scanning, both within the IO and among wider national and international bodies, particularly for early-stage technologies.

Methods

Overview

A rapid scoping review was undertaken to efficiently examine the published literature and answer the predetermined research questions on methods, tools, and purpose for patent landscape analysis [7]. We used a scoping review approach to explore the breadth of the subject area and to map the recent patent analysis methods research landscape, while also accelerating some of the traditionally more time-consuming aspects of a systematic review by embracing the recommendations for rapid reviews set out by the Cochrane Rapid Review Methods working group [8]. The use of rapid methods applied to scoping reviews has been documented as an increasing trend in big umbrella reviews due to the efficiency gain [9,10]. We followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) extension for scoping reviews for the reporting of items relevant to this review. This review did not quality appraise the included studies as this was considered out of scope for the objectives of this project. A preagreed protocol outlining the methods and objectives of this rapid scoping review was registered in the Open Science Framework in June 2024 [7].

Inclusion Criteria

To outline the inclusion criteria for this rapid scoping review, we followed the Cochrane protocol guide. The review was structured based on the SDMO framework (study type, data, methods, outcomes) [11]. Studies eligible for inclusion needed to meet the following criteria: (1) any type of study or conference abstract in English language, (2) data related to the health care technology were reported, (3) methods and tools used for the analysis were mentioned, and (4) all reported outcomes were considered for inclusion although they were not deemed mandatory for the inclusion of studies in this review in line with the recommendation from Higgins et al [11].

Search Strategy

Following the recommendation for rapid searches, a targeted search strategy was devised and run in Embase (Ovid), which contains MEDLINE, by an experienced information specialist and checked against the PRESS checklist [12]. Our search strategy consisted of subject heading terms in combination with text words in title and abstract. Given the specificity of the topic and to maximize the sensitivity of our searches, we focused on the Method concept (Patent) from the SDMO framework outlined above. This concept was searched in combination with terms for the different types of studies such as “trend,” “analysis,” “landscape,” “mining” or more broadly “research.” This search was then translated and run in 2 more databases selected for their comprehensive coverage of technological and scientific topics: IEEE Xplore digital library and Web of

XSL•FO
RenderX

Science. We searched in the title, abstract, and keyword fields. Time limits were imposed to retrieve records published since 2020 to capture the most contemporary tools and sources. Due to the lack of current guidelines for the application of time limits in searches for rapid reviews, this was a pragmatic decision informed by the recently updated Cochrane Rapid Review Methods guidance and agreed with the information specialist [8]. This approach ensured that our review remained focused on the latest developments and advancements in the field, providing the most relevant and up-to-date information. No language limit or any other limits were used. Records were downloaded into Endnote 20 (Clarivate Analytics) for deduplication. Full search strategies with results are provided in Multimedia Appendix 1.

Data Collection

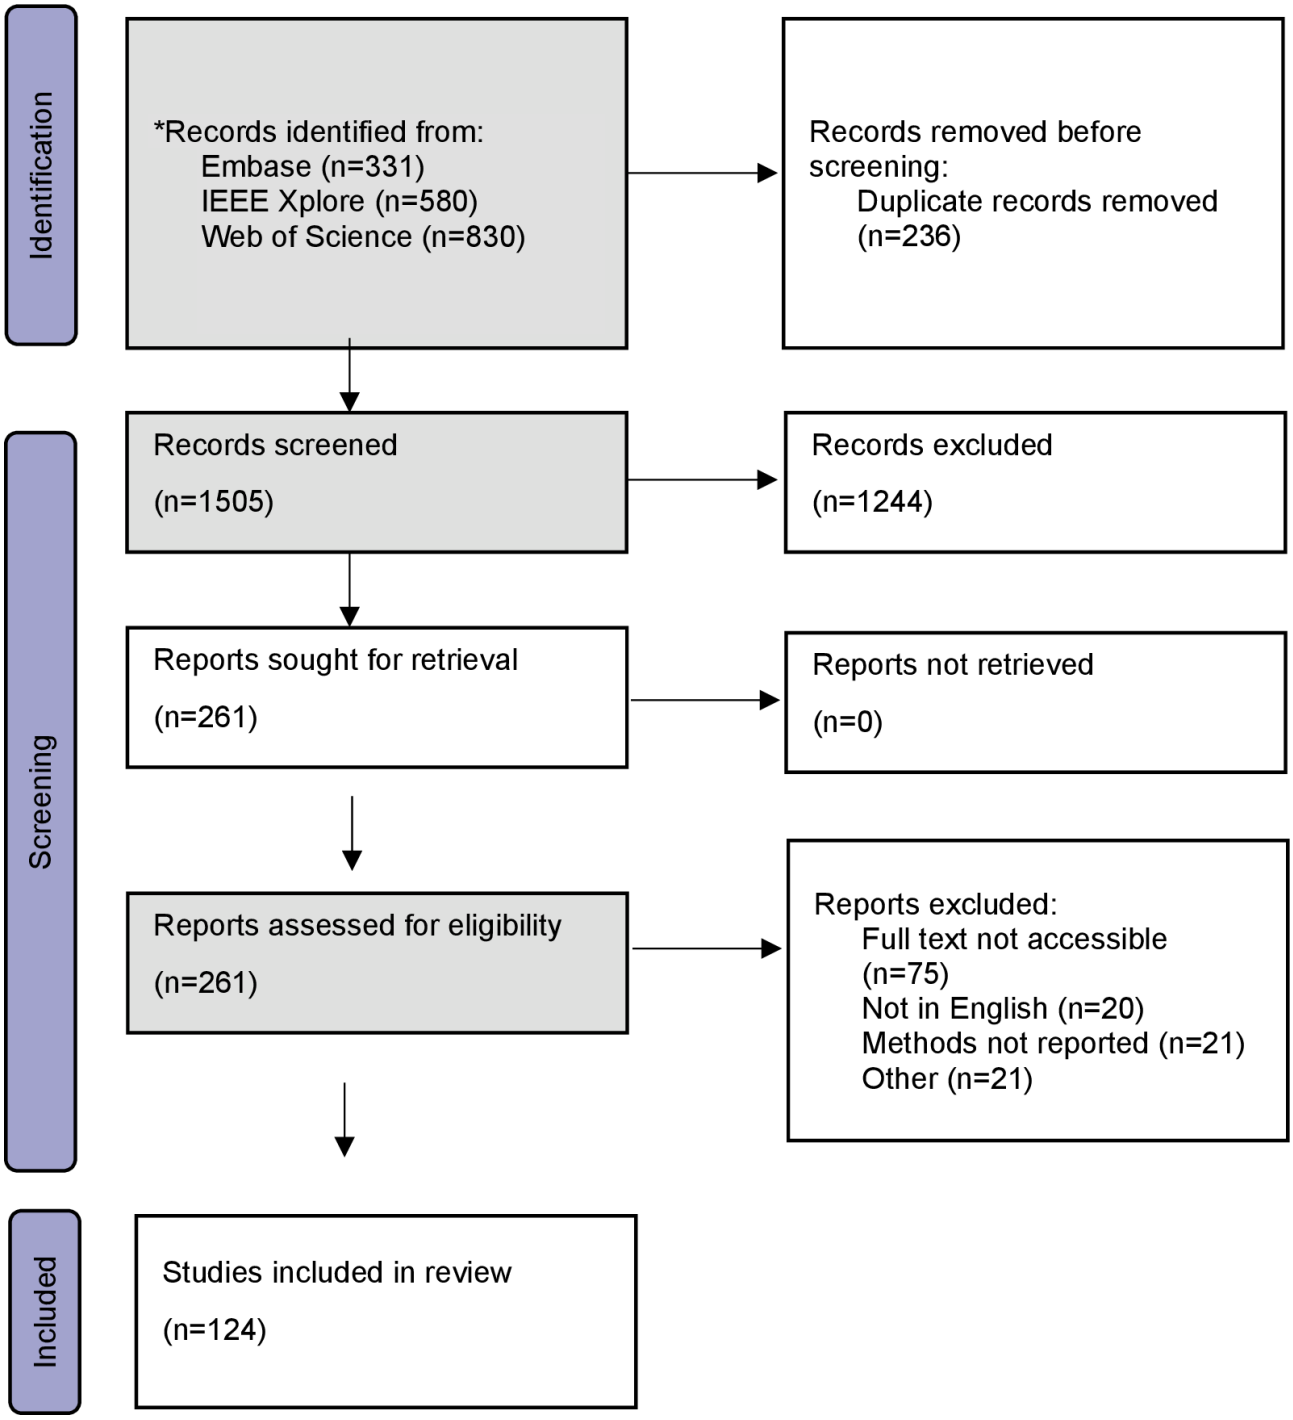
Deduplicated results were single screened at the title and abstract stage by 3 independent reviewers (SGGM, EP, and OE) separately using Rayyan (Qatar Computing Research Institute [QCRI]), a screening software for systematic reviews [13]. Consultation between reviewers was practiced at this stage on multiple occasions. In case of doubt due to ambiguity of titles or lack of clear reporting in abstracts, records were included for full-text screening. At full-text screening, the same 3 reviewers proceeded independently to single screen the full texts for inclusion. One-to-one consultation was exercised regularly throughout this process, and disagreements were resolved by checking with a fourth reviewer.

Data Extraction

To ensure data extraction followed the recommendations of rapid review methods, an abbreviated data extraction form was developed to meet the agreed objectives of this review and was reported in the published protocol [7]. The original data extraction form was then piloted by the reviewers testing the relevance of data fields deemed for extraction. This step did not result in further alterations to the original data extraction form. Three independent reviewers extracted data, and one independently assessed its quality. We extracted bibliographic details; study-related characteristics such as the type of technologies, health condition, and objectives of the study; methods-related data including the sources searched, the geographical coverage of the sources, the time period searched, and the use, if any, of automated methods and tools.

Data Synthesis

We used narrative and tabulated methods for summarizing and synthesizing data collected during our data extraction stage. Whenever possible, charts have been used to visually present information relevant to the objectives of this study. We used the National Institute for Health and Care Excellence (NICE) disease classification system [14] to map the 96 studies (75%) [15-110] that reported specific disease indications or population groups. A total of 178 separate topic references throughout the 96 papers were extracted and mapped against the NICE classification. Despite some second-level disease indications (eg, COVID-19) that can be mapped to multiple NICE first-level disease classifications, each mention of disease was only mapped once to avoid inflation of results.



Results

Overview

Our searches identified a total of 1741 records. After deduplication, 1505 remained. We sought the full text of 261 records, of which only 124 were considered for inclusion in this review. Figure 1 presents a PRISMA flowchart of the retrieval and selection process for this review.

XSL•FO
RenderX

Figure 1. PRISMA flowchart for study selection via searching databases. Gray shading denotes rapid methods, for example, reduced number of databases searched, single screening, and single data extraction. PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses.

The selection criteria focused on relevance and the potential to contribute to the review's objectives. This rigorous process ensured the reliability and comprehensiveness of the findings presented.

Study Characteristics

From the 124 studies included, 67 (54%) [15-61,111-130] were original research papers, 54 (43.5%) [62-107,131-138] corresponded to reviews, 2 were conference papers [108,109], and 1 short presentation [110]. The majority of sources considered patent databases only (85, 68%) [illegible] with the rest of the included studies using a combination of different sources. These 124 studies were published in 94 different journals. *Nature Biotechnology* was the most frequent journal in our dataset (n=9 studies) [15,23,24,52-54,123-125]. A table outlining the characteristics of the included studies is presented in Multimedia Appendix 2 [15-138].

Research Objectives of Included Studies

The objectives of each paper were extracted verbatim directly from the papers. In order to analyze these, and in line with recommendations on how to analyze and present data from scoping reviews [139], 3 reviewers (SG, EP, and OE) grouped them by common topics. This produced a final list of 9 topics or reasons (Table 1). These were presented and agreed with the

XSL•FO
RenderX

rest of the review team. The most common reason reported for the study of patents (62 studies, 50%) [5,7,9,14,17,21,23,27,28,31,33,36,39,41,43,44,46,47,49,50,52,53,55,58,60,61,63,65,66,68,70,72,74,76,77,79,80,82,83,85,87,88,90,91,93,94,96,97,99,101,103,104,106,107,109,111,113,114,116,117,119,120,122,123,125,126,128,129,131,132,134,136,138] was to investigate trends within specific fields, followed by those aiming to provide recommendations for future research, policy, and strategy development (25 studies, 20%) [20,22,23,25,26,32,33,35,44,121,58,62,127,69,70,76,80,84-86,89,91,92,100,135]. Two other frequent objectives were: the study of specific patented technologies (13 studies, 10%) [18,29,112,34,115,38,48,57,64,71,75,106,109] and the identification of emerging technologies (13 studies, 10%) [18,29,112,34,38,115,48,57,64,71,75,106,109]. Less frequent objectives included the development of methodological frameworks for patent analysis (4 studies) [56,88,117,122], analysis of global patent trends (3 studies) [50,96,137], cross-sectoral applications of emerging technologies (1 study) [55], summarize recent research in specific fields (1 study) [138], analyze patent application pipeline (1 study) [49], and develop patent research methods (1 study) [118].

Table . Reasons for conducting a patent research study by themes.

Patent analysis objective	Number of studies
Identify and analyze patent trends	62
Provide future directions	25
Identify emerging technologies	13
Analyze patented technologies	13
Methodological framework	4
Compare global patent trends	3
Cross-sectoral applications	1
Summarize recent research	1

Develop patent research methods	1

Sources of Patent Data

Eighty-five studies [5,7,9,14,17,21,23,27,28,31,33,36,39,41,43,44,46,47,49,50,52,53,55,58,60,61,63,65,66,68,70,72,74,76,77,79,80,82,83,85,87,88,90,91,93,94,96,97,99,101,103,104,106,107,109,111,113,114,116,117,119,120,122,123,125,126,128,129,131,132,134,136,138] used patents alone, whereas 39 studies [1,2,4,8,10,11,13,15,16,18,19,22,24,26,30,34,35,37,40,42,45,48,51,54,57,59,62,64,67,69,73,75,78,81,84,89,92,95,98,100,102,105,108,110,112,115,118,121,124,127,130,133,135,137] used various sources that included gray literature, research papers, and clinical trials. Two studies [89,96] did not report which patent database had been used. More than 27% (34/124) of papers described the use of more than 1 patent database. As such, across the 124 papers, there were 47 databases listed. Table 2 presents the distribution of the top 10 named databases across all papers.

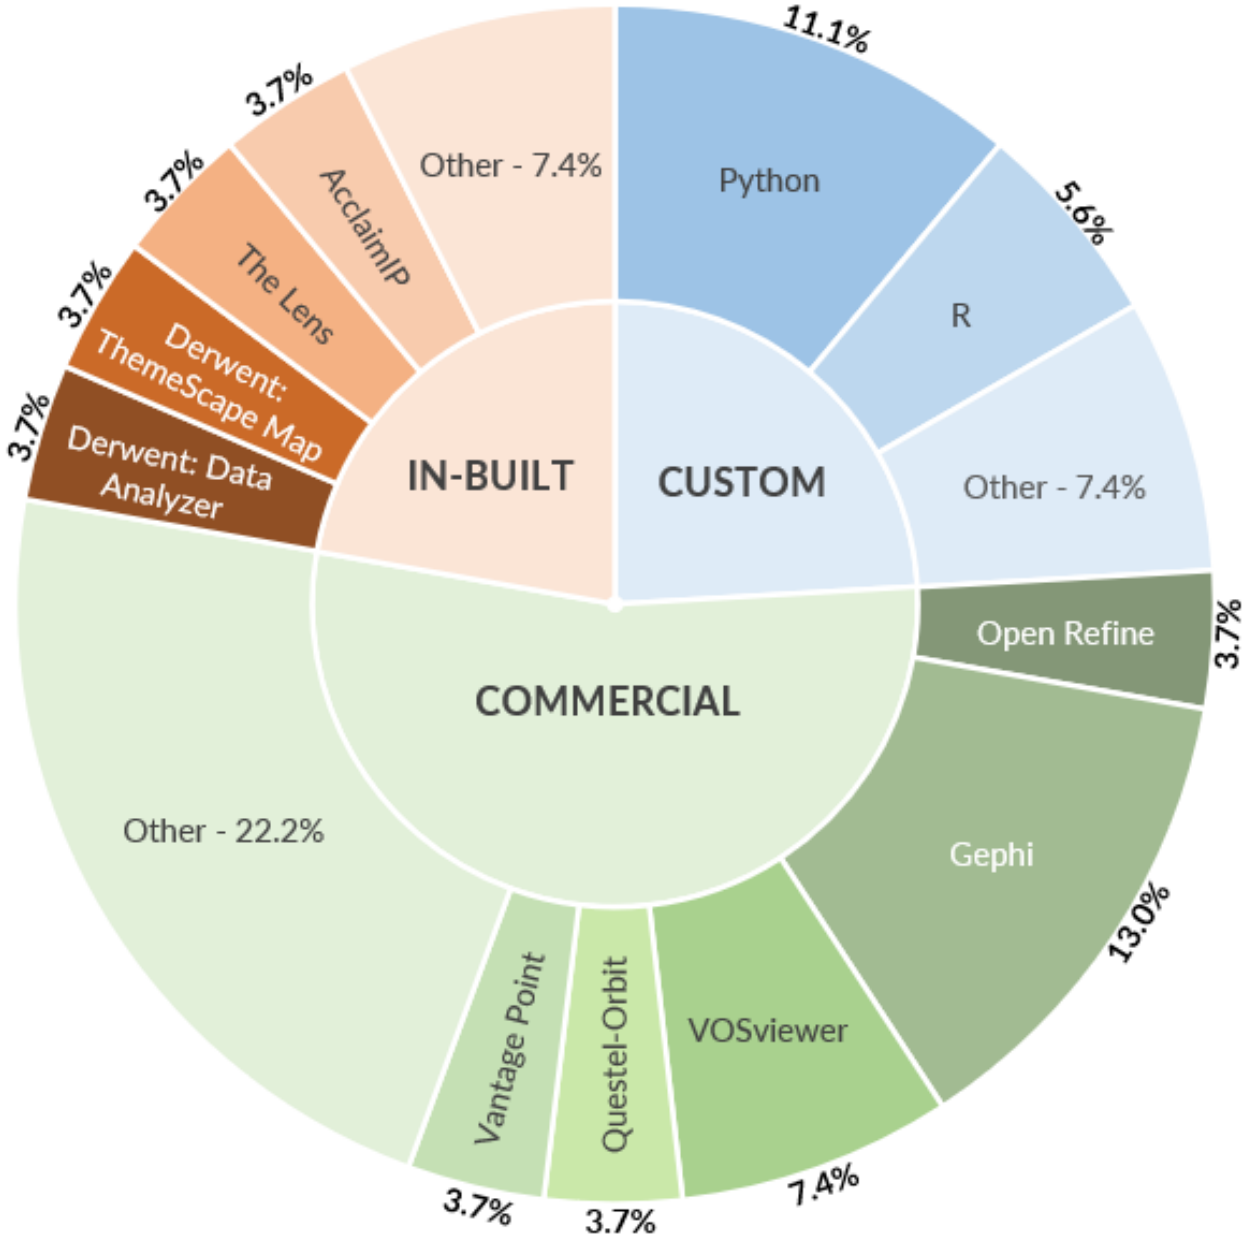
Time Horizons of Patent Scans



Of the 124 included papers, 44 (35.5%) papers [15,23,31,33,36,38,42,45,47,48,52,53,55,58,60,61,63,64,66,67,73,75,76,80,83,85,88,89,93,95,99,100,104,108,109,114] did not report the time period searched during patent analysis or gave incomplete timelines with only an end date leaving 80 papers [16,17,19,20,22,24,25,27,28,30,32,34,35,37,39,40,43,44,46,49,50,51,54,56,57,59,62,65,68,69,70,71,72,74,77,78,79,81,82,84,86,87,90,91,92,94,96,97,98,101,102,103,105,106,107,110,111,112,113,115,116,117,118,119,120,121,122,123,124] with completed data on time horizons.

The mean time length covered in those 80 papers was 24.6 years (SD 2.37) [16,17,19,20,22,24,25,27,28,30,32,34,35,37,39,40,43,44,46,49,50,51,54,56,57,59,62,65,68,69,70,71,72,74,77,78,79,81,82,84,86,87,90,91,92,94,96,97,98,101,102,103,105,106,107,110,111,112,113,115,116,117,118,119,120,121,122,123,124] 7 papers [21,29,41,46,91,106,131] searched a time period of over 50 years with the broadest time period searched being from 1900 to 2019 [140]. Around 19% (15/78) of papers with a reported time horizon searched a period between 3 months and 10 years. Up to 15% (12/78) of papers searched a 20-year period. It was common for authors to backdate searches to the start of the year 2000, although the rationale was not provided.

Methods and Automated Approaches Used

Of the 124 included papers, 43 (34.6%) studies [15-35,111-117,62-72,131,132,108,109] reported the use of automated or semiautomated approaches during patent analysis. In these 41 papers, there were 43 unique tools that were used for patent analysis. Figure 2 presents all tools categorized into whether the tool was available as an in-built analysis module by the patent database searched (IN-BUILT), a custom patent analysis script (CUSTOM), or a commercially offered tool (COMMERCIAL).

Figure 2. Reported tools used for automated or semiautomated analysis.

Some studies mentioned more than 1 tool, a full account of each tool used and their frequency distribution across the 41 studies is available in Table 3. These tools were used mainly in 4 different methods: data mining (understood as the statistical

XSL•FO
RenderX

technique of processing raw data in a structured form), text mining (the part of data mining which involves processing of text from documents) [141], data transformation (the process of converting and cleaning raw data from one data source to meet the requirements of its new location) [142], and network visualization (understood as the graphical representations of network devices, network metrics, and data flows) [143]. Network visualization was by far the most popular method, used in 50% of the tools described. The most popular tool for network visualization was the freely available software Gephi (Gephi Consortium), used in 7 separate studies [21-26,113]. Table 3 presents a breakdown of these tools classified by their type and the number of studies that used them.

NICE Disease Classification Mapping

Of the 124 papers, 28 (22.6%) [111-116,117-122,123-129,130-132,133-138] did not sufficiently refer to any level of NICE classification. Between the remaining 96 papers [15-110], there were 177 specific mentions of NICE guidance categories, which are detailed below (Table 4). Overall, "Cancer" was the most prevalent NICE topic with 19.4% (19/96) of the 124 included studies reporting cancer patents as either the primary or secondary finding. Of the 16.1% of papers [19,26,28,30,31,33,44,76,84,96,100,104] that reported "Respiratory conditions," 60% (9/15)19,26,30,44,76,84,96,100,104 of these were specific to "COVID-19" or other coronaviruses.

Table . Specific mentions of NICE[a] disease and other guidance topics as a percentage of 178 NICE guidance topics referenced in the results of 94 papers that reported specific NICE topics in their results.

NICE guidance (first level)	Number of mentions	Percentage of papers
Cancer	24	19.4
Infections	20	16.1
Respiratory conditions	19	15.3
Diabetes and other endocrine, nutritional, and metabolic conditions	11	8.9
Injuries, accidents, and wounds	11	8.9
Neurological conditions	11	8.9
Blood and immune system conditions	10	8.1
Cardiovascular conditions	9	7.3
Oral and dental health	9	7.3
Skin conditions	8	6.5
Health and social care delivery	8	6.5

Discussion

Principal Findings

Our rapid scoping review aimed to explore the recent literature on patent research studies to identify patent sources, tools, and methods used to understand how patent analyses may support horizon scanning methods in the detection of early innovations. To our knowledge, this is the first rapid scoping review focused on methodological approaches for patent research.

This review has identified several key findings that may be used to inform horizon scanning methods. First, our review has revealed an array of methodological approaches, tools, and reasons why patents are being used to discover signs of innovation. We identified 47 different sources for patent data retrieval with some studies using more than one source per study; for example, clinical trials and published or unpublished literature. The compilation of these sources in this review provides an up-to-date published list of patent data sources and insights into how researchers triangulate patent data with information on how, or whether, the innovation is being used in clinical studies and emerging research. This is an important finding for horizon scanning projects in general, and those undertaken by the IO, with particular value for the prioritization of scalable innovation. Patents alone may not be enough to assess the scalability of innovations in health care services such as the UK NHS. Combining patent data with clinical trials, publications, and clinical development analysis offers a more meaningful approach to evaluating technology adoption potential.

Second, this study showed that patent data are mostly used in trend analysis, perhaps due to the accessibility to retrospective global patent data. This finding aligns with what we already know about methods used for scanning emerging technologies and predicting innovations [3,144]. However, this review revealed a less common but notable application of using patent analyses to guide future policy, research, and strategy, similar to the "bottom-up" approach of the European Commission's Joint Research Centre for detecting weak signals [145]. Most importantly, this approach can also reveal research gaps, thereby aiding in directing future funding and policies to address these gaps, thus contributing to eliminating health inequities and disparities. These findings will contribute to consolidating the IO's methodological application of patent trend analysis studies to underpin "the push" or "bottom-up approach" to informing UK national future policy, research, or strategy on emerging innovation trends or identified innovation gaps.

Third, from our mapping of disease areas, not surprisingly, cancer, respiratory conditions, and infections were the top 3 topics addressed by the included studies. Considering that this rapid scoping review limited the included studies to only those published between 2020 and 2023, it was expected that COVID or, more broadly, respiratory conditions appeared in our dataset quite prominently. However, the focus on cancer technologies may respond to the growing burden of cancer worldwide and its impact on underserved populations [146]. Likewise, the emphasis on infection topics may respond to the antimicrobial resistance crisis that we are currently facing as well as the challenges posed by the growth of communicable diseases worldwide that continue to be the cause of substantial morbidity and mortality [147]. The alignment with real-world health challenges highlights innovators' responses and reinforces the need for horizon scanning systems to adopt these methods for studying innovation in major health issues.

Fourth, the analysis showed that tools used for patent data analysis primarily focus on creating graphs and network visualizations, with examples including Gephi [148], VOSViewer (Leiden University) [149], and ThemeScape Map (Derwent Innovation, Clarivate) [150]. Data manipulation tools such as Pandas (Wes McKinney in Python) [151] also played a key role. In addition, Python and R were the most common programming languages used to develop custom tools. Findings from this review highlighted that data transformation and visualization are methods often used for detecting emerging trends. This finding is in line with previously published studies into patent landscaping in the field of life sciences innovation [152]. Since there are no established methodological frameworks for analyzing patent data in horizon scanning, based on these results, it would be reasonable to assume that whenever tools are used for patent data analysis, some level of data transformation (or curation) is needed and therefore this step and the tools needed to undertake it should be part of the repertoire of methods for any horizon scanning practitioner and, more specifically, for the IO's methods toolkit.

Finally, our review identified a wide range of technologies for which patent analyses were undertaken (Table 3, Multimedia Appendix 2). Due to the short time frame of our analysis, we could not establish a methodological link between analysis methods and technology types. A longer time frame would have yielded more historical data that could have allowed some trend analysis on patent study methods by technology type. Notwithstanding, our results suggest the broad applicability of patent studies to any type of technology.

Our study has some limitations. First, we imposed a short time frame for our bibliographic database searches, which may have meant that we missed some relevant methodological studies. However, this was a pragmatic decision justified by the rapid nature of this review. Given the aims and objectives of our review, which consisted of finding methods and sources for patent landscape analysis studies, we do not think that limiting the search to the last 3 years of publication has biased our methodological conclusions; if anything, it has provided the most up-to-date view on tools and methods. Second, a longer time period would have provided more data allowing us to study the link between technology types and methods providing a more holistic view of patent analysis methods. Third, we used single screening to select studies, so we did not assess interrater agreement. While this practical choice may have led to some relevant studies being missed, we believe it would not have significantly affected our overall conclusions. Finally, our review was not able to ascertain if deduplication of data, a critical step to prevent data inflation and ensure accurate analyses of innovation clusters, was addressed by the included studies [152].

RenderX

Conclusions

Our findings highlight a broad range of methodological approaches and tools which may suggest that in the health care technology context, the continuous search for signs of innovation is driving methods and tools development. Our study has shed light on the usefulness and purpose of patent research studies in the context of health care technology innovation, but it has not solved some methodological aspects such as deduplication processes and possible links between technology types and methods. Notwithstanding, when conducting such studies, particular attention should be given to the processes of data manipulation, transformation, and deduplication—especially when integrating multiple data sources—and these methods should be transparently documented and reported in the final output to ensure reproducibility and data quality. Implementing existing guidelines for reporting items for patent landscapes is also strongly recommended [2,153].

The IO aims to provide a systematic approach to horizon scanning across the 3 horizons of health care technology development: emerging, transitional, and imminent. The findings from this study will support the practice of horizon scanning in the emerging technology horizon. In summary, we expect that the findings from this rapid scoping review would be of value to a wide range of horizon scanning practitioners as well as those planning to undertake patent research studies in the field of health care innovation.

Acknowledgments

This study would not have been possible without the support of the Innovation Observatory. We thank Oleta Williams for the Information Specialist support provided for scoping and running the bibliographic databases searches for this rapid scoping review. This project is funded by the National Institute for Health and Care Research (NIHR) (HSRIC-2016 - 10009/Innovation Observatory).

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

SGGM and AM contributed to conceptualization, methodology, supervision, and project administration. SGGM, ER, OE, EG, JE, and AM were involved in data curation, formal analysis, validation, and visualization. All coauthors participated in writing – original draft, writing – review and editing, and approval of the final manuscript.

Abstract

Background: Electronic resources have become a predominant modality for health information dissemination in recent years. eHealth literacy (eHL) means individuals' competencies to effectively acquire and use health information from electronic sources. Enhancing eHL is thus essential to facilitate individuals' effective engagement with electronic resources and promote improved health management.

Objective: This scoping review aimed to synthesize the characteristics of eHL interventions, thereby providing a reference for future intervention strategies.

Methods: A comprehensive search of PubMed, Embase, Cochrane Library, Web of Science, ProQuest, CINAHL, CNKI, VIP, Wan Fang Data, and Sino Med limited to Chinese and English-language studies published before August 2024 was conducted. The interventional studies included had the explicit primary objective of enhancing eHL. We also incorporated studies that assessed eHL as a secondary outcome or mediator influencing health behaviors or clinical outcomes. All publications were required to provide publicly accessible complete datasets. We excluded conference abstracts and protocols. Academic theses and dissertations were included if they underwent institutional quality assurance through rigorous academic review processes and met predefined eligibility criteria.

Results: A total of 35 studies were included in this review. The most prevalent eHL interventions (12/35, 34%) were delivered via mobile apps and devices in various settings, including educational institutions, public spaces, health care facilities, and community centers. These interventions predominantly focused on enhancing information literacy, health literacy, and computer literacy across the 6 domains of eHL: traditional, health, information, scientific, media, and computer literacy. A majority of the interventions were conducted on a weekly basis (6/13, 46%) and had a duration of 24 weeks (6/35, 17%). However, 77% (27/35) of interventions did not assess long-term effects. The primary outcomes of eHL interventions encompassed perceived eHL, actual eHealth knowledge and skills, health literacy, health behavior, and clinical outcomes, with 86% (30/35) indicating positive effects. The eHealth Literacy Scale was the most frequently used assessment tool.

Conclusions: This study synthesizes the characteristics of eHL interventions. Current eHL interventions exhibit limitations in theoretical grounding, longitudinal tracking, and traditional or media literacy components. Overreliance on self-reported metrics constrains validity assessment. Future work should strengthen theoretical frameworks, integrate objective metrics, and enhance longitudinal designs.

KEYWORDS

eHealth literacy; intervention; scoping review; digital health; health literacy; eHL

Introduction

Background

With the advancement of eHealth technologies, individuals increasingly access information related to diseases, treatment options, medications, and healthy lifestyles through electronic resources. As of 2024, the number of internet health care users in China has reached 365 million, constituting approximately 26% of the total population [1]. This statistic highlights the public's reliance on eHealth resources and underscores the significant role that electronic resources play in the acquisition of health information. Nevertheless, the quality of eHealth information available is highly variable, necessitating that users possess specific skills to discern and evaluate its authenticity and reliability.

In this context, the concept of "eHealth literacy" (eHL) has emerged. Initially proposed by Norman and Skinner [2], eHL

XSL•FO
RenderX

refers to the capacity to access, comprehend, evaluate, and apply health-related information from electronic resources to address health-related issues. Building upon this concept, Norman and Skinner [2] further proposed the Lily Model. According to this model, eHL encompasses 6 key domains: traditional literacy, information literacy, media literacy, health literacy, scientific literacy, and computer literacy. These 6 domains are interrelated and together form the capacity for individuals to effectively use health information in the digital environment.

eHL serves as the foundation for the effective use of eHealth resources and plays a crucial role in encouraging healthy behaviors, maintaining and promoting health, and preventing diseases [3]. However, eHL levels among populations globally require urgent improvement. A survey conducted in Northwest Ethiopia [4] revealed that over half (235/423, 56%) of the participants exhibited eHL levels below the population average. Similarly, research conducted in Germany [5] indicated that approximately 42% of surveyed individuals demonstrated inadequate performance on eHL assessments, where cancer patients particularly faced challenges in effectively navigating eHealth information. Studies from China [6,7] further substantiate this trend, consistently reporting suboptimal eHL proficiency within the general population in China. In recent years, a diverse array of eHL interventions has emerged. Conducting a review and analysis of these interventions can provide a comprehensive understanding of their implementation methodologies, application contexts, and key characteristics. This endeavor facilitates the identification of prevalent trends and existing limitations, thereby establishing a robust scientific foundation for optimizing intervention designs. Current research predominantly focuses on comprehensive analyses of individual eHL levels, measurement tools, and the relationship between eHL and health behaviors [8-10]. A preliminary search on PubMed revealed only 3 reviews on eHL interventions: 2 reviews summarized the effects of eHL interventions on older adults, both noting positive impacts on their health and management but lacking detailed intervention references [11,12], while another review summarized the application of eHL models in digital health interventions, revealing that the Lily Model has not been fully applied across its various modules [13]. Despite numerous studies investigating the effectiveness and characteristics of eHL interventions, there remains a notable absence of systematic reviews that comprehensively summarize the diverse array of these interventions. A thorough review of eHL interventions is urgently warranted to guide future research efforts and inform practical applications.

Objectives

This study aimed to synthesize existing eHL interventions, concentrating on intervention formats, learning methods, delivery settings, components of the intervention, theory, duration, frequency, evaluation timelines of the intervention, primary outcomes and measures, and intervention effects, as well as commonly used eHL assessment tools. By identifying the characteristics and limitations of current research, this study aimed to provide a reference for health care professionals and researchers, facilitating a deeper understanding of the implementation patterns of eHL interventions and providing evidence-based guidance for future initiatives.

Methods

Overview

This scoping review was conducted and reported in strict accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic reviews and Meta-Analyses extension for Scoping Reviews) guidelines [14]. This study did not conduct a formal critical appraisal or methodological quality assessment, as the purpose of this scoping review was to identify and map the characteristics of eHL interventions rather than to draw conclusions regarding intervention effectiveness. This checklist can be found in Checklist 1.

Identifying the Research Question

This study seeks to address these questions: (1) What are the characteristics of eHL interventions? and (2) In which domains do eHL interventions exhibit limitations?

Eligibility Criteria

The inclusion criteria for this review were based on the "Population-Concept-Context" framework: (1) participants of any groups; (2) for concept, the primary aim of eHL interventions was to enhance eHL itself or to improve health behaviors or clinical outcomes through its enhancement. Furthermore, this review also included studies in which eHL was assessed as a secondary outcome, allowing for a comprehensive assessment of both the interventions' effectiveness and their impact on health outcomes; and (3) for context, potential settings for the implementation of eHL interventions encompass a range of environments, including educational institutions, residential settings, health care facilities, public libraries, and diverse digital platforms.

Furthermore, in alignment with the PRISMA-ScR guidelines [14] for scoping reviews, this study included degree theses and dissertations that were significantly pertinent to the research topic, offered detailed descriptions of interventions, and provided thorough methodological accounts, all of which had undergone institutional quality assurance through academic review processes. This inclusion aimed to mitigate publication bias and present a more comprehensive representation of the available evidence.

The exclusion criteria included (1) research proposals or conference titles; (2) studies written in non-English or non-Chinese; (3) to guarantee the integrability of the studies included and the robustness of the research outcomes, this study ruled out those with incomplete or missing raw data reports; and (4) unavailability of the full text.

Information Sources

A comprehensive search was conducted in the following databases: PubMed, Embase, Cochrane Library, Web of Science, ProQuest, CINAHL, CNKI, VIP, Wan Fang Data, and Sino Med.

Search Strategy

The search strategy incorporated Medical Subject Headings terms, free-text terms, and Boolean operators. Moreover, reference lists were reviewed to uncover any further relevant

XSL•FO
RenderX

studies. The final search was performed on August 9, 2024. The full search strategies for each database are available in Multimedia Appendix 1. English search terms included: "digital health literacy," "eHealth literacy," "e-Health literacy," "electronic health literacy," "telehealth literacy," "internet-based health literacy," "online health literacy," "health information literacy," "health information seeking," "health information searching," "intervention," "strateg*," "program*," "protocol," and "practice." Chinese search terms included: "eHealth Literacy," "digital health literacy," "intervention," "program," and "strategy." A specific example of how the search was conducted in the PubMed database includes:

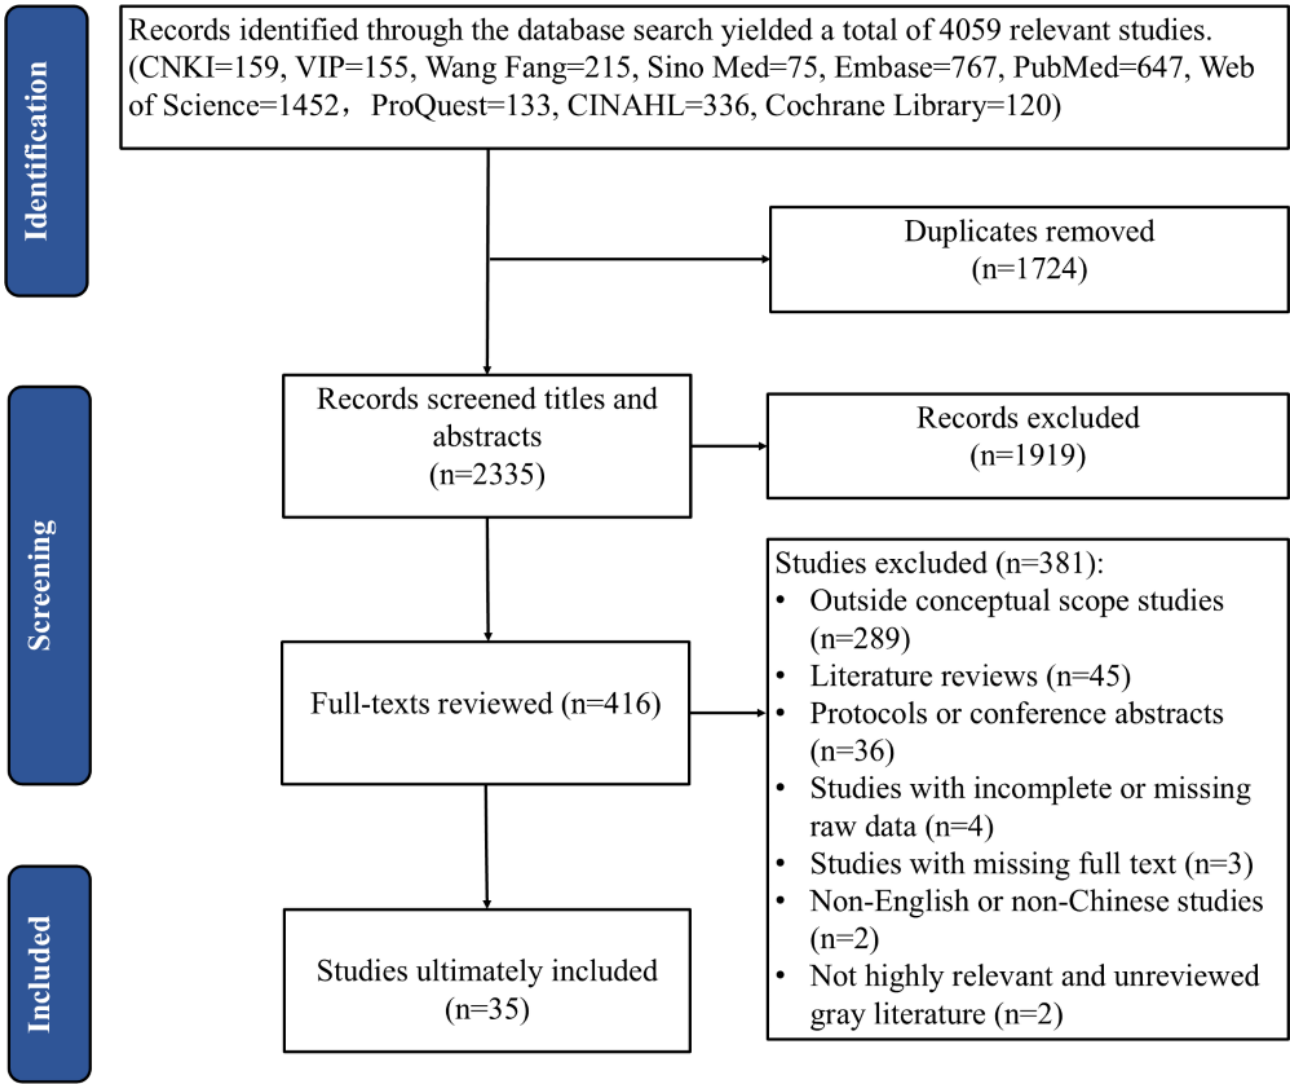
#1 was "digital health literacy" [Title/Abstract] OR "eHealth literacy" [Title/Abstract] OR "e-Health literacy" [Title/Abstract] OR "electronic health literacy" [Title/Abstract] OR "telehealth literacy" [Title/Abstract] OR "internet-based health literacy" [Title/Abstract] OR "online health literacy" [Title/Abstract] OR "health information literacy" [Title/Abstract] OR "health information seeking" [Title/Abstract] OR "health information searching" [Title/Abstract];

#2 was "intervention" [Title/Abstract] OR "strateg*" [Title/Abstract] OR "program*" [Title/Abstract] OR "protocol" [Title/Abstract] OR "practice" [Title/Abstract] OR "trial" [Title/Abstract] OR "experiment*" [Title/Abstract] OR "therapy" [Title/Abstract];

#3 was #1 AND #2.

Selection of Study and Data Extraction

The retrieved records were imported into EndNote (version X9; Clarivate) for consolidation and duplicate removal. Two researchers (YW and YN), who were familiar with eHL interventions, independently screened the titles and abstracts based on inclusion and exclusion criteria. Next, the full texts of relevant studies were retrieved for further detailed screening. Any disagreements were resolved through discussion between the researchers, or if necessary, adjudicated by a third researcher (AW). For data extraction, the same two researchers (YW and YN) independently extracted information using a standardized form. The extracted data were then cross-checked, and disagreements were resolved through consensus discussion. In cases of uncertainty, a third researcher (AW) was consulted to make the final determination. Data were extracted on the following elements: (1) author, year of publication, country, study design, participants, sample size, and theory; (2) formats, learning methods, delivery setting and components of intervention, duration, frequency and evaluation timelines of intervention, primary outcomes and measures, intervention effects, and eHL assessment tools. A descriptive synthesis was conducted to categorize the characteristics of eHL interventions into structured tabulations (Multimedia Appendix 2 [15-49]).



Results

Search Results

Initially, 4059 studies were retrieved. After the removal of 1724 duplicates, 1919 studies were excluded during title and abstract screening. Following a full-text review, an additional 381 studies were excluded, leading to the final inclusion of 35 studies. The detailed process is depicted in Figure 1.

XSL•FO
RenderX

Figure 1. PRISMA flow diagram of the screening process. PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses.

Basic Information of Included Studies

Of the 35 studies [15-49] selected, 9 studies [27-29,31,32,37-39,48] were in Chinese and 26 were in English. Of these, 9 studies [15,27-29,31,32,37,38,48] comprised master's or doctoral dissertations, with the three most represented countries being China, the United States, and South Korea. The study designs included 12 randomized controlled trials and 23 quasi-experimental studies, with sample sizes ranging from 26 to 1389 participants. The publication years spanned from 2005 to 2024, reflecting an exponential increase in research output over this period, culminating in a peak in 2023. Participants in eHL interventions predominantly included individuals with chronic diseases, older adults, students, and those affected by infectious diseases. Among these groups, patients with chronic diseases emerged as the most frequently targeted demographic, with 16 studies specifically addressing this population. Older adults constituted the second largest group, as indicated in 8 studies. Interventions directed at students were documented in 4 studies, while 3 studies focused on individuals living with HIV. Furthermore, eHL interventions have been implemented for other distinct populations, including pregnant women, adolescents with epilepsy and their parents, adults, families, and health care professionals. Comprehensive information regarding the included studies is presented in Table 1, while specific details of the interventions are provided in Multimedia Appendix 2 [15-49].

Characteristics of eHL Interventions

Formats of Intervention

The most prevalent of the included studies (12/35, 34%) used digital interventions through mobile apps or devices [19,20,23,24,28,35,36,40,41,43,46,49]. Website-based digital interventions were also relatively common, comprising 26% (9/35) of the included studies [15-18,22,25,42,44,47]. In contrast, a smaller proportion of studies (8/35, 23%) used face-to-face interventions [21,26,29,30,34,37,38,45]. Additionally, fewer studies (5/35, 14%) implemented remote digital interventions using video or communication programs [27,31-33,39], along with a combination of mobile apps and face-to-face interventions [48].

Learning Methods of Intervention

During the intervention process, various instructional methods were used, primarily categorized into interactive learning, independent learning, and a blended approach that combines both. Interactive learning emphasizes the active engagement of learners with the learning content, tasks, or problems, encompassing communication and collaboration among learners, as well as between learners and facilitators [50]. Within the 35 studies included, a substantial proportion (24/35, 69%) used independent learning methods [18,19,21-29,31,34-36,39-43,45-48]. The blended approach, integrating independent and interactive learning, was also common, comprising 23% (8/35) of the studies [16,17,20,32,37,38,44,49]. In contrast, research concentrated

XSL•FO
RenderX

on interactive learning was less prevalent, representing only 9% (3/35) of the studies [15,30,33].

Delivery Setting

Among the 35 studies included in this review, 14 studies [16-18,20,21,25,26,30,34,36,39,44,45,48] provided comprehensive reports on the intervention settings, which can be classified into 5 primary categories: educational institutions, public learning spaces, health care facilities, welfare centers, and recreational venues. Health care facilities were the most frequently reported settings, encompassing primary care clinics [20,30], general practice clinics [36], outpatient waiting areas [25,45], and hospital wards [39,48]. A total of 7 studies [20,25,30,36,39,45,48] were conducted within this category. Public learning spaces [16-18,44] and educational institutions [21,26] were the next most commonly reported settings. Furthermore, one study was conducted at a welfare center [34] and another at a recreational venue [44].

Components of Intervention

Overview

Using the 6 components of the Lily Model—information literacy, scientific literacy, health literacy, media literacy, traditional literacy, and computer literacy—the eHL intervention content of the included studies was systematically analyzed and summarized. The findings indicated that only one study [45] comprehensively addressed all 6 domains. The majority of studies (22/35, 63%) concentrated on a single domain, with health literacy being the most frequently targeted, as evidenced by 11 studies [20,23-25,28,35,36,40,46,47,49]. This was followed by information literacy and computer literacy, reported in 6 studies [15,16,21,27,32,43] and 5 studies [17,18,22,26,31], respectively.

Notably, some studies, although not encompassing all 6 domains, addressed multiple domains. For instance, one study [39] incorporated intervention content spanning 4 domains: information literacy, scientific literacy, health literacy, and computer literacy. Additionally, 3 studies [37,38,42] addressed three domains: information literacy, health literacy, and computer literacy. Furthermore, 8 studies focused on two domains, including combinations of information literacy and health literacy [19,29], health literacy and computer literacy [30,41], and information literacy and computer literacy [33,34,44,48].

Theory

In this study, less than half of the research (13/35, 37%) applied theories to guide the interventions [20,22,28,29,32,34,37-39,41,43,46,48]. Among these studies that applied theories, the majority of studies (7/35, 20%) drew on health behavior change fields [20,29,32,34,37,38,46], while relatively few studies incorporated theories in the fields of education and nursing training [28,29,41,43]. Additionally, apps in health informatics fields (2/35, 6%) [39,48] and health psychology fields (1/35, 3%) [22] were also limited.

The Information-Motivation-Behavioral Skills theory was the predominant framework in the domain of health behavior change, as evidenced by its application in 3 studies [34,38,46]. Additionally, the field also integrated various other theoretical frameworks, including the Behavior Change Wheel [32], the Health Promotion Model [37], the Capability, Opportunity, Motivation, and Behavior model [20], and the Ecology of Health [29]. Collectively, these theories illuminate the multidimensional aspects of behavior change, emphasizing the intricate interplay between individuals' intrinsic motivations and their external contexts.

The theories used in the domains of education and nursing training encompass the health as expanding consciousness theory [28], Self-Determination Theory [29], and the Analysis, Design, Development, Implementation, and Evaluation model [41,43]. These frameworks underscore the significance of individual cognition and self-identity within the educational process. In the realm of health informatics, the Transactional Model of eHealth Literacy [39] and information ecology theory [48] were prominently used. Furthermore, in health psychology, the self-efficacy theory [22] was applied.

Overall, the theories underpinning eHL interventions primarily focused on individual behavior change. These theories were designed to address various aspects of individual motivation, behavior, and the surrounding environment in developing intervention strategies.

Duration, Frequency, and Evaluation Timelines of Intervention

The duration of eHL interventions varied significantly, ranging from 2 weeks to 1 year. Most of the selected studies (6/35, 17%) [15,24,29,32,43,46] chose a duration of 24 weeks for the intervention. This was followed by 6 weeks [26,30,42,47,49] and 12 weeks [25,28,33,39,45], with 5 studies each. In addition, a small number of studies [17-19,22,27,31,34,40,44] reported intervention durations between 2 to 5 weeks, as well as 8 weeks [37,41], and 1 year [20,23,35,36].

The majority of studies (22/35, 63%) [15,16,20-23,25,26,28,29,32,33,35,36,38-41,43,45,46,48] did not provide specific details regarding the frequency of the interventions. However, among the 13 studies [17-19,24,27,30,31,34,37,42,44,47,49] that reported intervention frequency, most interventions [30,34,37,42,47,49] were conducted once weekly, followed by those occurring twice weekly [17,18,27,44]. Additionally, one study [24] reported an intervention frequency of once every 2 weeks, while another specified a daily intervention frequency [19]. Notably, in the study by Zhou [31], the frequency of community outreach was conducted daily, whereas the intervention delivered through instructional videos occurred once per week.

The evaluation timelines for outcome indicators primarily included before and after the intervention, as well as during the intervention and follow-up. Most of the studies (18/35, 51%) [16-19,23,25,27,28,31,33,37,38,40,42,43,47-49] chose to evaluate outcomes at the two critical time points of pre- and postintervention. Additionally, 8 studies [21,22,26,30,34,41,44,45] included follow-up assessments based on evaluations conducted before and after the intervention to assess its long-term effects. Among these studies, a majority (5/8, 63%) [21,22,30,41,45] of the interventions exhibited

XSL•FO
RenderX

sustained positive effects over the long term. However, 2 of these interventions [21,22] did not demonstrate statistically significant differences when compared to the control group during follow-up assessments. Furthermore, 3 additional studies [26,34,44] reported initial improvements immediately following the interventions; nonetheless, these effects did not persist throughout the follow-up periods, although the outcomes remained above baseline levels. A total of 9 studies [15,20,24,29,32,35,36,39,46] assessed outcome indicators both before and after the intervention, as well as during the intervention. Among these, only 1 study [35] reported significant positive effects in the first half of the intervention, but this effect was not evident during the remaining intervention period. Conversely, the other 8 studies [15,20,24,29,32,36,39,46] demonstrated improvements in primary outcomes compared to baseline, both during the entire intervention period and following its completion. However, in 2 of these studies [15,36], no statistically significant differences were observed between the intervention effects and the control group.

Primary Outcomes and Measures

The primary outcomes of eHL interventions encompassed perceived eHL, actual eHealth knowledge and skills (the specific eHealth competencies being tested), health literacy, and their impacts on health behaviors and clinical outcomes. These studies used multidimensional outcomes to comprehensively evaluate the effectiveness of eHL interventions.

The majority (18/35, 51%) of interventions had only one primary outcome. Among these, the most common was perceived eHL, reported in 10 studies [15,19,21,31,33-35,39,40,48], followed by health behaviors in 3 studies [23,41,46] (the adherence to guideline-recommended medications [≥80% of days covered for blood pressure and stain medications] [23], health-promoting lifestyle [41], and self-care behaviors [46]). Additionally, 2 studies [38,47] used health literacy as the primary outcome (health literacy on chronic diseases [38] and the knowledge of medication safety [47]), 2 studies [18,22] used actual eHealth knowledge and skills (computer and web knowledge [18], and patient portal knowledge [22]), and 1 study [20] exclusively used a clinical outcome (patient activation) as the primary outcome.

Additionally, 17 interventions [16,17,24-30,32,36,37,42-45,49] involved multiple primary outcomes. Among the 11 interventions with 2 primary outcomes, 9 of these [16,17,25-28,30,42,44] included perceived eHL as one of the primary outcomes, in combination with other aspects: actual eHealth knowledge and skills [16,17,27,44], health behaviors [26,28,42], or health literacy [25,30]. Of the remaining interventions, one [24] focused solely on health behaviors and clinical outcomes, while another [49] concentrated on health literacy alongside health behaviors. Among the 4 interventions with 3 primary outcomes, 2 studies [32,36] measured perceived eHL, health literacy, and clinical outcomes, 1 study [37] assessed perceived eHL, health behaviors, and clinical outcomes, while 1 study [43] assessed perceived eHL, health literacy, and health behaviors. For the 2 interventions with 4 primary outcomes, one [45] evaluated mobile eHL, actual eHealth knowledge and skills, health behaviors, and clinical outcomes, while the other [29] examined perceived eHL, health literacy, health behaviors, and clinical outcomes.

The majority of interventions (25/35, 71%) [15,19-23,25,26,28-31,33-35,38-43,46-49], measured primary outcomes via participant self-reports, while the remaining 10 studies used either objective tests alone [18] or a combination of self-reports and objective tests [16,17,24,27,32,36,37,44,45] for outcome measures.

Intervention Effects

Among the 22 studies [19,20,22,24,25,27-30,32,33,35,37-39,41,42,45-49] that adopted a between-group comparison approach instead of a within-participants pre-post comparison, eHL interventions significantly improved participants' perceived eHL [19,25,27-30,32,33,35,37,39,42,45,48] (eHL [19,25,27-30,32,33,37,39,42,48], literacy in using technology to process health information [35], and mobile eHL [45]), and health literacy [25,29,30,32,38,47] (HIV-related health literacy [30], health literacy on chronic diseases [32,38], epilepsy knowledge [25], knowledge of medication safety [47], and knowledge of stroke [29]). In terms of actual eHealth knowledge and skills, the interventions notably enhanced participants' knowledge and skills of mobile technology and the internet [45], and online health information discernment ability [27]. Regarding health behaviors, the interventions significantly promoted the participants' health behavior [29], self-management level [28], and health-promoting lifestyle [37,41]. Additionally, they encouraged children's dietary behavior of consuming sugar-free candy [24] and improved sufficient health behavior [49], as well as self-care behaviors [46]. For clinical outcomes, eHL interventions significantly reduced participants' liver fat content [32], perceived stress and depression [29], controlled the severity of early childhood caries [24], and improved bone health status [37], patient activation [20], and average blood glucose level over 3 months [45].

Among the 8 studies [16-18,26,34,40,43,44] using within-participants pre-post comparisons, eHL interventions significantly enhanced participants' perceived eHL [16,17,26,34,40,43,44]. These interventions also demonstrated significant improvements in participants' actual eHealth knowledge and skills, including website evaluation skills [16], as well as computer and web knowledge and skills [17,18,44]. Furthermore, the interventions significantly increased participants' knowledge of heart failure [43], while positively modifying and enhancing self-care behaviors [43].

Additionally, in 5 interventions [15,21,23,31,36], although the primary outcomes demonstrated some improvement postintervention compared to baseline, no statistically significant differences were observed between the intervention and control groups.

eHL Assessment Tools

Of the 33 studies [15-17,19-48] that measured eHL, the majority [15-17,19-34,36-39,41-48] used the eHealth Literacy Scale (eHEALS) for measurement. Developed by Norman and Skinner [2] in 2006, the eHEALS assesses individuals' self-perceived abilities to evaluate, locate, and apply eHealth information to

XSL•FO
RenderX

address health-related issues through eight concise questions. Owing to its broad applicability and the availability of multiple language versions, the scale has emerged as the most widely used tool for assessing eHL.

In addition to the eHEALS, one investigation used the eHealth Literacy Questionnaire (eHLQ) as a measure of eHL [35]. Developed by Kayser et al [51] in 2018, the eHLQ consists of a self-administered questionnaire comprising 35 items designed to evaluate several dimensions of eHL. These dimensions include the capacity to process health information via technology, understanding of health concepts and terminology, active participation in digital services, perceived feelings of safety and control, proactive engagement with digital services, and access to effective digital resources that are tailored to meet individual needs. The validity of this instrument has been confirmed across numerous countries.

Furthermore, Dimitri et al [40] did not use any standardized instruments; rather, a custom-designed questionnaire was developed specifically to align with the objectives of the study in evaluating eHL, including the definition of eHL and the digital tools for improving the detection of growth disorders.

In summary, approximately 97% (32/33) of the studies used validated or standardized instruments for measuring eHL, thereby enhancing the reliability and validity of the research findings, as well as improving the comparability and reproducibility of the results.

Discussion

Principal Findings

This study synthesized and analyzed the characteristics of eHL interventions, including intervention formats, learning methods of intervention, delivery settings, components of the intervention, theoretical foundations, intervention duration, frequency, evaluation timelines of the intervention, primary outcomes and measures, intervention effects, and eHL measurement tools. The findings provided a detailed reference for the design and implementation of future intervention studies in this domain.

The formats of eHL interventions exhibited considerable diversity across various delivery settings. For instance, 2 studies [21,26] within educational environments used face-to-face intervention methods, likely due to the availability of resources and an environment conducive to in-person interactions. Conversely, 4 studies [16-18,44] conducted in public libraries used web-based interventions, leveraging the open and quiet nature of these settings, which are particularly well-suited for such approaches. In health care institutions, the predominant modalities for intervention delivery included mobile apps or devices [20,36], websites [25], and video communication programs [39]. This preference for digital interventions in health care settings may be attributed to constraints related to equipment and physical space, rendering digital solutions a more practical and scalable alternative. Among the studies included, the predominant format of eHL interventions was digital delivery via mobile apps or devices, which aligns with the findings of Bashir et al [52]. This preference can be attributed to the convenience of this approach, which facilitates intervention monitoring and enables broader scalability beyond specific study samples. Given that eHL emphasizes the capacity to locate, access, understand, evaluate, and use health information through electronic resources to address health-related issues, interventions using mobile apps or devices gain wider adoption. However, the majority of these studies [19,20,23,24,28,35,36,40,41,43,46,49] originated in high-resource countries, with merely 3 studies [24,28,49] conducted in resource-limited countries. Notably, eHL interventions in resource-limited countries predominantly adopt face-to-face offline or remote delivery via video or communication programs. This disparity underscores the persistent global digital divide: pervasive high-speed internet access and elevated smartphone penetration in high-resource countries establish an enabling environment for mobile app or device-dependent eHL interventions. Conversely, most resource-limited countries, with China constituting a notable exception, continue to face persistent challenges such as fragmented network coverage and prohibitive device costs [53]. In such settings, in-person sessions or asynchronous delivery methods could become pragmatic alternatives to mitigate access barriers. Therefore, eHL intervention designs should be context-specific, prioritizing infrastructure-appropriate implementation frameworks. Finally, although independent learning was the most commonly used intervention method in this study, a meta-analysis [54] demonstrated no significant association between the learning method and the intervention effect. This finding implies that the learning method may not be the primary determinant influencing the efficacy of the intervention.

This study, guided by the 6 domains of the Lily Model, conducted a thorough analysis of the content within eHL interventions and identified variations in the focal areas across different initiatives. Overall, these interventions predominantly emphasized health literacy, information literacy, and computer literacy. This observation aligns with Benny et al's findings [13]. Several factors may explain this trend: first, within the fields of health care and nursing, health literacy is widely recognized as a crucial determinant of patients' ability to manage their health and prevent diseases [55]. Many eHL interventions aim to enhance individuals' eHL with the overarching goal of improving their overall health, which naturally prioritizes health literacy. Second, with the increasing diversification of health information sources in recent years, the significance of information literacy and computer literacy has also escalated. Notably, only one study [45] incorporated intervention components that addressed all 6 domains of the Lily Model, while traditional literacy and media literacy received the least coverage. This finding aligns with a recent review by Benny et al [13], indicating that the limited focus on these domains constrains the generalizability of the efficacy of interventions. Furthermore, this suggests that eHL research and practice demonstrate relative deficiencies in attention and investment in traditional literacy and media literacy domains. We recommend emphasizing content integrity when implementing the Lily Model to ensure intervention comprehensiveness and efficacy generalizability [13].

XSL•FO
RenderX

The theory plays a crucial role in intervention strategies, which can provide guidance for intervention design, implementation, and evaluation. Brownell [56] emphasized that an appropriate theory would help identify risk factors for specific diseases and guide the development of interventions. A systematic review by Wong and Morrison [57] revealed that a lack of theoretical support frequently resulted in inadequate systematic and targeted approaches, potentially leading to content that fails to comprehensively address the needs of the target population. However, this study demonstrated that a significant majority (22/35, 63%) of included studies failed to incorporate theoretical frameworks in their interventions, which may limit the depth of understanding and analysis concerning the mechanisms by which certain interventions may be effective or ineffective. This finding aligns with the results of Chang et al [58], which highlighted the lack of theoretical support in the formulation and implementation of eHL interventions. Notably, this finding contrasts with the results of Dong et al [12], who reported that more than half of the 7 studies included in their review used theory. This discrepancy may be attributed to the smaller number of studies analyzed in their review. Furthermore, among the 13 interventions that incorporated theories, the majority emerged from the domain of health behavior change. These theories aim to design effective interventions by elucidating individuals' behavioral motivations, capabilities, and social environments, thereby enhancing individuals' eHL. Therefore, future eHL interventions should place greater emphasis on the application of theoretical frameworks, enhancing the scientific rigor and effectiveness of interventions.

In terms of the duration, frequency, and evaluation timelines of eHL interventions, this study found that the most commonly used intervention duration was 24 weeks, followed by shorter durations of 6 and 12 weeks. This finding is similar to the results of Dong et al [12], who reported that interventions lasting 4 weeks or more significantly improved individuals' eHL. The limited effectiveness of shorter interventions may be attributed to insufficient time for participants to fully absorb and apply the knowledge acquired, thereby affecting the overall impact of the intervention. In contrast, relatively longer intervention durations allow participants to repeatedly apply the learned skills in practice, thereby enhancing their confidence and capabilities, which in turn improves their eHL. In the design of intervention studies, the frequency of the intervention may significantly influence its effectiveness [59]. However, we found that most studies (22/35, 63%) omitted detailed information regarding intervention frequency, limiting understanding of the relationship between intervention effects and frequency. Among those studies that did specify frequency, the majority implemented interventions on a weekly basis. This finding provides a valuable reference for future eHL interventions. Future research should explore the specific effects of varying intervention frequencies on outcomes and assess whether the effectiveness of intervention frequencies differs across various health issues and target populations. Furthermore, the majority (27/35, 77%) of interventions did not conduct follow-up assessments of the intervention effects. This limitation may hinder researchers' ability to fully comprehend the true effects of the interventions, consequently impacting evaluations of their long-term feasibility and effectiveness [60]. Among the studies that addressed the sustainability of intervention effects, a majority (5/8, 63%) of the interventions reported that the interventions yielded long-term positive outcomes. Notably, Nokes et al [21] and Nahm et al [22] reported no statistically significant between-group differences during follow-up, suggesting that improvements in primary outcomes may not be solely attributable to the intervention effects but could also be influenced by various other factors. Therefore, future research should continue to investigate the factors that contribute to the long-term effectiveness of eHL interventions, including various aspects such as the intervention's form, duration, and frequency, as well as the characteristics of the target population.

The primary outcomes of eHL interventions encompass multiple dimensions, including perceived eHL, health literacy, actual eHealth knowledge and skills, health behaviors, and clinical outcomes. Notably, single primary outcomes were the most prevalent, comprising 51% (18/35) of the total, with perceived eHL being the most frequently reported at 56% (10/18). Among studies measuring multiple primary outcomes, the majority (11/17, 65%) focused on 2 types, with the combination of perceived eHL and actual eHealth knowledge and skills being the most prevalent (4/11, 36%). This finding is consistent with the results of a recent systematic review [54]. However, Watkins and Xie [11] found that most studies relied primarily on health outcomes as the main measure to evaluate eHL interventions. Compared to health outcome measures, composite indicators of perceived eHL and actual eHealth knowledge and skills can more directly and comprehensively focus on the core elements of eHL itself. This approach avoids the complexities and uncertainties that may arise from indirectly measuring eHL through health outcomes [61]. Regarding assessment tools for eHL, 3 instruments were identified: the eHEALS, the eHLQ, and custom-designed questionnaires. The findings indicated that 97% (32/33) of researchers used validated standardized self-report tools, with eHEALS being the predominant instrument. This trend aligns with the results reported by Kim et al [9]. One possible explanation for this preference is that eHEALS is more concise than the eHLQ, which contains 35 items and is available in multiple language versions. The excessive number of items in the eHLQ may lead to participant fatigue, potentially compromising the validity of the information collected. In contrast, while the custom-designed questionnaire developed by Dimitri et al [40] consists of only 10 questions, its validity has not been established, and it lacks generalizability. The results of this study showed that the majority of eHL interventions (30/35, 86%) achieved positive effects. However, notably, the assessment of primary outcome measures in most studies (25/35, 71%) relied solely on self-reported data from participants, which may compromise the reliability of findings and potentially lead to an overestimation of intervention effects [62]. Moreover, over half (23/35, 66%) were not randomized controlled trials, resulting in poor control of confounding factors. In light of this, future interventions should optimize research design and methods of outcome assessment.

Limitations

The limitations of this review are primarily manifested in several key areas. Due to potential constraints in cross-linguistic data extraction and analytical precision, this study exclusively

XSL•FO
RenderX

included English and Chinese literature. While this approach reinforces methodological rigor, future research could enhance evidence synthesis through multilingual collaboration. Nevertheless, given that most publications in this field are in English, our findings remain representative of the prevailing evidence. Furthermore, during literature screening and data extraction, this study did not formally calculate interrater reliability. While individual interpretation differences are inevitable, we implemented rigorous measures to minimize subjective bias, including predefined inclusion criteria to standardize decision-making, dual independent screening and extraction by two researchers, consensus resolution for initial discrepancies, and third-party arbitration for unresolved cases, with documented disagreement points. Our records indicate minimal divergence, as only two studies (both grey literature) necessitated arbitration during screening. Following the third-reviewer discussion, these studies were excluded from analysis.

Conclusions

This study reviewed eHL interventions, highlighting key characteristics and limitations. Predominant frameworks used health behavior theory, with mobile apps or devices serving as the primary intervention format; a 24-week duration was most frequent. Setting selection reflected contextual adaptability: educational and health care institutions favored in-person interactions, whereas public libraries and health care systems preferred digital interventions. Challenges include inadequate theoretical guidance, a lack of long-term follow-up, and overreliance on self-reported measures. Content emphasizes health literacy, information literacy, and computer literacy, but insufficient traditional literacy and media literacy coverage may limit effect generalizability. Although most interventions reported positive outcomes, nonrandomized designs and subjective assessments weaken the strength of the evidence. We recommend that future research prioritize enhancing theoretical integration, adopting more objective assessment methodologies, and improving the long-term follow-up of intervention effects to bolster the scientific rigor and practical value of eHL interventions.

Acknowledgments

This study was funded by the National Social Science Foundation (24CSH086). The funders had no role in the study design, data collection, analysis, interpretation, manuscript writing, or decision to publish. No generative artificial intelligence tools were used in the writing of this manuscript.

Authors' Contributions

YW, YN, RX, QZ, SJ, and AW conceptualized and designed the study; YN, RX, and QZ conducted the literature search and reference management. YW and YN selected relevant studies and performed data collection and assembly. YW and YN conducted data analysis and result interpretation. YW and AW drafted the manuscript. AW and SJ jointly provided supervision and timeline control of the study as senior authors. All authors will participate in the revision of the manuscript and approve the final manuscript.

Abstract

Background: The pathogenesis of atherosclerotic thrombosis primarily involves platelet activation and aggregation, making antiplatelet therapy the cornerstone of treatment for such diseases.

Objective: This meta-analysis aimed to compare the safety and efficacy of aspirin and indobufen in antiplatelet therapy for patients with atherosclerotic diseases.

Methods: We searched the Cochrane Library, PubMed, Embase, Web of Science, and the Chinese Wanfang databases. The literature was screened according to predefined inclusion and exclusion criteria. Risk ratio (RR) was used to assess the magnitude of risk associated with exposure and our inclusion criteria are as follows: (1) the study population comprised adults (aged 18 years and older) with coronary heart disease caused by coronary artery atherosclerosis or stroke caused by intracranial atherosclerosis; (2) the intervention was represented by indobufen in the study groups versus aspirin in the control groups; (3) the primary outcome was the incidence of major adverse cardiovascular and cerebrovascular events or any bleeding or Bleeding Academic Research Consortium 2/3/5 bleeding; (4) the secondary outcomes were cardiovascular death, myocardial infarction, and ischemic stroke; adverse cardiovascular events such as coronary thrombus reformation, heart failure, myocardial infarction, stroke, angina pectoris, and cardiovascular death; stroke; myocardial infarction; and cardiovascular death; and (5) the studies were randomized clinical trials with either crossover or parallel designs or prospective observational trials.

Results: Eighteen trials with a total of 12,981 patients were included in this study. Compared to aspirin, indobufen reduced the risk of (1) bleeding events (RR 0.54, 95% CI 0.41 - 0.71; *P*<.0001), (2) Bleeding Academic Research Consortium 2/3/5 bleeding (RR 0.50, 95% CI 0.26 - 0.94; *P*=.03), (3) adverse cardiovascular events (RR 0.43, 95% CI 0.30 - 0.61; *P*<.00001), and (4) myocardial infarction (RR 0.60, 95% CI 0.41 - 0.89; *P*=.01). However, there were no significant differences between the 2 groups in terms of major adverse cardiovascular and cerebrovascular events, stroke, or cardiovascular mortality.

Conclusions: Compared with aspirin, indobufen demonstrated better safety and was not inferior to aspirin in terms of efficacy, with superior results in some aspects (eg, fewer risks of adverse cardiovascular events and myocardial infarction). Further studies with larger sample sizes or longer follow-up periods may provide additional evidence.

KEYWORDS

atherosclerotic disease; antiplatelet therapy; aspirin; indobufen; PRISMA

Introduction

Atherosclerotic diseases include a variety of conditions caused by the buildup of plaque within arteries, leading to their narrowing and hardening [1]. This type of plaque is primarily composed of cholesterol, lipids, and other substances, which progressively restrict blood flow to key organs. Common manifestations include coronary atherosclerosis, intracranial atherosclerosis, and carotid artery and peripheral artery atherosclerotic disease. They increase the risk of cardiovascular events such as heart attacks and strokes. Major risk factors include elevated cholesterol, hypertension, diabetes, smoking, and obesity [2].

The pathogenesis of atherothrombosis is mainly the activation and aggregation of platelets, and platelet reactivity might be associated with the severity of atherosclerosis [3]. Therefore, antiplatelet therapy is the cornerstone of treatment. This activation triggers the release of various signaling molecules, including thromboxane A2 (TXA2), which is synthesized from arachidonic acid via the cyclooxygenase-1 (COX-1) enzyme [4]. TXA2 plays a critical role in amplifying the platelet activation process by promoting the recruitment of additional

XSL•FO
RenderX

platelets to the injury site, thereby increasing platelet aggregation [5]. The importance of the COX-1 enzyme in platelet activation is evident in the mechanism of antiplatelet drugs such as aspirin and indobufen [6,7]. This disruption in the TXA2 pathway significantly lowers the risk of thrombus formation, making COX-1 inhibitors essential for the prevention and treatment of atherosclerotic disease. In summary, the COX-1/TXA2 pathway is central to platelet aggregation, and its inhibition is a key therapeutic strategy for managing atherosclerotic diseases [8].

In patients with atherosclerotic disease, the primary benefit of antiplatelet therapy is the reduction in adverse cardiovascular events related to arterial stenosis, ischemia, and occlusion [9]. The main adverse reaction, however, is mucosal bleeding caused by platelet aggregation inhibition [10]. Given that aspirin has a greater risk of intracranial and gastrointestinal bleeding than other antiplatelet agents do and that some patients may develop resistance, recent studies have focused on alternatives to aspirin [11,12]. Indobufen is gradually attracting the attention of clinicians because of the potential safety profile. Currently, Chinese guidelines acknowledge the feasibility of indobufen as an antiplatelet agent but do not consider it a replacement for aspirin [13]. In contrast, indobufen is less frequently mentioned as a treatment option for patients in the European and American guidelines due to the insufficient clinical evidence. Its further use on a global scale may require additional clinical evidence to attract more attention from clinicians.

In the evaluation of the efficacy and safety of antiplatelet therapy for patients with atherosclerotic disease, commonly assessed outcomes include the incidence of major adverse cardiovascular and cerebrovascular events (MACCEs) [14,15]. MACCEs is a composite end point comprising cardiovascular death, nonfatal myocardial infarction (MI), clinically driven repeated revascularization, definite or probable stent thrombosis, and nonfatal ischemic stroke. Moreover, safety can be evaluated on the basis of the incidence of bleeding events. The Bleeding Academic Research Consortium (BARC) defines the primary safety end point as type 2, 3, or 5 bleeding, also known as major bleeding [16]. Another safety outcome is any bleeding, including mild to severe bleeding.

This paper comprehensively reviewed clinical trials and cohort studies on the efficacy and safety of indobufen in the treatment of atherosclerotic diseases such as stroke and coronary heart disease (CHD), with aspirin as the control. Through meta-analysis, we aimed to integrate existing clinical studies to explore the incidence of MACCEs during the treatment of patients with atherosclerosis with indobufen, evaluate its efficacy, and assess the safety of the drug through the incidence of mucosal bleeding to provide a reference for the clinical application of indobufen and emphasize the necessity of further large-sample prospective studies. Our study aims to contribute to this evidence of indobufen, and we hope that our work will further inform the clinical safety and efficacy of indobufen, inspiring more global clinical research to validate these findings and ultimately contribute to the optimization of pharmacological treatment for atherosclerotic disease.

Methods

Literature Review Design and Literature Search

This study is registered with PROSPERO (CRD42024588250) and was conducted in accordance with the 2020 version of the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement (the PRISMA checklist is provided in Checklist 1) [17]. Four English databases (Cochrane Library, PubMed, Embase, and Web of Science) and 1 Chinese database (Wanfang) were searched, and the publication deadline for the literature was October 1, 2024. We searched each database to identify MeSH (Medical Subject Headings) (eg, “aspirin,” “indobufen,” and “clinical trial”) and related free terms (eg, Acetylsalicylic Acid*, Acetysal*, Acylpyrin*, Aloxiprimum*, Colfarit*, Ibustrin*, controlled trial*, and Trial*). The search strategy was developed via a combination of MeSH terms and related free terms . Moreover, the references of all included studies were browsed and screened to complement the eligible literature not retrieved. Owing to the limited number of randomized controlled trials (RCTs) in the relevant field, we also included eligible well-conducted cohort studies in our analysis to enhance statistical power and generalizability. This approach of combining RCTs and nonrandomized studies is acceptable when the objective is to evaluate both efficacy and effectiveness in broader clinical settings [18].

Study Selection

For inclusion in the systematic review and meta-analysis, we selected clinical trials that investigated the antiplatelet impact of indobufen and aspirin and their safety in human participants. The following inclusion criteria were applied: (1) the study population comprised adults (aged 18 years and older) with CHD caused by coronary artery atherosclerosis or stroke caused by intracranial atherosclerosis; (2) the intervention was represented by indobufen in the study groups versus aspirin in the control groups; (3) the primary outcome was the incidence of MACCEs or any bleeding or BARC 2/3/5 bleeding; (4) the secondary outcomes were cardiovascular death, MI, and ischemic stroke; adverse cardiovascular events such as coronary thrombus reformation, heart failure, MI, stroke, angina pectoris, and cardiovascular death; stroke; MI; and cardiovascular death; and (5) the studies were randomized clinical trials with either crossover or parallel designs or prospective observational trials. We have supplemented the secondary outcome measures from the registered protocol in order to enhance the guiding value of clinical practice. Our exclusion criteria were as follows: (1) lack of control group studies, (2) no studies reporting cardiovascular or cerebrovascular events or bleeding during the follow-up or research group period, (3) follow-up time of less than 6 months or no mention of follow-up time, and (4) case control studies, cross-sectional studies, ecological studies, case reports, and other descriptive studies. Reviews, conference abstracts, and commentaries were also excluded. Two authors (WHP and LEG) independently searched the appropriate studies from all the databases. Two authors (WHP and LEG) independently screened the studies and removed the papers that were duplicates or not relevant after carefully screening the titles and abstracts. In the next step, we further independently examined the

XSL•FO
RenderX

remaining trials and excluded the ineligible trials according to the full text. We resolved disagreements between the authors by discussion. And a third researcher (HCZ) further resolved any conflicts.

Data Extraction

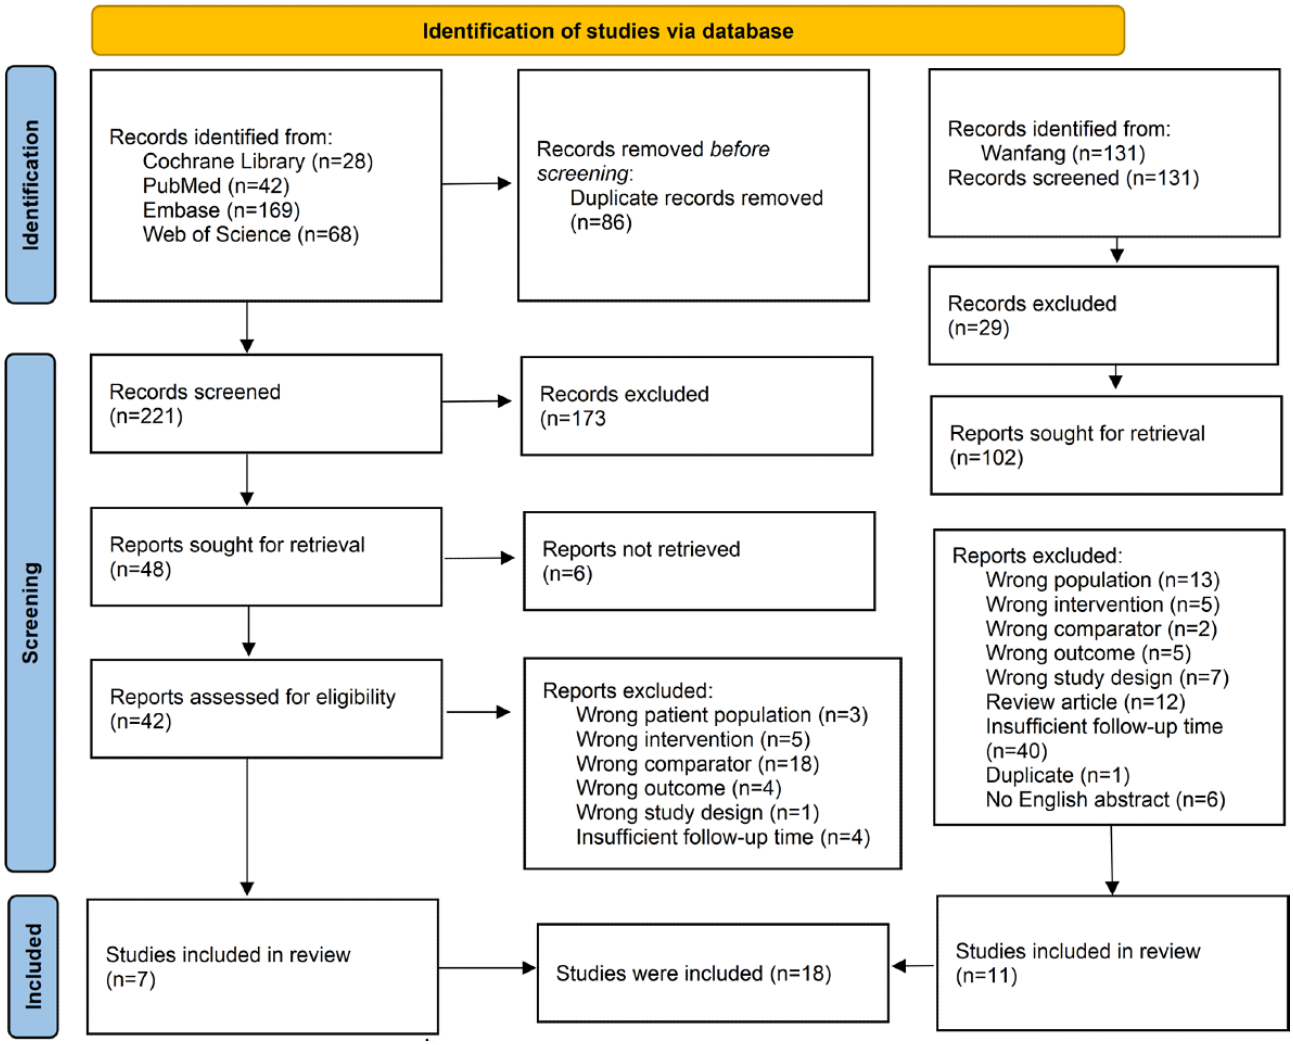
Two researchers (WHP and LEG) independently extracted the following characteristics from the trials via a standardized data extraction form: year of publication, lead author, country of publication, total sample size of the trial in the intervention and control groups, duration of follow-up (months), age at entry, participants' sex percentage, drug dosage (mg per day), and sample size for the occurrence of outcome indicators.

Statistical Analysis

Our data were managed via Excel, and we used Review Manager 5.3 (The Cochrane Collaboration) and Stata SE 18.0 (Stata Corp LLC) to combine and analyze outcomes from the selected trials. All the data were pooled to calculate the risk ratio (RR) and 95% CIs via a fixed-effects model. Between-trial heterogeneity was assessed by using an I^2 test, and a value of >50% was regarded as considerable heterogeneity. If heterogeneity was high, we used a random-effects model. Statistical significance was defined as a P value <.05. If the number of pooled studies was greater than 10, publication bias was surveyed by visual inspection of the funnel plot and Egger test.

Assessment of Risk of Bias and Sensitivity Analysis

We divided all the included studies into RCTs and non-RCT trials. Two researchers (WHP and LEG) independently assessed the quality of RCTs on the basis of the Cochrane risk-of-bias criteria according to the following criteria [18]: (1) allocation concealment, (2) random sequence generation, (3) blinding of participants and personnel, (4) blinding of outcome assessment, (5) incomplete outcome data, (6) selective reporting, and (7) other probable sources of bias. The Newcastle Ottawa Scale was used to evaluate risk of bias for non-RCTs across domains such as selection, intervention classification and comparability, missing data, outcome measurement, and result reporting [19]. Studies with a score of ≥7 were considered high-quality studies. We performed leave-one-out sensitivity analyses to test the robustness of the results.



Results

Results of the Literature Search

As reported in Figure 1, 307 papers from the English database were initially retrieved. A total of 86 duplicate studies were removed. Among the remaining 221 papers, 173 were excluded after the titles and abstracts were carefully screened. In the next step, 48 trials were further examined, and 41 additional trials were excluded for the following reasons: the population studied in 3 papers did not meet the inclusion criteria, the intervention methods used in 5 papers did not meet the requirements, 4 studies did not report the required outcome measures, 18 studies did not provide a proper comparison with aspirin, 1 study's design method did not meet the criteria, 4 papers had a follow-up time of less than 6 months or did not mention the follow-up time, and 6 papers did not retrieve the results. Finally, 7 studies (Dai et al [14], Wu et al [15], Bai et al [20], Dai et al [21], Pan et al [22], Shi et al [23], and Ren et al [24]) were included in our meta-analysis. An additional 11 studies (Chen et al [25], Chen [26], Lin et al [27], Liu [28], Ma [29], Tu et al [30], Wen and Cui [31], Wu [32], Yang [33], Rui et al [34], and Zhou et al [35]) from the Chinese database Wanfang were included in the study. A total of 12,981 patients were included in this analysis.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram for the search and selection of included studies.

Trial Characteristics

The mean age of the participants varied from 47.20 to 72 years. The sample sizes of the eligible studies ranged from 19 to 2723 participants. All the studies were performed in China. The literature we have included has focused primarily on populations with ischemic stroke caused by cerebral vascular atherosclerosis and CHD, which includes stable angina pectoris, acute coronary syndrome, and coronary artery stent implantation or coronary artery bypass grafting due to CHD. The dose of indobufen given to these participants ranged from 100 mg daily to 100 mg twice a day, and the daily dose of aspirin was 100 mg. The characteristics of the included studies are summarized in Table 1. Figure 2 and Table 2 provide information regarding the quality assessment for the risk of bias for each study included in the meta-analysis.

Meta-Analysis Results

Major Adverse Cardiovascular and Cerebrovascular Events

Five studies reported MACCEs (Dai et al [14], Wu et al [15], Bai et al [20], Dai et al [21], and Pan et al [22]). The pooled results revealed no significant difference in MACCEs with indobufen compared with aspirin (RR 1.12, 95% CI 0.98 - 1.28; I^2=0%; *P*=.09; Figure S1 in Multimedia Appendix 1 [14,15,20-22]).

Any Bleeding

Seventeen studies reported any bleeding (Dai et al [14], Wu et al [15], Bai et al [20], Dai et al [21], Pan et al [22], Shi et al [23], Ren et al [24], Chen et al [25], Chen [26], Lin et al [27], Liu [28], Ma [29], Tu et al [30], Wen and Cui [31], Yang [33], Rui et al [34], and Zhou et al [35]). However, 1 study was excluded because there were no outcome events in either the experimental group or the control group. The combined results revealed a significant reduction in any bleeding with indobufen compared with aspirin (RR 0.54, 95% CI 0.41 - 0.71; I^2=51%; *P*<.0001; Figure S2 in Multimedia Appendix 1 [14,15-21,22-29,30-33,34,35]).

BARC 2/3/5 Bleeding

Five studies reported BARC type 2, 3, or 5 bleeding (BARC 2/3/5 bleeding; Dai et al [14], Wu et al [15], Dai et al [21], Shi et al [23], and Liu [28]). Two studies were excluded from the pooled meta-analysis because both groups in these studies reported zero events. The heterogeneity (I^2=84%; *P*=.002) was high, so we used a random-effects model to assess the outcome. The combined results revealed a reduction in BARC 2/3/5 bleeding with indobufen compared with aspirin (RR 0.50, 95% CI 0.26 - 0.94; I^2=84%; *P*=.03; Figure S3 in Multimedia Appendix 1 [14,15,21,23,28]).

Adverse Cardiovascular Events

Thirteen studies reported adverse cardiovascular events (Bai et al [20], Ren et al [24], Chen et al [25], Chen [26], Lin et al [27], Liu [28], Ma [29], Tu et al [30], Wen and Cui [31], Wu [32], Yang [33], Rui et al [34], and Zhou et al [35]). The pooled results revealed a significant decrease in adverse cardiovascular events with indobufen compared with aspirin (RR 0.43, 95% CI 0.30 - 0.61; I^2=0%; *P*<.00001; Figure S4 in Multimedia Appendix 1 [20,24-35]).

Stroke

Seventeen studies reported stroke (Dai et al [14], Wu et al [15], Bai et al [20], Dai et al [21], Pan et al [22], Ren et al [24], Chen et al [25], Chen [26], Lin et al [27], Liu [28], Ma [29], Tu et al [30], Wen and Cui [31], Wu [32], Yang [33], Rui et al [34], and Zhou et al [35]). Five studies were excluded because of zero events. The pooled results revealed no significant difference in the incidence of stroke between patients treated with indobufen and those treated with aspirin (RR 1.07, 95% CI 0.92 - 1.25; I^2=0%; *P*=.37; Figure S5 in Multimedia Appendix 1 [14,15,20-22,24-35]).

Myocardial Infarction

Seventeen studies reported MI (Dai et al [14], Wu et al [15], Bai et al [20], Dai et al [21], Pan et al [22], Ren et al [24], Chen et al [25], Chen [26], Lin et al [27], Liu [28], Ma [29], Tu et al [30], Wen and Cui [31], Wu [32], Yang [33], Rui et al [34], and Zhou et al [35]). Four studies were excluded because of zero events. The pooled results revealed a significant decrease in MI with indobufen compared with aspirin (RR 0.60, 95% CI 0.41 - 0.89; I^2=0%; *P*=.01; Figure S6 in Multimedia Appendix 1 [14,15,20-22,24-35]).

Cardiovascular Death

Sixteen studies reported cardiovascular death (Dai et al [14], Wu et al [15], Bai et al [20], Dai et al [21], Pan et al [22], Chen et al [25], Chen [26], Lin et al [27], Liu [28], Ma [29], Tu et al [30], Wen and Cui [31], Wu [32], Yang [33], Rui et al [34], and Zhou et al [35]). Eight studies were excluded because of zero events. The pooled results revealed no significant difference in cardiovascular death between indobufen and aspirin (RR 1.13, 95% CI 0.71 - 1.79; I^2=0%; *P*=.61; Figure S7 in Multimedia Appendix 1 [14,15,20-22,25-35]).

Sensitivity Analysis

In this meta-analysis, the results of any bleeding and BARC studies revealed a high level of heterogeneity, with I^2 values of 51% and 84%, indicating substantial heterogeneity, possibly due to the small sample size. To further explore the source of this heterogeneity, we conducted a sensitivity analysis. This involved sequentially excluding individual studies to assess their influence on the overall pooled estimate. Although the limited number of studies restricts the depth of the analysis, the results showed that the pooled effect estimate remained stable, indicating relative robustness (Figures 3 and 4). However, variations in heterogeneity were observed when individual studies were excluded, suggesting that 1 or more studies might have contributed to the observed heterogeneity. We attribute the source of the heterogeneity primarily to the use of the second antiplatelet agent in the dual antiplatelet therapy (DAPT) regimen, as well as to variations in sample size and concomitant use of proton pump inhibitors.

Publication Bias

For outcomes with more than 10 papers included in the literature, we plotted funnel plots and performed Egger tests. There are 16, 13, 12, and 13 studies on outcomes of any bleeding events, adverse cardiovascular events, stroke events, and MI, respectively. The *P* values of the Egger tests for any bleeding or adverse cardiovascular events were .249 and .235, respectively, both of which are greater than .05. We believe that the publication bias is small, but the *P* values of the Egger tests for stroke and MI were .000 and .001, indicating a certain degree of publication bias. All funnel plots are included in Multimedia Appendix 1.

Discussion

Principal Findings

In this systematic review and meta-analysis involving 18 clinical trials and 12,981 patients, we compared antiplatelet therapy involving indobufen with that involving aspirin. Although we did not impose any language restrictions for the included studies, all the clinical trials ultimately retrieved were conducted in China. This may be because indobufen is not widely approved as a routine antiplatelet agent in Europe and the Americas and is used only as a reference drug in specific studies [36]. These results suggest that, compared with aspirin, indobufen can effectively reduce the incidence of mucosal bleeding (including both major and minor bleeding) in patients with cardiovascular and cerebrovascular atherosclerosis. Additionally, on the basis of the studies included in our analysis, indobufen was shown to reduce the incidence of adverse cardiovascular events (a composite outcome of coronary thrombus reformation, heart failure, MI, stroke, angina pectoris, and cardiovascular death) as well as MI. However, MACCEs, stroke, and cardiovascular death rates were similar between the 2 groups, which may be related to the limited follow-up time. The heterogeneity for any bleeding and BARC 2/3/5 bleeding was high, but the sensitivity analysis revealed no difference in outcomes. There was significant publication bias for stroke, MI, and cardiovascular death. The effects of indobufen on MACCEs, stroke, and cardiovascular death were similar to those of aspirin, demonstrating no inferiority in efficacy.

Antiplatelet therapy in patients with atherosclerosis remains a topic of considerable debate. Current guidelines recommend aspirin for secondary prevention in patients with coronary atherosclerotic heart disease, and DAPT is advised for patients with a high risk of thrombosis and a low risk of bleeding or those undergoing interventional treatment [37]. For patients who require DAPT but are intolerant to aspirin, indobufen is being investigated as a potential alternative to aspirin [38,39].

The antiplatelet effect of aspirin is achieved by irreversibly inhibiting and permanently blocking COX-1 in platelets, thereby preventing the formation of thromboxane A2 (TXA2) [40]. This effect lasts for the lifespan of the platelet (7 - 10 days) [41]. In contrast, indobufen is a reversible COX-1 inhibitor, meaning that it temporarily inhibits the enzyme but does not cause persistent inhibition [42]. This reversible action allows for shorter-term effects on platelet function than does aspirin [43]. The inhibitory effects of indobufen on platelet function returned to baseline within 24 hours after discontinuation. Additionally, indobufen does not substantially impact prostacyclin, potentially minimizing the risk of aspirin-gastric side effects [25]. While both drugs seek to reduce platelet aggregation and associated thrombosis, the irreversible inhibition of aspirin leads to protracted platelet inhibition, whereas indobufen offers a reversible and potentially safer alternative, particularly in patients at greater risk for bleeding.

Aspirin's first-line status in the prevention and treatment of cardiovascular and cerebrovascular diseases is supported by a large body of evidence-based research [10,44,45]. In comparison, although the clinical application of indobufen has evolved, it remains very limited at present. Initially, owing to its reversible inhibition of COX, it was not recommended, as it was considered insufficient to effectively inhibit platelet aggregation in vivo [46]. However, subsequent clinical trials have led some meta-analyses to consider indobufen similarly to aspirin. Cataldo G et al [47], in their combined analysis of 2 multicenter coronary artery bypass grafting studies, concluded that indobufen is as effective as aspirin and dipyridamole in preventing graft occlusion. Bhana and McClellan [48], in their review, suggested that indobufen may be an effective alternative to aspirin for patients with nonrheumatic atrial fibrillation who have contraindications to anticoagulation or a greater risk of bleeding. In a meta-analysis of 9 clinical studies, Zhang et al [49] reported that indobufen had fewer gastrointestinal reactions, a lower risk of bleeding, and could be a viable option for patients at high risk of bleeding or with gastrointestinal ulcers.

Strengths and Limitations

The strengths of our study include the following: compared with previous studies, our meta-analysis incorporated a larger number of clinical trials and patients with homogeneous outcome definitions and a large patient population, making the results more generalizable to the broader population. Additionally, the follow-up duration in all the included studies exceeded 6 months, enhancing the credibility of our findings. We also conducted publication bias and sensitivity analyses to further emphasize the reliability of this meta-analysis.

There are several limitations to this study. All the studies included focused on Chinese populations, which may limit the generalizability of our findings to other regions of the world. But we believe that with the accumulation of further clinical evidence in China, the safety profile of indobufen as a potential alternative to aspirin will gain stronger support, paving the way for the development of larger multicenter studies with longer follow-up periods and more diverse populations across different regions—including global clinical trials. Additionally, because antiplatelet therapy is a long-term treatment requiring good patient adherence, the included trials were open-label, which might raise concerns about potential bias, although none of the studies carried a high risk of bias. Owing to the lack of available data, we were unable to perform subgroup analyses on the basis of individual patient characteristics, and the efficacy and safety of indobufen in specific populations require further investigation.

XSL•FO
RenderX

Conclusions

Our meta-analysis indicates that, compared with aspirin, indobufen offers a safer profile for antiplatelet therapy in patients with cardiovascular and cerebrovascular atherosclerosis, as it reduces the incidence of mucosal bleeding. In terms of efficacy, indobufen is associated with a lower incidence of adverse cardiovascular events and MI, while its impact on MACCEs and cardiovascular mortality is similar to that of aspirin. Indobufen demonstrated no overall inferiority in effectiveness, with superior results in some aspects (adverse cardiovascular events and MI). This provides additional robust evidence supporting the feasibility of using indobufen as an alternative antiplatelet therapy, particularly in patients who are intolerant to aspirin.

Abstract

Background: Understanding long-term retention rates and complications associated with different materials for fabricating pediatric crowns for primary teeth is crucial for material selection and optimizing clinical outcomes.

Objectives: This systematic review aimed to descriptively analyze the crown-retention rates and complications associated with crown retention, as well as the biological and technical complications of pediatric crowns, for primary teeth. The meta-analysis reported herein was performed to estimate long-term (3-year and 5-year) retention rates of these pediatric crowns fabricated using various materials.

Methods: Using the PICOS (Population, Intervention, Comparison, Outcomes, and Study design) paradigm, a systematic search was conducted between July and August 2023 in the Cochrane, Embase, and PubMed databases to identify randomized controlled trials (RCTs) and clinical (prospective and retrospective) studies reporting retention rates, complications of crown retention, and biological and technical complications. After selecting studies with a predefined set of selection criteria, data from included studies were used for a systematic review aimed at a descriptive analysis of factors associated with the failure of crowns for primary teeth. Data from the included RCTs were used for meta-analysis, wherein 3-year and 5-year crown-retention rates were estimated using Poisson regression models.

Results: This systematic review included 13 RCTs and 5 clinical studies on dental crowns for primary teeth, involving 454 children (1172 crowns) in RCTs and 810 children (2667 crowns) in clinical studies. The median follow-up durations were 12 months for RCTs and 20.8 months for clinical studies, with a 10.6% (124/1172) dropout rate in RCTs. Meta-analysis of pooled 5-year retention rates for different crown materials revealed the following retention rates: 88.90% for compomer crowns, 92.18% for composite resin crowns, 90.30% for resin-modified glass ionomer cement (RMGIC) crowns, and 97.88% for stainless steel crowns. Additionally, strip crowns exhibited a retention rate of 83.48%, while zirconia crowns had a retention rate of 97.09%. Poisson regression estimated 3-year and 5-year crown-retention rates, indicating good outcomes across materials. Complications included secondary caries (up to 21.8% in zirconia crowns) and marginal adaptation issues (up to 22.2% in compomer crowns). These findings highlight material-specific considerations necessary for optimizing outcomes in pediatric dental crown treatments.

Conclusion: While retentive complications such as chipping, material loss, and fractures do occur across materials, compomer, composite resin, stainless steel, strip, and zirconia crowns all have clinically acceptable retention rates. However, the differences in biological and technical complications between materials may provide insights for selecting appropriate materials for pediatric crowns based on clinical considerations.

Introduction

Dental caries is a highly prevalent chronic disease affecting millions of children worldwide, leading to pain, infection, and difficulties in eating and speaking [1-3]. Untreated caries of the primary teeth may affect over 621 million children globally [1]. Early intervention with fillings is essential to manage caries, but in cases where the tooth structure is significantly compromised, pediatric dental crowns become necessary to preserve the tooth's functionality and prevent premature loss [4].

Several studies have documented the usefulness and efficacy of materials such as stainless steel, zirconia, composite resin, and polycarbonate materials for fabricating pediatric dental crowns [5-8]. Despite notable advancements in dental materials and restorative techniques, various biological and technical factors persist in influencing the longevity and acceptability of pediatric dental crowns [8]. Biological factors such as the oral microbiome, the presence of cariogenic bacteria, and the immune response play significant roles in the success or failure of pediatric dental crowns [8]. Additionally, technical factors including crown preparation, cementation methods, and occlusal adjustment can impact the longevity and performance of these restorations [8]. Understanding these factors is crucial for clinicians to make informed decisions regarding treatment planning and material selection.

Chisini et al [8], in their systematic review, highlighted that composite resin crowns exhibited the lowest annual failure rate (1.7% to 12.9%), while stainless steel crowns had the highest success rate (96.1%). This report [8], published in 2018, identified secondary caries as the main reason for the failure of pediatric crowns and recommended an anticariogenic, health-promoting approach. Furthermore, several systematic reviews (published between 2021 and 2023) have also reported on the efficacy of individual restorative materials such as stainless steel, zirconia, and prefabricated crowns [9-11]. Since the publication of these systematic reviews, several randomized controlled trials (RCTs) have been published, warranting an updated systematic review to include these additional articles.

In the context of overall public health, ensuring the longevity and success of pediatric dental crowns not only addresses the immediate dental needs of children but also contributes to their overall health and well-being [12,13]. Improving the success rates of these restorations can reduce the burden of dental diseases and associated health care costs, enhancing the quality of life for affected children. On the premise of this background, this systematic review and meta-analysis aims to provide a comprehensive qualitative assessment of crown-retention rates and the impact of technical and biological factors on crown success and acceptability for primary teeth.

Methods

Overview

The protocol for this systematic review and meta-analysis [14] was registered with PROSPERO (CRD42023442266) and conducted in accordance with the MOOSE (Meta-Analysis of Observational Studies in Epidemiology) and PRISMA-P (Preferred Reporting Items for Systematic Review and Meta-Analysis Protocols) guidelines [15,16].

Eligibility Criteria

RCTs and clinical studies (prospective and retrospective) evaluating crowns fabricated using stainless steel, zirconia, composite resin, compomer, and resin-modified glass ionomer cement (RMGIC) were included. The predefined inclusion criteria for this systematic review encompassed studies with an English abstract that evaluated crown restorations in pediatric patients aged 1-10 years, reporting crown-retention data, reasons for retentive loss, and technical and biological complications. Qualitative interviews, quasi-experimental studies, single-case studies, and series of single-case studies were excluded. Additionally, articles based on conference abstracts and dissertations were excluded.

Biological factors in this analysis included secondary caries and periodontal pathology (including the periodontal index, which assesses the severity of periodontal disease). Clinical parameters included the gingival index (evaluating gingival inflammation) and other periodontal health indicators. Technical factors included anatomic form, marginal adaptation, color match, surface texture, and wear on the opposing tooth. Success rates, if reported, were also included for the purposes of this systematic review and meta-analysis.

Data Sources and Search Strategy

Using a database-appropriate search strategy, electronic databases, including Cochrane, Embase, and PubMed (MEDLINE), were systematically searched to identify RCTs and clinical studies (prospective and retrospective) based on the eligibility criteria described above. The PICOS (Population, Intervention, Comparison, Outcomes, and Study design) format for this systematic review and meta-analysis was as follows:

- Population: children with primary tooth decay
- Intervention: crown restorations
- Comparators: materials such as stainless steel, zirconia, composite resin, compomer, and RMGIC
- Outcomes: crown retention, as well as technical and biological factors
- Study design: RCTs and clinical studies (prospective and retrospective)

Multimedia Appendix 1 presents the search syntax used for searching the electronic databases. The search strategy was considered adequate to reduce the risk of selection and detection bias.

Selection of Studies

The search results were imported into Zotero, and duplicates were removed to create a virtual library. Study selection was conducted in 2 stages. In the first stage, 2 independent reviewers (SL and KJ) screened the titles and abstracts of identified studies to determine their eligibility. In the second stage, the same 2 reviewers independently assessed the full-text articles of potentially relevant studies to confirm whether they met the eligibility criteria. Quality assessment of included RCTs and prospective and retrospective clinical studies was also

XSL•FO
RenderX

independently performed by SL and KJ. Any disagreements at any stage, including study selection, quality assessment, and data extraction, were resolved through discussion. If consensus could not be reached, a third expert (DG) was consulted, with DG making the final decision.

Data Extraction

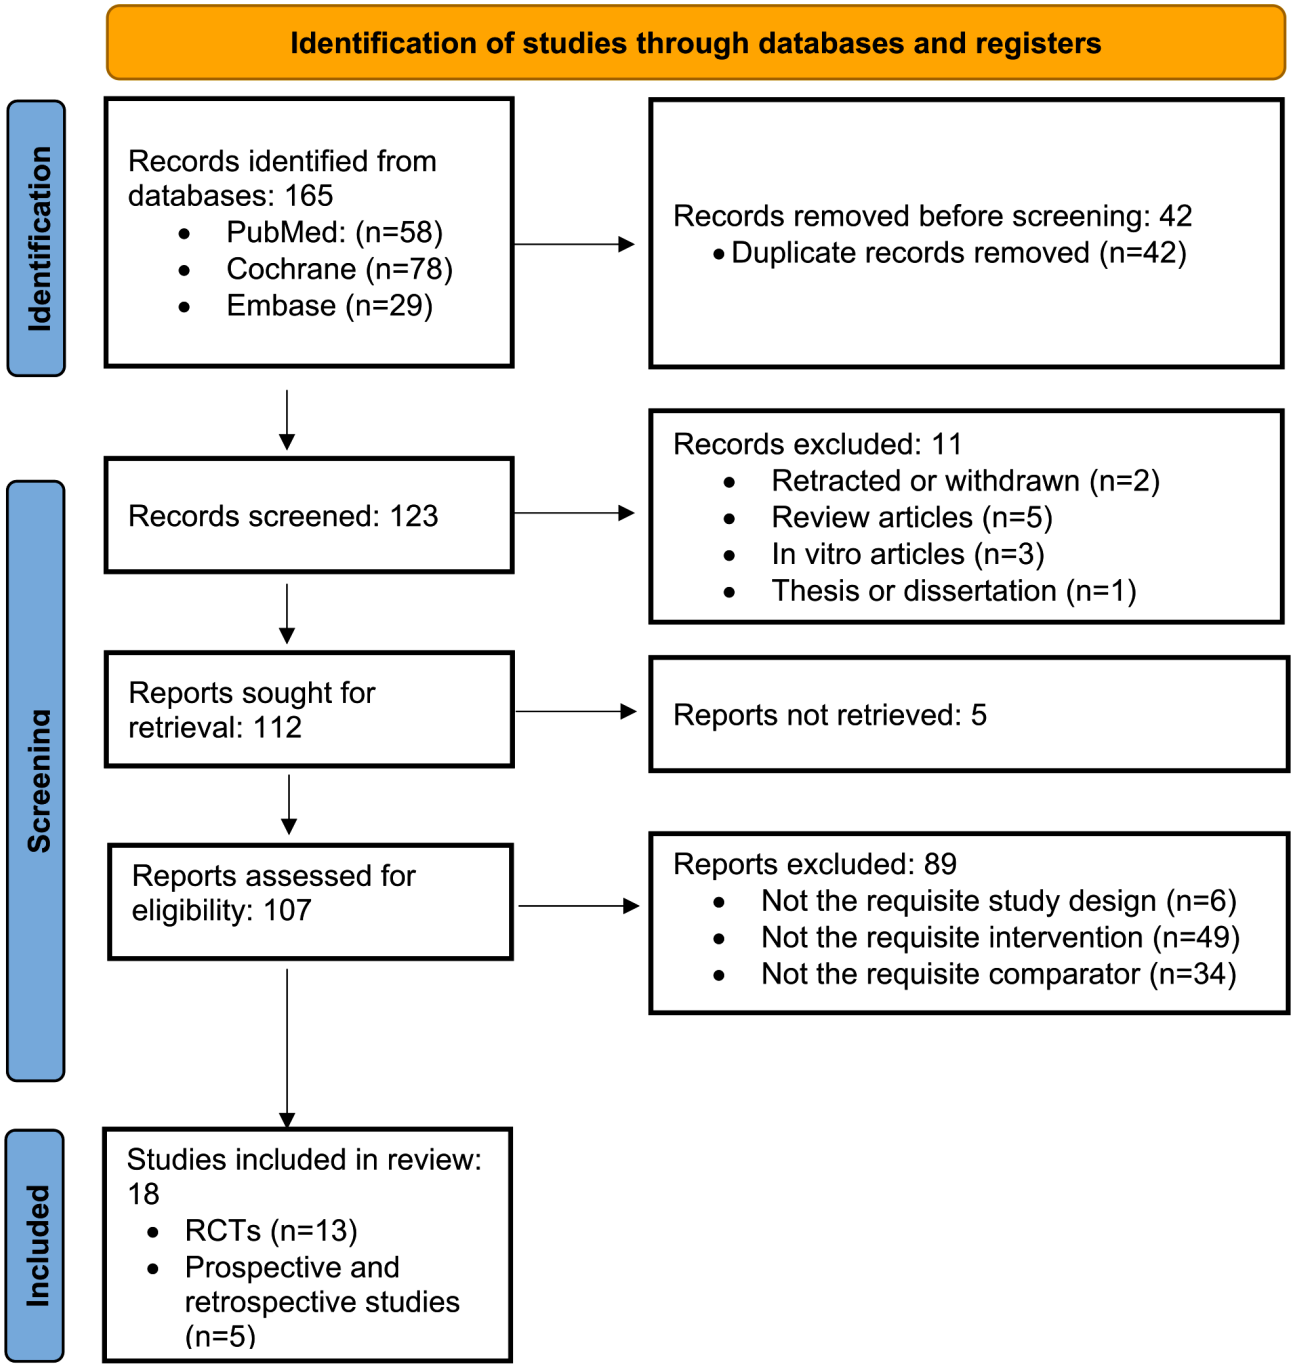
Data extraction was independently conducted by 2 reviewers (SL and KJ) using a standardized data extraction form. Extracted data included author details, year of publication, number of children, age, number of teeth, tooth type, crown material, dropout, follow-up duration, crown retention, and retention complications including biological and technical complications. Discrepancies in data extraction were resolved through discussion between the 2 reviewers. If consensus could not be reached, a third expert (DG) was consulted to make the final decision.

Risk-of-Bias Assessments

The Risk of Bias 2 tool developed by the Cochrane Collaboration was used to assess the quality of included RCTs [17]. Two independent reviewers evaluated various bias domains in RCTs, including randomization, allocation concealment, blinding of participants and personnel, blinding of outcome assessment, incomplete outcome data, selective reporting, and other sources of bias. After assessing each included RCT for risk-of-bias domains specified by the Risk of Bias 2 tool, an overall risk-of-bias judgment (low, some concerns, or high) was assigned to each trial [17]. A checklist proposed by Moga et al [18] was adapted for assessing the risk of bias in the included prospective and retrospective clinical studies. Only studies with a moderate or low risk of bias were included in this analysis. Furthermore, a funnel plot was generated to assess for any publication bias.

Meta-Analytic Approach

For quantitative analysis (meta-analysis), retention was defined as the number of crowns that were in situ, regardless of technical and biological complications. Total exposure time refers to the cumulative duration that all crowns remain in the mouth across all included studies. It is calculated by summing the duration each crown is in place for each study and then aggregating these times across all studies. Failure rates resulting from retentive complications were calculated by dividing the number of failures by the total exposure time. Exposure time for each included study was calculated by summing the exposure time for all restorations. A Poisson regression model was used to analyze the calculated rates. Proportions of crowns retained at 3 years and 5 years were estimated with an assumption of constant event rates. The Pearson goodness-of-fit test was performed to assess heterogeneity across studies and to determine whether a fixed-effects or random-effects model should be used. Since no statistically significant heterogeneity was detected in any of the individual groups and rates (P>.05), a fixed-effects Poisson regression model was used to estimate the parameters. A P value <.05 was considered significant. All analyses were performed using R statistical software (version 4.1.2; R Core Team).



Results

Selection of Studies and Risk-of-Bias Assessments

A total of 13 RCTs and 5 clinical studies (prospective and retrospective) were included in this systematic review [19-31]. Figure 1 presents the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram illustrating the study selection process. Tables 1 and 2 provide the risk-of-bias assessments for the included RCTs and clinical studies, respectively.

Qualitative Analysis of the Included Studies

Table 3 summarizes the 13 included RCTs, presenting data on crown retention and retentive complications [19-31]. These RCTs were conducted between 2014 and 2022 and recruited 454 children who received a total of 1172 crowns [19-31]. The follow-up duration ranged from 6 to 36 (median 12, IQR 9) months, with a cumulative dropout rate of 10.6% (124/1172

XSL•FO
RenderX

crowns). Table 4 outlines the 5 included clinical studies, reporting data on crown retention and retentive complications [32-36]. These clinical studies were conducted between 2008 and 2020 and included data from 810 children, with a follow-up duration ranging from 12 to 24 (median 20.8, IQR 5) months [32-36].

Figure 2 provides a descriptive analysis of retention rates for crowns fabricated with different materials, as reported in the included RCTs [19-31]. Retention rates varied from 77.8% to 100%, from 80.6% to 100%, and from 92.3% to 100% for compomer, composite resin, and stainless steel crowns, respectively. Additionally, retention rates for strip crowns and zirconia crowns ranged from 78% to 100% and from 86.4% to 100%, respectively. Table 5 illustrates various retentive complications reported in the RCTs for different materials. Regarding clinical studies, debonding and loss of crown were reported for zirconia crowns, while crown fractures were reported for composite resin crowns (Table 4).

Figure 2. Retention rates for crowns fabricated with different materials, as reported in the included randomized controlled trials.

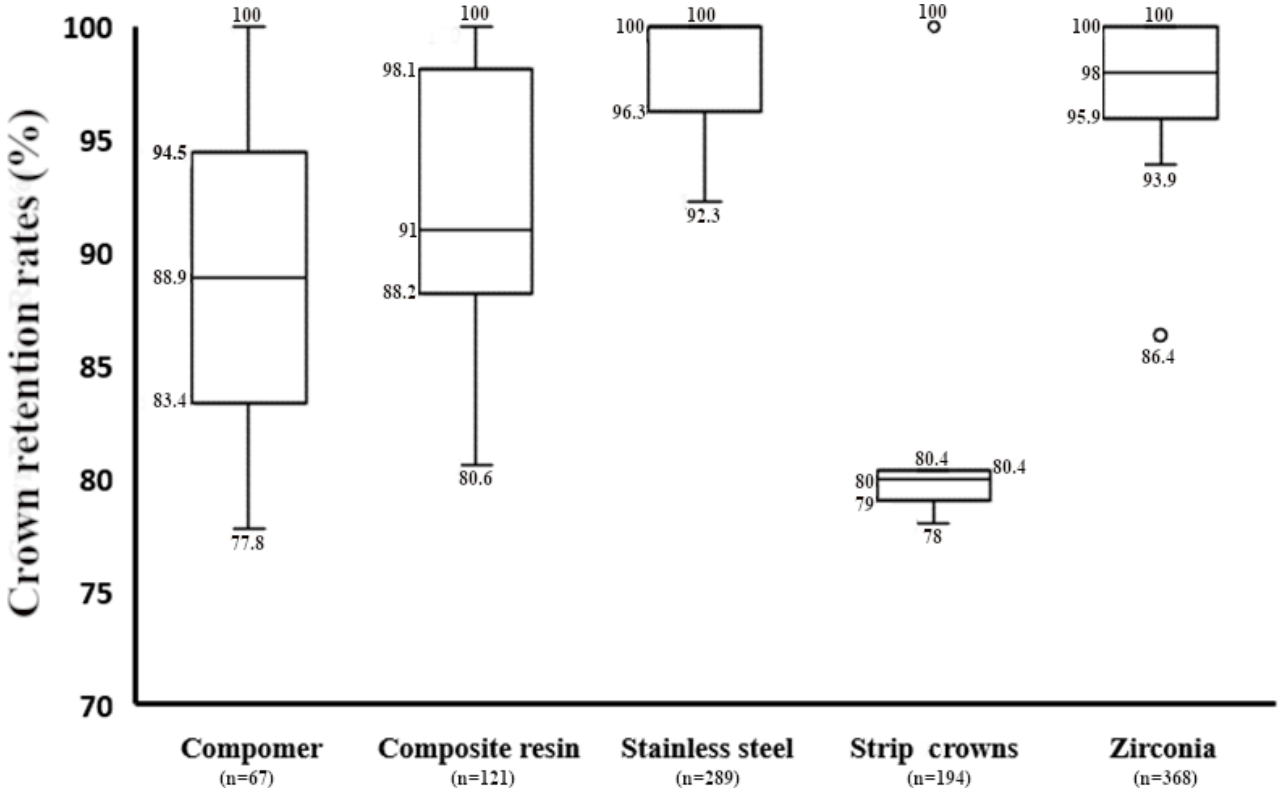

Table . Retentive complications reported in the randomized controlled trials for different materials.

Crown material	Decementation, n	Chipping[a], n	Crown fracture[b], n	Poor anatomic form, n	Complete crown loss, n	Partial material loss[c], n
Compomer	0	0	8	0	0	0
Composite resin	0	12	3	3	1	2
Stainless steel	0	0	0	0	0	0
Strip crowns	0	3	0	0	7	19
Zirconia	5	0	0	0	1	1

[a]Chipping: loss of small fragments or pieces from the surface of the crown.

[b]Crown fracture: severe damage where the crown splits or breaks into two or more parts.

[c]Partial material loss: a more substantial loss of crown material compared to chipping but does not constitute a complete fracture.

Biological Complications Reported in the Included Studies

Table 6 depicts the distribution of biological complications reported in the included RCTs [18-30]. In the prospective and retrospective clinical studies, 8.3% (6/67) of children receiving compomer crowns and 8.8% (11/121) receiving composite resin crowns reported secondary caries [31-35]. Additionally, 3.3% (10/289) and 21.8% (80/368) of children with stainless steel crowns and zirconia crowns, respectively, in these studies exhibited gingival inflammation [32-36].

Table . Biological and clinical complications reported in the randomized controlled trials for different materials.

Biological and clinical complications	Compomer (n=67)	Composite resin (n=121)	Stainless steel (n=289)	Strip crowns (n=194)	Zirconia (n=368)
Secondary caries, n (%)	4 (5.97)	3 (2.47)	13 (4.54)	12 (6.18)	0 (0)
Gingival inflammation, n (%)	0 (0)	29 (24.24)	23 (7.85)	14 (7.21)	13 (3.5)
Plaque index[a], n (%)	0 (0)	0 (0)	0 (0)	0 (0)	25 (6.76)
Bleeding on probing, n (%)	0 (0)	0 (0)	0 (0)	0 (0)	43 (11.77)

[a]Plaque Index: a clinical measure used to assess the amount of dental plaque on teeth.

Technical Complications Reported in the Included Studies

Table 7 outlines the distribution of technical complications reported in the included RCTs [18-30]. In the prospective and retrospective clinical studies, 29% (19/67) of compomer crowns exhibited marginal adaptation complications, while stainless steel crowns did not demonstrate marginal adaptation issues [32-36]. No marginal discoloration or plaque retention complications were observed for compomer crowns. Among the 399 zirconia crowns evaluated, 4.8% (19/399) demonstrated shade mismatches, and 1% (4/399) exhibited marginal integrity complications [32-36].

Table . Percentage of technical complications reported in the included randomized controlled trials [19-31].

Crown material	Surface roughness	Occlusal wear	Marginal adaptation	Marginal discoloration	Marginal integrity	Staining	Plaque retention	Shade mismatch	Opposing tooth wear
Compomer (n=67), n (%)	0 (0)	0 (0)	19 (29)	0 (0)	0 (0)	0 (0)	0 (0)	0 (0)	0 (0)
Composite resin[a] (n=154), n (%)	2 (1.3)	17 (11)	8 (5.2)	2 (1.3)	0 (0)	24 (15.6)	20 (13)	45 (29.2)	0 (0)
Stainless steel (n=242), n (%)	0 (0)	0 (0)	0 (0)	0 (0)	1 (0.4)	7 (2.9)	0 (0)	0 (0)	33 (13.6)
Strip crowns (n=194), n (%)	0 (0)	0 (0)	14 (7.2)	0 (0)	7 (3.6)	6 (3.1)	0 (0)	41 (21.11)	31 (16)
Zirconia (n=399), n (%)	1 (0.3)	0 (0)	2 (0.5)	0 (0)	4 (1)	7 (1.8)	2 (0.5)	19 (4.8)	34 (8.5)

[a]Technical complications were reported more for composite resin in the included studies.

Quantitative Analysis (Meta-Analysis) of the Included Studies

Table 8 presents the estimated 3-year and 5-year retention rates of crowns fabricated using various materials, as reported in the included RCTs [19-31].

The Pearson goodness-of-fit test was performed to assess heterogeneity across studies and to determine whether a fixed-effects or random-effects model should be used. Since no statistically significant heterogeneity was detected in any of the individual groups and rates (P>.05), a fixed-effects Poisson regression model was used to estimate the parameters.

Meta-analysis of pooled 5-year retention rates for different crown materials revealed the following retention rates: 88.90% for compomer crowns (Figure 3), 92.18% for composite resin crowns (Figure 4), 90.30% for RMGIC crowns (Figure 5), and 97.88% for stainless steel crowns (Figure 6). Additionally, strip crowns exhibited a retention rate of 83.48% (Figure 7), while zirconia crowns had a retention rate of 97.09% (Figure 8). Figure 9 presents the retention rates, irrespective of the material, and found a retention rate of 92.20% (95% CI 92.14% - 92.26%).

Discussion

This systematic review examined data from RCTs and prospective and retrospective clinical studies to evaluate the performance of dental crowns for primary teeth. Key findings include significant biases in RCTs affecting the assessment of crown efficacy, variability in age distribution impacting retention rates, and varying complications across different crown materials. Despite these challenges, stainless steel crowns consistently demonstrated superior retention rates, while complications such as secondary caries and gingival inflammation varied among materials.

In our analysis, stainless steel crowns exhibited the highest retention rates, corroborating findings from previous studies [8,10], which also highlighted the superior performance of stainless steel crowns in terms of retention and durability. The study by Chisini et al [8] indicated an annual failure rate between 0% and 29.9%, with stainless steel crowns showing the highest success rate of 96.1%. In this study, the estimated 3-year and 5-year retention rates ranged from 75.7% to 100% and from 62.8% to 100%, respectively. Zirconia and composite resin crowns also demonstrated high retention rates, although they were associated with different types of complications. These results align with another study by Alzanbaqi et al [9], which noted improved gingival and periodontal health, excellent retention, and high fracture resistance with zirconia crowns for primary teeth. Regarding complications, strip and composite resin crowns showed higher instances of chipping and partial material loss, likely due to the inherent brittleness of these materials and their susceptibility to fracture under masticatory forces [37-39]. Crowns fabricated with composite resins and newer materials like compomer exhibited a higher incidence of fractures, possibly due to inadequate bonding strength and less favorable mechanical properties compared with stainless steel and zirconia [39,40]. Composite resin crowns also exhibited higher rates of gingival inflammation, likely due to plaque accumulation and potential marginal leakage. Conversely, zirconia crowns showed minimal gingival inflammation, attributed to their smooth surface and biocompatibility [40-42]. Secondary caries was a significant issue across all materials but was particularly prevalent in crowns with poor marginal adaptation, emphasizing the need for precise placement and proper maintenance to mitigate caries risk [42,43]. While the findings demonstrate the efficacy of stainless steel crowns, material choice should consider the specific needs and conditions of pediatric patients. Clinicians must weigh the benefits of high retention rates against the potential for biological complications. The included RCTs displayed a notable prevalence of allocation concealment, performance bias, and detection bias (Table 1) [19-31]. These biases, inherent to the nature of interventions that often preclude optimal double blinding, necessitate careful consideration in assessing the risk of bias for studies involving crowns for primary teeth. These findings align with a previous systematic review by Chisini et al [8], which also identified a high risk of bias. The assessment of publication bias in our meta-analysis revealed noteworthy findings (Figure 10). The Egger test for zirconia crowns suggested potential publication bias. In contrast, for stainless steel, composite resin, and strip crowns, the limited number of studies precluded robust evaluation of small study effects. Thus, caution is warranted in interpreting these outcomes due to the small sample size. The significant results indicate asymmetry in the funnel plot, potentially influencing effect size estimates.

XSL•FO
RenderX

Figure 10. Funnel plots for assessments of publication bias in the included studies for (A) zirconia, (B) stainless steel, (C) composite resin, and (D) strip crowns. For part A, the Egger test was performed (t_9=9.07, P<.001). For parts B-D, the number of studies was below the recommended threshold for robustly assessing publication bias, and the potential for small study effects should be considered with prudence.

The age distribution of the study population is often not reported, posing challenges in determining optimal retention rates for a smooth transition from primary to permanent teeth, especially in younger age groups. The age of children in the RCTs and prospective and retrospective clinical studies ranged from 1 to 10 years and from 3 to 10 years, respectively [19-31]. The reported crown-retention rates for different age groups suggest potential nuances in the transition from primary to permanent teeth, underscoring the need for future studies to provide detailed age-distribution data. Another major limitation of this review is the varying sample sizes across studies, which could influence the generalizability of the results. However, the application of Poisson regression allowed for the adjustment of these differences, providing a more accurate comparison of retention rates [44]. Despite these limitations, this review provides a comprehensive analysis of crown retention and associated complications in primary teeth, offering valuable insights for evidence-based clinical decision-making.

Future studies should aim to include larger sample sizes and longer follow-up periods to validate the findings of this review. Additionally, research should focus on the development and evaluation of new materials and techniques that could enhance crown retention and reduce complications. Investigating advanced fabrication methods such as 3D printing and computer-aided design and computer-aided manufacturing technology holds promise for improving the fit and longevity of dental crowns.

In conclusion, while stainless steel crowns remain a gold standard for primary teeth restorations due to their high retention rates and durability, the choice of material should be tailored to individual patient needs, considering both mechanical properties and potential biological complications. Ongoing research and clinical advancements will continue to refine these treatment modalities, ultimately improving outcomes for pediatric dental patients.

Abstract

Background: Chronic diseases such as diabetes and cardiovascular disease are global health challenges, affecting millions of people worldwide. Traditional health care often falls short in chronic disease management. This has led to the exploration of innovative solutions, such as mobile health (mHealth) technologies. mHealth, which leverages mobile and wireless technologies, has the potential to transform health care delivery by providing continuous, accessible, and personalized care. However, the effectiveness of mHealth, particularly when integrated with traditional health care interventions delivered by professionals, warrants comprehensive investigation. Understanding the combined impact of mHealth and professional-led interventions is critical to maximizing the potential of mHealth to improve patient outcomes and adherence.

Objective: This study aims to investigate the effectiveness of combining mHealth and health professional–led intervention for improving health-related outcomes in chronic diseases

Methods: This systematic review and meta-analysis focused on randomized controlled trials. We searched Web of Science, CENTRAL, MEDLINE, and CINAHL through July 17, 2023. The study targeted patients aged 18 years and older, experiencing at least 1 chronic condition. The interventions were a combination of mHealth and the use of a health care professional. The comparison groups consisted of participants receiving either general care and follow-up or those using mHealth devices without any health care professional involvement. The outcomes measured in this review included hemoglobin A_{1c} (HbA_{1c}), quality of life (QoL), and physical activity.

Results: The study included 26 research papers, encompassing 7360 individuals. Meta-analysis was conducted for HbA_{1c}, QoL, and physical activity. For HbA_{1c}, short-term improvement was significant (standardized mean difference [SMD] –0.43; 95% CI –0.64 to –0.21; I^2=69%) and medium term (SMD –0.49; 95% CI –0.49 to –0.09; I^2=21%). However, in the long term, the improvement was not significant (SMD –0.23; 95% CI –0.49 to 0.03; I^2=88%). For QoL, significant improvements were observed in the short term (SMD –0.23; 95% CI –0.42 to –0.05; I^2=62%), and in the medium term (SMD –0.16; 95% CI –0.24 to –0.07; I^2=0%). In the long term, however, the improvement was not significant (SMD –0.12; 95% CI –0.41 to 0.16; I^2=71%). For physical activity, both subjective (questionnaire) and objective (number of steps) outcomes were analyzed. In the short term, subjective outcomes showed significant improvement (SMD 0.31; 95% CI 0.12-0.50; I^2=0%), while objective outcomes did not (SMD 0.11; 95% CI –0.05 to 0.27; I^2=0%). Medium- and long-term subjective outcomes showed no significant improvement. Meta-analysis for objective outcomes in the medium and long term was not possible due to insufficient studies.

Conclusions: This study confirmed short- and medium-term benefits of mHealth combined with professional interventions for HbA_{1c}, QoL, and short-term physical activity, supporting effective chronic disease management.

Introduction

Background

Mobile health (mHealth) is the delivery of medical and public health services using mobile handsets, mobile kiosks, and other wireless terminals in real-world environments [1]. Interventions in mHealth can take various forms, including the creation of original apps for the management of health conditions and communication, simple text message-based interventions, as well as those using voice calls or the accumulation of device data on mobile apps for data management [2]. Many interventions in the field of mHealth primarily emphasize self-management without any direct human involvement [3]. Likewise, there are interventions that involve periodic health care professional assistance and the additional use of health devices [4,5].

The growing disease burden of chronic diseases, on the other hand, is one of the global challenges [6]. Chronic diseases include conditions such as cardiovascular diseases, stroke, cancer, diabetes, respiratory conditions, and arthritis [7]. Furthermore, obesity is now defined as a disease, and the most common chronic disease [8]. While the assistance of health care professionals is essential for the management of these chronic conditions, mHealth may be valuable in filling the gaps between medical consultations or support, as well as in the monitoring of disease conditions remotely. In fact, the efficacy of therapeutic apps prescribed by physicians has also been reported [9]. The effectiveness of mHealth is currently being investigated through a systematic review [10]. The quality of research methodologies is often limited, and consistent conclusions have not been reached yet. Among the reasons for this is that the definition of mHealth intervention methods varies widely, and depending on the definition, conclusions about effectiveness can differ. Some reports suggest that no significant effects have been observed. There is a discrepancy in research on health interventions that focus on self-monitoring for chronic diseases, and it is unclear if there are any conclusive benefits [11-13]. A systematic review evaluating the effectiveness of remote monitoring in various types of chronic diseases found only limited improvements in general health status and clinical outcomes [14].

From a behavioral science perspective, effective management of people with chronic conditions requires more than just the use of mHealth technologies. It also requires consistent support from health care professionals over medium and long terms. In particular, studies focused on obesity have used interaction with professionals as an indicator of engagement. This interaction has been shown to play a significant role in achieving long-term (ie, 1 year) weight loss outcomes [15] although these definitions may vary between studies, potentially affecting the interpretation of results. Therefore, to maximize the potential of mHealth, we hypothesized that combining mHealth with health professional–led interventions would be more effective than relying solely on health care use. To investigate this hypothesis, our study focused exclusively on interventions that integrated mHealth with professional-led chronic disease strategies and then evaluated their effectiveness for each different duration.

Objectives

With this systematic review and meta-analysis, we investigated the effectiveness of combining mHealth and health professional–led intervention for improving health-related outcomes in chronic diseases.

Methods

Study Design

This was a systematic review and meta-analysis of randomized controlled trials.

Protocol and Registration

This systematic review was preregistered in the PROSPERO database (CRD42022337882) and conducted following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (Multimedia Appendix 1).

Search Strategy

Our search spanned 4 databases from their start dates until July 17, 2023. These included Web of Science, CENTRAL, MEDLINE, and CINAHL, as they are the four most used databases in similar research. Manual searches systematically screened the reference lists of all studies identified in the database search. The same inclusion criteria were applied to these references and the titles and abstracts were reviewed to determine whether they were included studies. Our systematic search strategy used both medical subject heading terms and keywords derived from subject headings. We limited our inclusion to randomized controlled trials published in English, excluding gray literature. The detailed search strategy is available in Multimedia Appendix 2.

Identification and Selection of Trials

Population

The population of interest included patients aged 18 years and older with at least 1 chronic condition. This was a change from the original protocol (CRD42022337882), which specified a minimum age of 20 years, in order to increase the generalizability of the findings by including all adults.

Interventions

This study's interventions comprised a mix of mHealth and direct health care professional involvement. The World Health Organization defines mHealth as "the use of mobile and wireless technologies to support health objectives" [16]. We excluded interventions that primarily used computers, categorizing them

XSL•FO
RenderX

as eHealth. Additionally, interventions where participants used smartphones solely for calls or text messages, without using specific apps, were not included to avoid overlapping mHealth and eHealth interventions and to ensure a clear distinction. The health care professionals involved in our study spanned various fields, including doctors, nurses, physiotherapists, occupational therapists, and dieticians. These professionals were actively engaged in delivering the mHealth intervention, beyond just explaining or reviewing app data. The methods used by health professionals for interventions included face-to-face interactions, phone calls, and text messaging.

Comparison

The comparison groups in this study consisted of the general control groups used in each individual study. For example, control groups were defined as those with only general care and follow-up, or those using mHealth-related devices but no involvement of a health care professional.

Outcomes

This systematic review assessed the following primary outcomes: HbA_{1c} levels, quality of life (QoL), and physical activity. These outcomes were chosen for their relevance in chronic disease management and were analyzed across different follow-up periods (short, medium, and long terms) to evaluate intervention effectiveness over time.

Selection Process

Rayyan software was used. Two authors (MK and TS) independently assessed the title and abstract records to identify eligible studies. The same authors then conducted a full-text screening to assess whether the criteria were met; in cases where the 2 authors' judgments conflicted, a third author (TM) decided and ultimately reached a consensus.

Assessment of Methodological Quality

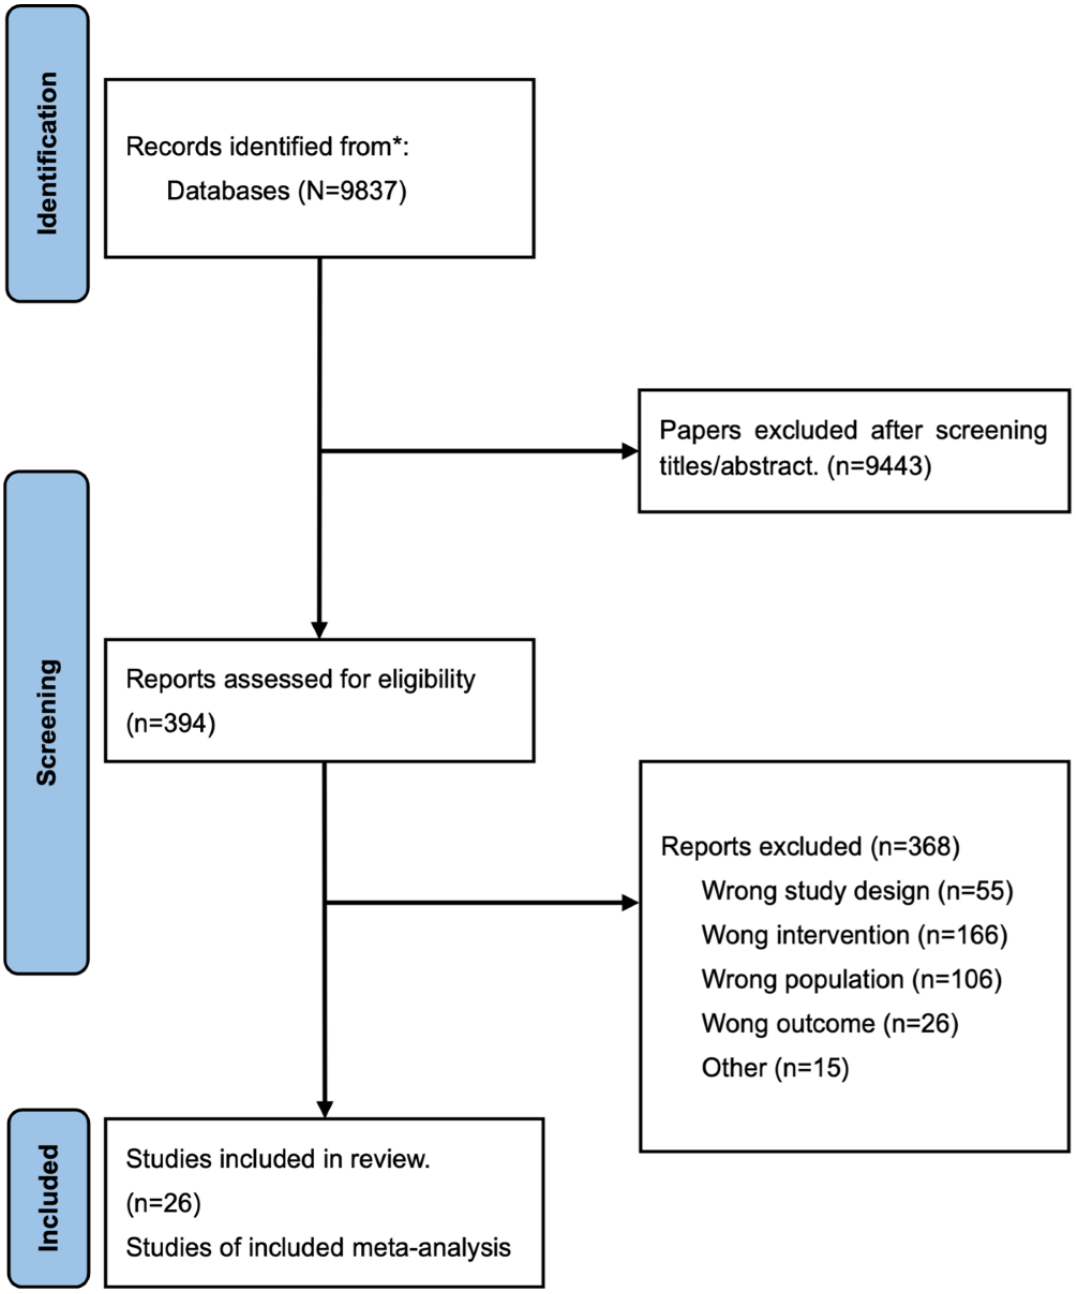
The risk of bias for individual studies was assessed using the Cochrane Risk of Bias Framework for sequence generation, allocation concealment, blinding, completeness of outcome assessment, selective reporting, and other biases. Data were extracted by 2 authors (TM and MK). Disagreements were reviewed by a third author and a final consensus was reached. For the quality of the clinical evidence, the GRADE (Grading of Recommendations Assessment, Development, and Evaluation) system was used to evaluate the results.

Data Extraction

Data were extracted by 2 authors (TM and MK). Disagreements were reviewed by a third reviewer and a final consensus was reached. Data were extracted on (1) basic information about the study, such as authors, year of publication, country, and region where the intervention took place; (2) target population; (3) intervention group description; (4) control group description; (5) outcomes; and (6) key findings.

Data Analysis

When two or more studies assessed the same outcome, a meta-analysis was performed using Review Manager 5.4 (Nordic Cochrane Centre). The results of the intervention groups were compared with the control group in each meta-analysis. The combined app and professional intervention was considered the intervention group and compared to the control group when there were more than 2 groups. The meta-analysis evaluated 3 different categories of time periods: short-, medium-, and long-term effects. Short term was defined as the closest to 3 months, medium term as the closest to 6 months, and long term as the closest to 12 months. For each follow-up point, the mean and SD were calculated. The group mean was calculated from the SE, CI, and *P* value of the difference between the means in trials that did not report SDs for each intervention group. In studies that only reported the median and IQR without providing SDs, we estimated the mean using the median value directly and approximated the SD by multiplying the IQR by 1.35. This method follows established meta-analytic conventions for handling summary statistics in studies with limited data [17]. All meta-analyses were presented as standardized mean difference (SMD) to account for adjusted and unadjusted means, due to the different data presentation formats of the included studies [17]. The authors of the studies in which the data were presented in a graphical format were contacted to obtain the exact values. If the reporting of results was still unclear after the above procedure, studies were excluded from the meta-analysis. For each meta-analysis, heterogeneity was assessed using I^2. When the I^2 value exceeded 75%, sensitivity analysis was conducted by sequentially excluding studies with the largest effect sizes, as these studies contributed significantly to the overall heterogeneity. This stepwise exclusion continued until heterogeneity dropped below the 75% threshold. By reducing the influence of studies with disproportionately high effect sizes, we aimed to create a more consistent and interpretable dataset, enhancing the reliability of the pooled effect size and minimizing the risk of bias or misinterpretation due to extreme variability among studies [18].



Results

Study Selection

The initial search identified 9837 records, which were screened for title and text as primary screening after removing duplicates. A number of 394 were selected for secondary screening after the first screening. Finally, 26 studies were finally selected. Figure 1 shows the flow chart of the selection process.

XSL•FO
RenderX

Figure 1. Flow diagram.

Characteristics of Included Trials and Intervention Description

Regarding the country, studies were conducted at outpatient or community practices in the following countries: Pakistan (2/26, 8%) [19,20], Spain (4/26, 15%) [21-24], Mexico (2/26, 8%) [25,26], United Kingdom (4/26, 15%) [27-30], United States (2/26, 8%) [31,32], China (4/26, 15%) [33-36], Singapore (2/26, 8%) [34,37]; and one each in Netherlands [38], Australia [39], Canada [40], Germany [41], Indonesia [42], and Thailand [43].

Regarding the disease, diabetes was the most common disease, with 12 of 26 trials [21,22,25,29-31,33,34,36,39,42,43]. Seven studies included type 2 diabetes [21,25,30,31,33,34,39] and 5 studies included both [22,29,36,42,43]. No study included only type 1 diabetes. The next most common was heart disease, which accounted for 7 of the 26 cases [19,20,24,35,37,38,44]. Other disease areas included cancer (2 studies) [26,32], respiratory diseases (1 study) [28], chronic diseases (2 studies) [23,40], metabolic syndrome (1 study) [41], and depression (1 study) [27].

The most common outcome was quality of life. There were 15 studies [20,22,24-27,30,32,34,37-41,44]. Ten studies used physical activity as an outcome [19,21,26,28,30,32,35,39,40,44]. Details are provided in Multimedia Appendix 3 [19-44].

Risk of Bias Assessment

The results of the risk of bias assessment are summarized in Multimedia Appendix 4 [19-44]. The risk of bias assessment for studies on HbA_{1c}, QoL, and physical activity (steps and subjective measures) showed that most studies had a low risk of bias. For example, studies like Anzaldo-Campos et al [25] and Blair et al [26] were evaluated as low-risk. Some studies had some concerns, such as Azelton et al [31] and Gill et al [40], but none were classified as high risk. Several studies, including

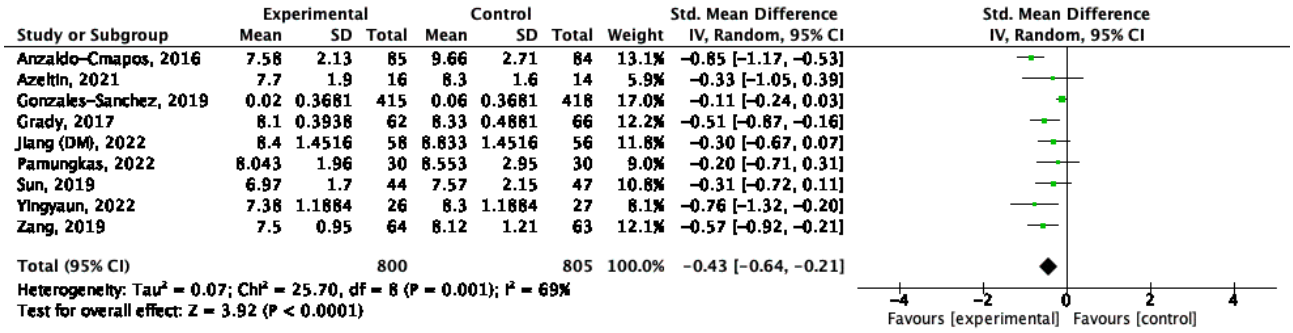
XSL•FO
RenderX

Franc et al [22] and Manzoor et al [19], did not have sufficient data for a full assessment.

Certainty of the Evidence According to the GRADE Approach

The certainty of evidence results using the GRADE approach are described in the results for each outcome. The GRADE assessment showed varying levels of evidence quality across outcomes. Most HbA_{1c} outcomes had very low to moderate certainty, with short-term outcomes showing very low certainty and medium-term outcomes showing moderate certainty. QoL outcomes generally had low to moderate certainty, with long-term outcomes showing very low certainty. Physical activity outcomes varied, with step counts showing moderate certainty and subjective measures ranging from very low to moderate certainty. These findings highlight the need for caution due to risks of bias and inconsistencies. A table with the results is provided in Multimedia Appendix 5.

Synthesis of Results: Meta-Analysis



One study was excluded because data were not available [24]. Therefore, a meta-analysis was performed from 25 studies. Our systematic review included a broad spectrum of conditions, but diabetes was the most frequently addressed condition among the included studies. Consequently, HbA_{1c} was chosen as a primary indicator due to its importance in diabetes management and its frequent reporting in the studies. QoL was selected as it is a critical outcome measure reflecting the overall well-being of patients with chronic conditions. Physical activity and subjective outcomes of physical activity were included because these measures are commonly used to assess lifestyle modifications and their impact on chronic disease management. These indicators were the most frequently reported across the studies we reviewed, making them the most relevant for our analysis.

HbA_{1c} Outcome

Short Term

Meta-analysis was performed on 9 studies [23,25,29,31,33,34,36,42,43]. There was a significant increase in improvement for the combination intervention (SMD –0.43; 95% CI –0.64 to –0.21; P<.001; I^2=69%; Figure 2 [23,25,29,31,33,34,36,42,43]).

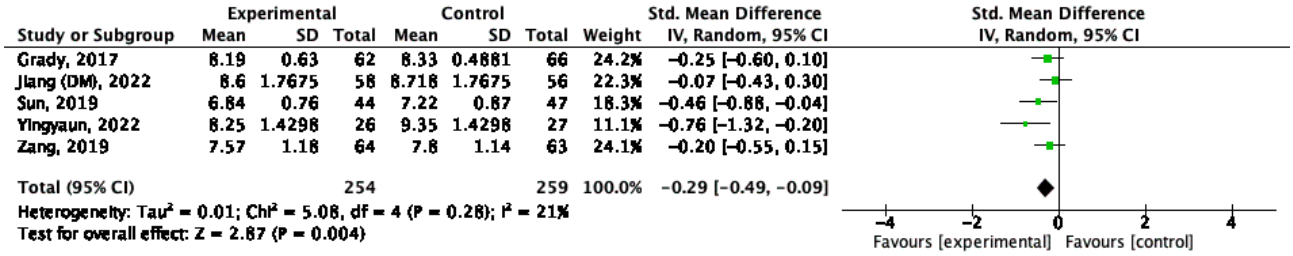


Figure 2. Hemoglobin A1c (HbA_{1c}) for short term [23,25,29,31,33,34,36,42,43].

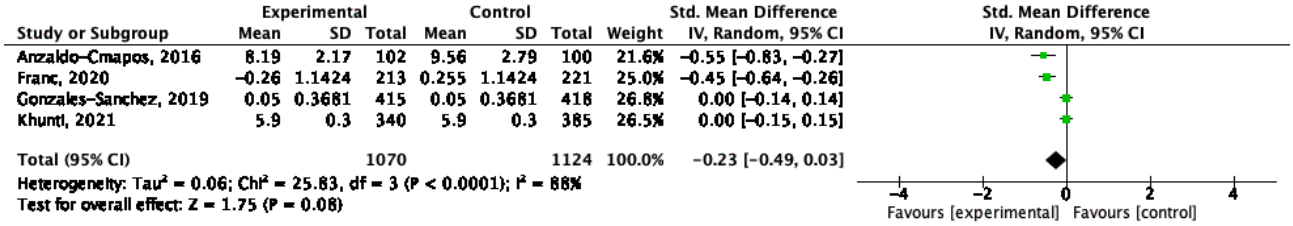
Medium Term

A meta-analysis was performed on 5 studies [29,33,34,36,43]. There was a significant increase in improvement for the combination intervention (SMD –0.49; 95% CI –0.49 to –0.09; P<.001; I^2=21%; Figure 3 [29,33,34,36,43]).

Figure 3. Hemoglobin A1c (HbA_{1c}) for medium term [29,33,34,36,43].

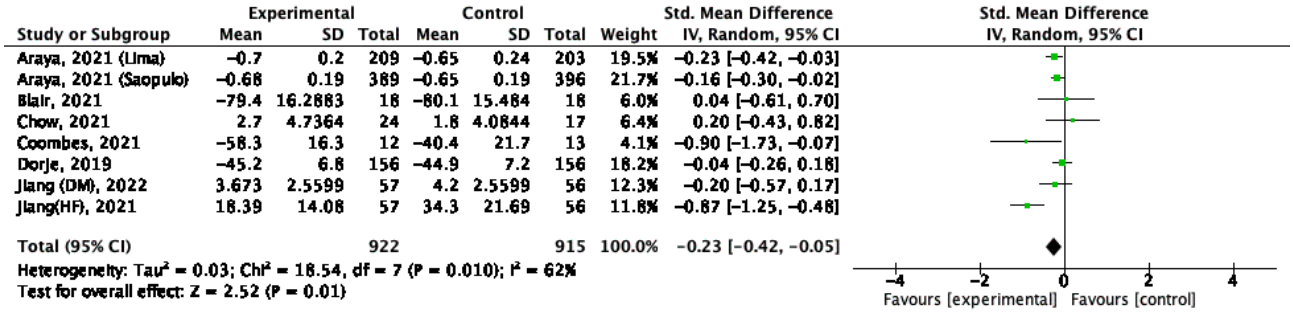


Long Term

One study was excluded because data were not available [24]. A meta-analysis was performed on 4 studies [22,23,25,30]. There was no significant increase in improvement for the combination intervention in the long term (SMD –0.23; 95% CI –0.49 to 0.03; P<.001; I^2=88%; Figure 4 [22,23,25,30]). Sensitivity analysis was performed because heterogeneity was >75%. Two studies [23,30] were excluded and did not reach statistical significance (SMD –0.00; 95% CI –0.10 to 0.10; P<.001; I^2=0%).

XSL•FO
RenderX

Figure 4. Hemoglobin A1c (HbA_{1c}) for long term [22,23,25,30].



QoL Outcome

Short Term

Seven studies were included. However, 1 study [27] considered each of the 2 real samples, so they were included in the meta-analysis separately. Therefore, a meta-analysis was performed as 8 studies [26,27,32,34,37,39,44]. There was a significant increase in improvement for the combination intervention in the short term (SMD –0.23; 95% CI –0.42 to –0.05; P<.001; I^2=62%; Figure 5 [26,27,32,34,37,39,44]).

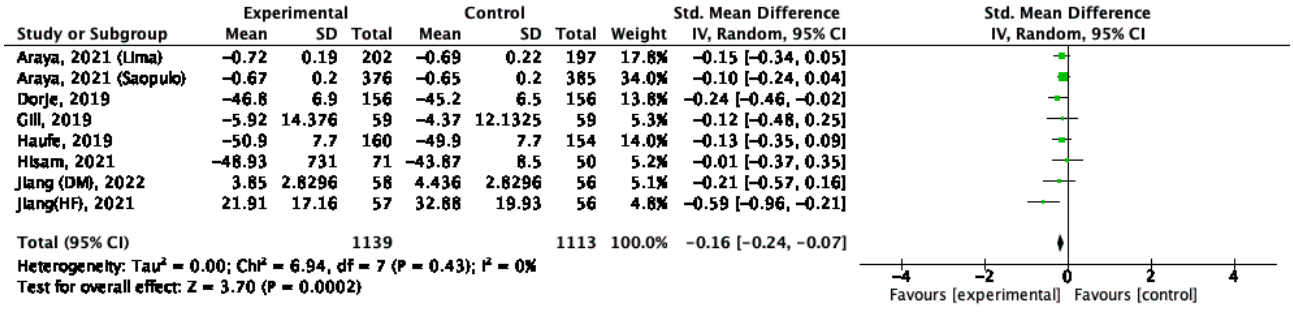


Figure 5. Quality of life for short term [26,27,32,34,37,39,44].

Medium Term

Seven studies were included. However, 1 study [27] considered each of the 2 real samples, so they were included in the meta-analysis separately. Therefore, a meta-analysis was performed as 8 studies [20,27,34,37,40,41,44]. There was a significant increase in improvement for the combination intervention (SMD –0.16; 95% CI –0.24 to –0.07; P<.001; I^2=0%; Figure 6 [20,27,34,37,40,41,44]).

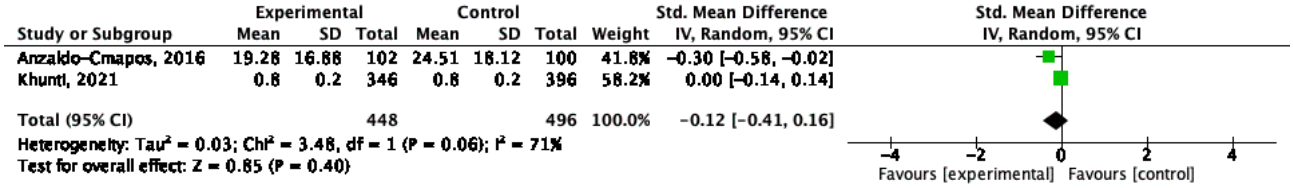

Figure 6. Quality of life for medium term [20,27,34,37,40,41,44].

Long Term

One study was excluded because data was not available [24]. A meta-analysis was performed on 2 studies [25,30]. There was no significant increase in improvement for the combination intervention (SMD –0.12; 95% CI –0.41 to 0.16; P=.04; I^2=71%; Figure 7 [25,30]).

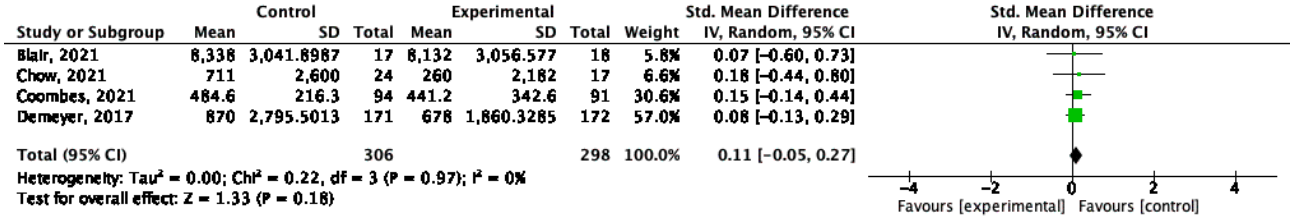
Figure 7. Quality of life for long term [25,30].

XSL•FO
RenderX

Physical Activity

We performed a meta-analysis of the outcome of physical activity, dividing the data into subjective (questionnaire) and objective (number of steps).

Objective Outcomes of Physical Activity



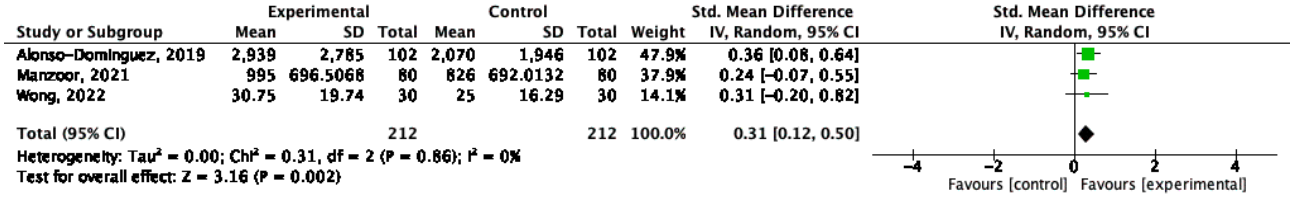
Overview

It was not possible to perform a meta-analysis for the medium and long terms because there was less than 1 study that corresponded to this time.

Short Term

Meta-analysis was conducted in 4 studies [26,28,32,39]. There was no significant increase in improvement for the combination intervention (SMD 0.11; 95% CI –0.05 to 0.27; P=.18; I^2=0%; Figure 8 [26,28,32,39]).

Figure 8. Physical activity (steps) for short term [26,28,32,39].



Subjective Outcomes of Physical Activity

Short Term

A meta-analysis of 3 studies was conducted [19,21,35]. There was a significant increase in improvement for the combination intervention (SMD 0.31; 95% CI 0.12-0.50; P=.002; I^2=0%; Figure 9 [19,21,35]).

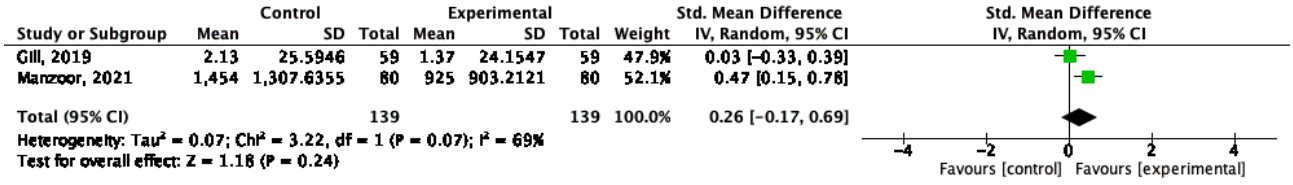


Figure 9. Physical activity (subjective) for short term [19,21,35].

Medium Term

Meta-analysis was conducted in 2 studies [19,40]. There was no significant increase in improvement for the combination intervention (SMD 0.26; 95% CI –0.17 to 0.69; P=.24; I^2=69%; Figure 10 [19,40]).

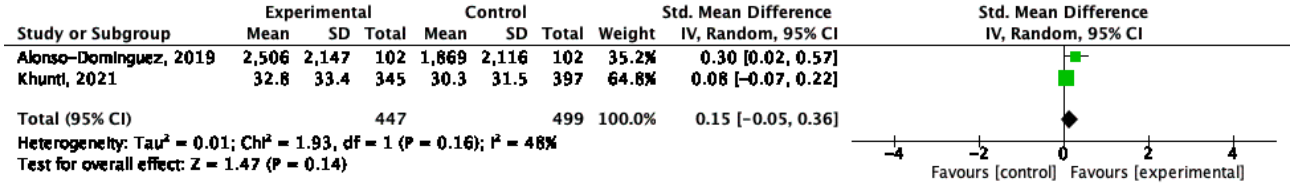

Figure 10. Physical activity (subjective) for medium term [19,40].

Long Term

Meta-analysis was conducted in 2 studies [21,30]. There was no significant increase in improvement for the combination intervention (SMD 0.15; 95% CI –0.05 to 0.36; P=.14; I^2=48%; Figure 11 [21,30]).

Figure 11. Physical activity (subjective) for long term [21,30].

Discussion

Principal Findings

This systematic review and meta-analysis showed that the combination of mHealth and health professional–led interventions improved health-related outcomes such as HbA_{1c} and QoL in chronic diseases. These effects were significant in the short and medium terms and there was no significant long term. For physical activity, there were no differences in intervention effects except for the short term as measured by questionnaires.

HbA_{1c}

In this systematic review, studies targeting patients with chronic diseases were included, and among the 26 studies, 12 incorporated HbA_{1c} as an outcome measure. In a meta-analysis that used mobile apps for lifestyle modification among diabetes patients, similar to our study, improvements in HbA_{1c} levels were demonstrated [45]. Furthermore, the meta-analysis indicated significant long-term effects in its subgroup analysis, defining long-term as 9-12 months [45], which differs from our study's definition. The impact of mHealth was indicated to diminish in the long term due to factors such as adherence fatigue [46]. However, another meta-analysis found that digital health–led diabetes self-management education and support (including mHealth, eHealth, and interventions using social networking services) were effective in improving HbA_{1c} at 6 and 12 months [47]. The discrepancies between our study and the other meta-analysis may be due to some factors. These factors include variations in digital health interventions, professional involvement levels, patient populations, and adherence. The other meta-analysis also included mHealth, eHealth, and interventions using social networking services, which may offer different engagement and support levels. These differences in intervention design and implementation could contribute to the varying long-term effectiveness observed. An overview of the studies we included in our systematic review, for example, Anzaldo-Campos et al [25] demonstrated that a smartphone app used for diabetes management significantly improved HbA_{1c} levels over a 6-month period, highlighting the potential of app-based interventions for glycemic control. In contrast, Franc et al [22] found that a telemonitoring system improved HbA_{1c} levels significantly over 12 months, suggesting that the integration of professional support enhances the effectiveness of digital health interventions. The differing results could be due to the varying levels of professional involvement and continuous monitoring provided in the telemonitoring system, which may help sustain patient adherence and engagement over a longer period. Additionally, Jiang et al [37] found that a nurse-led smartphone intervention significantly reduced HbA_{1c} levels over 6 months in patients with type 2 diabetes, emphasizing the importance of professional guidance in mHealth interventions. Conversely, Zhang et al [36] reported that a self-guided mobile app intervention without professional support did not result in significant improvements in HbA_{1c} levels, highlighting the potential limitations of mHealth interventions lacking continuous professional involvement. Our findings suggest that while the combination of mHealth and health professional–led interventions can be as diverse as those described above, continuous feedback and support to patients through other digital interventions to enhance engagement may be a key factor in achieving long-term benefits [48].

QoL

QoL was the most prevalent outcome measure among the studies included in this study. The results of our meta-analysis suggested that combining mHealth and health professional–led intervention can significantly improve QoL in chronic diseases in the short and medium terms. Studies conducting meta-analyses on the QoL in mHealth interventions for patients with chronic diseases are limited [49-51]. In a meta-analysis by Qin et al [50], mobile app–based interventions improved the QoL (SMD 0.39; 95% CI 0.27-0.51; $P<.001$) of patients with cancer. They emphasized that short-term interventions in particular (duration of 3 months or less), physician-patient interaction interventions, and cognitive behavioral therapy–based interventions may be most effective in improving QoL, which was consistent with this study. While extending beyond the scope of mHealth interventions, there is only 1 reported meta-analysis that indicated long-term improvements in QoL (mean difference 0.92; 95% CI 0.06-1.78; $P=.04$) resulting from cardiac telerehabilitation for patients with coronary artery disease [52]. For instance, Araya et al [27] found that a digital intervention combined with professional support significantly improved QoL in patients with cardiovascular diseases over 12 months. This improvement could be attributed to the continuous monitoring and personalized feedback provided by health care professionals, which likely enhanced patient adherence and engagement with the intervention. In contrast, Blasco et al [24] reported improvements in QoL among patients with acute coronary syndrome using a web-based telemonitoring system. The significant improvements observed in Blasco et al [24] study might be due to the comprehensive nature of the telemonitoring system, which included regular remote check-ins and the ability to promptly address patient concerns, thereby providing a sense of security and continuous care. Similarly, Manzoor et al [19] demonstrated that the mHealth-augmented cardiac rehabilitation program significantly improved QoL in patients with postacute coronary syndrome over 24 weeks, underscoring the importance of combining digital interventions with structured professional support. On the other hand, Wong et al [35] found that a self-guided mHealth intervention without professional involvement had limited effects on improving QoL, indicating that professional support is crucial for maximizing the benefits of digital health interventions. In our meta-analysis, focusing solely on mHealth interventions, it might be possible to identify long-term effects on the improvement of QoL by expanding the scope to include telehealth intervention or telerehabilitation as well.

Physical Activity

The results of our meta-analysis suggested that physical activity had no significant effect except for the short-term effect of subjective assessment. One reason for this might be that many mHealth interventions did not include specifications or support

XSL•FO
RenderX

to promote physical activity. This could be attributed to the predominant focus of many interventions on monitoring blood data and providing advice [22,24,25,29,31,33,34,36,42,43], potentially falling short of implementing behavior changes that could lead to promoting physical activity. In fact, among the 26 studies, only 8 studies adopted physical activity as the primary outcome. As an example of a study that adopted physical activity as the primary outcome, Gill et al [40] examined the effects of using a mobile app focused primarily on increasing physical activity and professional support for participants at risk for chronic disease and reported not only an increase in steps over the next 6 months but also maintenance of steps after 1 year. Dorje et al [44] found that a mHealth intervention including exercise modules improved physical activity levels in patients with coronary heart disease over 12 months, highlighting the potential of structured digital interventions. Conversely, Demeyer et al [28] reported that a self-guided digital intervention without professional support did not significantly increase physical activity levels in patients with chronic obstructive pulmonary disease, suggesting the need for continuous professional involvement to achieve sustained behavioral changes. In a different disease from the above, Blair et al [26] showed that a combination of mHealth and professional-led interventions for patients with cancer increased the number of steps taken, although there was no effect on outcomes related to sedentary behavior among physical activity measures. Thus, it would be valuable to identify in future studies which chronic diseases are more likely to improve physical activity with a combination of mHealth and professional-led interventions. Stavric et al [53] showed that digital physical activity and exercise interventions had positive effects on self-reported physical activity in people with chronic diseases, but not on objectively measured physical activity, which supports the results of our study. Their meta-analysis included self-guided digital mHealth interventions [53]. Therefore, there is room for future research to investigate whether self-directed digital or mHealth interventions or a combination of mHealth and health professional–led interventions, have more positive effects on physical activity.

Implications for Practice

The results of our study suggest that combining mHealth with professionally led interventions can be effective in chronic disease management, particularly in short and medium terms. This combination approach shows potential for improving important health outcomes such as HbA_{1c} and QoL. However, the lack of long-term effects indicates the need for sustained and adaptive intervention strategies. Health care providers should consider integrating ongoing digital support and feedback mechanisms to maintain patient engagement and adherence over time. In addition, the involvement of health care professionals in mHealth interventions should be designed to provide personalized and digital support, leveraging technologies such as telemedicine and mobile apps. For example, health care organizations should invest in training and infrastructure to support the seamless integration of mHealth technologies into traditional care models. This can improve the scalability and effectiveness of chronic disease management programs, ultimately leading to better patient outcomes and reduced health care costs.

Limitations

First, a major limitation of our study is the ambiguity in the definition of "health professional–led intervention." Our research focused on a combination of such interventions with mHealth strategies. However, the term may be misleading, as many studies typically include some level of health professional involvement in routine care. In contrast, our study specifically included cases with a more active role for health professionals than is typically seen in routine care. Additionally, the definition of the control group varied across studies. Some studies included only general care, while others provided mHealth devices without additional interventions. Second, our focus on health-related outcomes in chronic diseases limited our ability to conduct comprehensive meta-analyses due to the diverse nature of these diseases and their outcomes. Finally, we did not assess the cost-effectiveness of integrating health professional–led interventions with mHealth strategies. While the involvement of health professionals could potentially improve intervention effectiveness and reduce dropout rates, it could also lead to higher costs. Although mHealth interventions are known to struggle with high dropout rates [54], the cost implications of incorporating health professional support need to be further explored in future studies.

Conclusions

This systematic review and meta-analysis showed that the combined mHealth and health professional–led intervention had positive effects on HbA_{1c} and QoL in chronic conditions in short and medium terms. Positive effects on physical activity were only observed in the short term as measured by questionnaires. To achieve long-term effects of more than 1 year, it may be necessary to implement digital interventions that provide continuous feedback and support, tailored to a combination of mHealth and health professional–led interventions. Future research should explore the sustainability of these interventions over extended periods and investigate the specific components of mHealth and health professional input that contribute most to positive outcomes. Additionally, the integration of advanced technologies such as artificial intelligence and machine learning could further enhance the personalization and effectiveness of mHealth interventions.

Abstract

Background: As digital mental health delivery becomes increasingly prominent, a solid evidence base regarding its efficacy is needed.

Objective: This study aims to synthesize evidence on the comparative efficacy of systemic psychotherapy interventions provided via digital versus face-to-face delivery modalities.

Methods: We followed PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines for searching PubMed, Embase, Cochrane CENTRAL, CINAHL, PsycINFO, and PSYNDEX and conducting a systematic review and meta-analysis. We included randomized controlled trials comparing mental, behavioral, and somatic outcomes of systemic psychotherapy interventions using self- and therapist-guided digital versus face-to-face delivery modalities. The risk of bias was assessed with the revised Cochrane Risk of Bias tool for randomized trials. Where appropriate, we calculated standardized mean differences and risk ratios. We calculated separate mean differences for nonaggregated analysis.

Results: We screened 3633 references and included 12 articles reporting on 4 trials (N=754). Participants were youths with poor diabetic control, traumatic brain injuries, increased risk behavior likelihood, and parents of youths with anorexia nervosa. A total of 56 outcomes were identified. Two trials provided digital intervention delivery via videoconferencing: one via an interactive graphic interface and one via a web-based program. In total, 23% (14/60) of risk of bias judgments were *high risk*, 42% (25/60) were *some concerns*, and 35% (21/60) were *low risk*. Due to heterogeneity in the data, meta-analysis was deemed inappropriate for 96% (54/56) of outcomes, which were interpreted qualitatively instead. Nonaggregated analyses of mean differences and CIs between delivery modalities yielded mixed results, with superiority of the digital delivery modality for 18% (10/56) of outcomes, superiority of the face-to-face delivery modality for 5% (3/56) of outcomes, equivalence between delivery modalities for 2% (1/56) of outcomes, and neither superiority of one modality nor equivalence between modalities for 75% (42/56) of outcomes. Consequently, for most outcome measures, no indication of superiority or equivalence regarding the relative efficacy of either delivery modality can be made at this stage. We further meta-analytically compared digital versus face-to-face delivery modalities for attrition (risk ratio 1.03, 95% CI 0.52-2.03; P=.93) and number of sessions attended (standardized mean difference

XSL•FO
RenderX

–0.11; 95% CI –1.13 to –0.91; *P*=.83), finding no significant differences between modalities, while CIs falling outside the range of the minimal important difference indicate that equivalence cannot be determined at this stage.

Conclusions: Evidence on digital and face-to-face modalities for systemic psychotherapy interventions is largely heterogeneous, limiting conclusions regarding the differential efficacy of digital and face-to-face delivery. Nonaggregated and meta-analytic analyses did not indicate the superiority of either delivery condition. More research is needed to conclude if digital and face-to-face delivery modalities are generally equivalent or if—and in which contexts—one modality is superior to another.

Introduction

Background

Digital delivery of mental health interventions has gained increasing prominence in recent decades. Digital delivery provides solutions to many mental health intervention obstacles, such as limited access [1], geographical distance [2], financial constraints [3], and transportation issues [4]. These factors, and not least the COVID-19 pandemic [5], have contributed to increased delivery of digital modalities of mental health care [6]. One current line of research uses randomized controlled trials (RCTs) to determine the efficacy of digitally delivered family therapies [6] and parenting interventions [7], including but not limited to systemic approaches. This research supports the efficacy of the digital delivery of interventions and finds no evidence for digitally delivered interventions being inferior to face-to-face interventions [8-13]. However, most of the current literature does not compare face-to-face and digitally delivered interventions directly, does not differentiate between the types of digital delivery modalities (eg, therapist-guided videoconferencing and self-guided web-based programs), and does not consider how the modality differentially impacts specific disorders, outcomes, or populations. Furthermore, these studies aggregate findings across broad and diverse contextual definitions of family therapy and parenting interventions instead of applying unified and stringent theory-informed definitions. Although these reviews (eg, McLean et al [6] and Florean et al [7]) do not exclusively focus on a unified and stringent definition, they do provide evidence for systemic approaches in the broad context of family interventions. Many family therapists consider themselves to be systemic therapists, and there is an overlap between family therapy and systemic therapy (ST). However, ST is grounded in a theoretical treatment model, and unlike family therapy, it is not primarily defined by the therapy setting [14]. Thus, ST provides a unified and stringent definition that has practical consequences for research and clinical practice.

ST is a conceptual framework for mental health interventions that focuses on interpersonal relations, interactions, social surroundings and resources, perspectives, and constructions of problems; attempted solutions are appreciated and used as integral parts of the intervention [13,15,16]. Consequently, most family therapy and parenting interventions can be said to contain elements of ST to varying degrees while also potentially including elements from other conceptual frameworks, such as cognitive behavioral therapy and psychoeducation [17]. Conversely, as ST interventions often focus on families as important resources requiring incorporation into intervention delivery [18], they can, but need not be, similar to other family therapy or parenting interventions in terms of including other family members in their setting. The efficacy of ST as a face-to-face intervention is well documented in various reviews and meta-analyses for a range of psychological disorders for youth and adult populations [13,15-17,19]. In line with developments for other psychotherapeutic interventions, the implementation of digital delivery modalities of ST has rapidly increased in recent years [20-22]. The implementation of videoconferencing is particularly promising, and the experiences of practitioners implementing this delivery modality are overall positive [23]. Despite such indications, there are gaps in the literature [20,24]. There is an urgent need to provide an evidence base for practitioners to understand how face-to-face and digital delivery of the same ST intervention compare (compare McLean et al [6], Florean et al [7], and Fairburn and Patel [25]).

The need for greater granularity regarding the comparative efficacy of digital and face-to-face delivery modalities is in line with the more general requirement to identify “conditions under which systemic therapy works best” [16]. Thus, we simultaneously address both the need for a systematic review and meta-analysis that investigates (1) how various types of ST interventions, delivered in their traditional face-to-face form, compare to the same ST intervention delivered digitally with regard to their efficacy and (2) delivery modality as key contextual factors that modulate ST intervention outcomes.

Research Questions

We conducted a systematic review and meta-analysis to address the following research questions: (1) What are the characteristics, quality, and resulting evidence from published RCTs comparing the efficacy of ST interventions using digital treatment modalities with ST interventions using face-to-face treatment modalities across settings, populations, and outcomes? (2) If a meta-analysis of RCTs comparing ST interventions in digital and face-to-face modalities can be conducted, what is the difference in delivery modalities for mental disorder outcomes?

XSL•FO
RenderX

Methods

Overview

This systematic review followed reporting guidelines as laid out in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 statement (Multimedia Appendix 1 2020 checklist) [26]. We aimed to identify, evaluate, and synthesize findings from RCTs comparing digital and face-to-face delivery modalities for ST interventions across settings, target populations, and outcomes. This systematic review was preregistered (PROSPERO ID: CRD42022335013), with no deviation from the registered protocol.

Inclusion and Exclusion Criteria

We applied the following inclusion and exclusion criteria for articles to be considered for our systematic review within the following categories: (1) study design, (2) participants, (3) interventions, (4) digital delivery and face-to-face delivery modalities, (5) outcomes, and (6) article type.

RCTs of any type were included (eg, parallel, cluster, and quasi-RCTs). No minimum number of participants was prespecified.

Only those articles were deemed eligible for inclusion that involved individual participants of all ages and genders (1) with one or more diagnoses of a mental disorder, (2) identified as at risk in one or more mental or behavioral health domains, or (3) adversely affected by salient circumstances (eg, belonging to a structurally disadvantaged community and caring for a family member). Articles involving participants at the system level (eg, families) were also included as long as 1 member of the system fulfilled at least one of the aforementioned criteria. No further exclusion criteria were applied to increase the number of eligible studies.

We only included articles reporting on interventions delivered via at least 2 distinct delivery modalities: digital delivery and face-to-face delivery. Digital delivery was defined as exclusively relying on an external electronic medium (eg, videoconferencing hardware and software, telephone, and synchronous and asynchronous text-based conversations) for intervention delivery. While this allowed heterogeneity of digital delivery modalities across some dimensions (eg, synchronicity and extent of interaction with mental health practitioners), it kept other dimensions stable across all digital delivery modalities (use of electronic medium and no mental health practitioner physically copresent with recipients of intervention). Face-to-face delivery was defined as exclusively relying on in-person intervention delivery. This allowed for the use of external tools or media to supplement the intervention while specifying that intervention delivery had to occur solely between people physically present in the same physical space (eg, a clinician's office).

To increase the number of eligible studies, any relevant mental, behavioral, or somatic health efficacy; adherence and attrition; and further outcomes were included in this review. No a priori categorization of outcomes was applied. Efficacy outcomes were defined as any outcomes pertinent to improvement in relevant mental, behavioral, and somatic health domains. *Further outcomes* were defined as any outcomes not directly pertinent to improvement in relevant health domains (eg, subjective satisfaction rating of program delivery).

There were no restrictions imposed on the article type in terms of language or date. Articles published in peer-reviewed journals as full-text articles and other types of peer-reviewed full-text articles were included. Unpublished data (eg, dissertations), as well as study protocols, clinical trial registries, and non–peer-reviewed articles, were excluded.

Intervention Inclusion Criteria

Only articles reporting on ST interventions delivered via both digital and face-to-face delivery modalities were included. ST was operationalized based on 4 adapted definition criteria of ST [13], which were applied to the descriptions of the identified constituent primary parts (CPPs; eg, core sessions) of interventions. The definition criteria were derived from the following definition of ST (referred to as *systemic therapy*) with our adjustments in square brackets [13]:

> *We use systemic/systems-oriented therapy/therapies (ST) as a general term for a major therapeutic orientation that can be distinguished from other major approaches (e.g., CBT or psychodynamic therapy). We define systemic therapy as a form of psychotherapy that (1) perceives behavior and mental symptoms within the context of the social systems people live in; (2) focuses on interpersonal relations and interactions, social constructions of realities, and[/or] the recursive causality between symptoms and interactions; (3) includes family members and[/or] other important persons (e.g., teachers, friends, professional helpers) directly or indirectly through systemic questioning, hypothesizing, and specific interventions; and (4) appreciates and utilizes clients' perspectives on problems, resources, and[/or] preferred solutions.*

For each intervention, the appropriate unit of primary intervention delivery (as opposed to parts of the intervention labeled *supplementary*, *additional*, or *optional*, etc) was determined following the study's authors (eg, core sessions, core components, etc.). The total number of the intervention's CPPs was determined. If the intervention description did not afford to determine an appropriate unit of intervention delivery, the total number of CPPs was defined as 1.

For each description of content for any CPP, we assessed if it met any of our definition criteria of ST. Notably, any particular definition criterion could, in theory, be met by a set of CPP descriptions >1, allowing different content descriptions to meet the same criterion. This allowed a range of different interventions to be classified as being similar in kind (ie, being ST interventions), reflecting the integrative nature of clinical ST practice [27,28], rather than requiring all interventions to have identical CPPs.

All definition criteria of ST needed to be met by the respective CPPs, with at least 2 of the 4 definition criteria being met completely by all CPPs. If any of the definition criteria of ST were not completely met, at most 2 of the 4 definition criteria needed to be met by a minimum of at least 50% of all CPPs (or,

XSL•FO
RenderX

in the case of uneven numbers of CPPs, the closest possible number below the theoretical half point). The same CPP could satisfy >1 criterion. Definition criterion (1) could additionally be met by the relevant conceptual background provided.

Textbox 1 illustrates an example for 1 trial included in our study. Our approach used to screen trials against inclusion criteria for all trials is detailed in Multimedia Appendix 2 [13,29-32].

Textbox 1. Identified constituent primary parts (CPPs) of 1 trial against systemic therapy (ST) definition criteria for Behavioral Family Systems Therapy for Diabetes (BFST-D) intervention [33].

Number and unit of CPPs and 4 primary intervention components

1. Perceives behavior and mental symptoms within the context of the social systems people live in
   - Family functioning and maladaptive parent-child interactions were identified as central barriers to diabetes treatment adherence.
2. Focuses on interpersonal relations and interactions, social constructions of realities, or the recursive causality between symptoms and interactions: 3 of 4 CPPs
   - CPP1: family-problem solving (as a family, defining the problem, generating solutions, making decisions, implementing and monitoring results, and refining ineffective solutions)
   - CPP2: communication training (instruction, feedback, modeling, and rehearsal of approaches toward improving maladaptive communicative patterns)
   - CPP4: family restructuring (functional and structural approaches toward changing maladaptive or ineffective family system patterns and characteristics, such as weak parental coalitions or cross-generational coalitions).
3. Includes family members and other important persons (eg, teachers, friends, professional helpers) directly or indirectly through systemic questioning, hypothesizing, and specific interventions
   - All CPPs are delivered to the caregiver-adolescent dyad.
4. Appreciates and uses clients' perspectives on problems, resources, and preferred solutions: 2 of 4 CPPs are as follows:
   - CPP1 and CPP3: cognitive restructuring (addressing beliefs, attitudes, and attributions that could negatively affect effective interactions).

Search Strategy

Database Search

The following databases were searched from the earliest available date until March 15, 2022: PubMed, Embase (via Ovid), Cochrane CENTRAL (via Ovid), CINAHL (via EBSCO), PsycINFO (via EBSCO), and PSYNDEX (via EBSCO). The search strategy followed the guideline from Bramer et al [34], and the original search string was developed for use in PubMed and adapted manually for all other databases. The search strings contained a set of the following: (1) 1 compiled term for intervention type, (2) 1 compiled specificity term to define the target domain, and (3) 1 compiled delivery modality term. For the identification of RCT study design, we used the RobotSearch AI RCT highly sensitive filter [35], which provides high sensitivity in identifying RCTs [35-37]. Multimedia Appendix 3 [8,13,15,38-46] provides the full search strings, references of the published sources upon which we based our search terms, and explanations of the logical structure. On March 17, 2022, we conducted complementary searches in ClinicalTrials.gov, the International Clinical Trials Registry Platform, and the EU Clinical Trials Register (all via the respective standard website interface). On May 4, 2022, backward citation screening (articles cited) was conducted on identified relevant reviews and meta-analyses (Multimedia Appendix 4 [9,10,12,13,15,47-53]). On May 10, 2022, forward citation screening (articles citing included articles) was conducted via ISI Web of Science, backward citation screening on included articles was conducted via PubMed, and a "related articles" screening was conducted on included articles (first 20 articles listed as related articles) via PubMed.

Article Selection and Screening

Duplicates were removed using Automated Systematic Search Deduplicator [54]. The resulting list of search results was split into 2 sets (sorting by title in EndNote [version 20; Clarivate] and allocating alternating sets of approximately 100 consecutive references; number of articles=1816 and 1817) that were each assigned to 2 pairs of authors (PE and JB; MB and JB), with each author independently screening titles and abstracts using manualized standard operating procedures that we developed accommodating our inclusion and exclusion criteria. All discrepancies at the title and abstract screening stage were resolved through discussion between all 3 involved authors (PE, MB, and JB). PE and MB independently screened at the full-text stage. Discrepancies at this stage were resolved through discussion between PE and MB. GM was consulted as an independent author of this study in cases of persisting discrepancies after discussions at any stage. Because on several occasions a trial underlying an included article contributed data to >1 included article, article-trial correspondence was determined either via trial registration numbers (for 7 articles) or via references to articles on the same trial, unique trial names, as well as overlap in article authors, article dates, sample sizes and characteristics, interventions, and procedures (for 5 articles).

Data Extraction

Data were independently extracted by PE and MB using the Cochrane data collection form [55] for intervention reviews

XSL•FO
RenderX

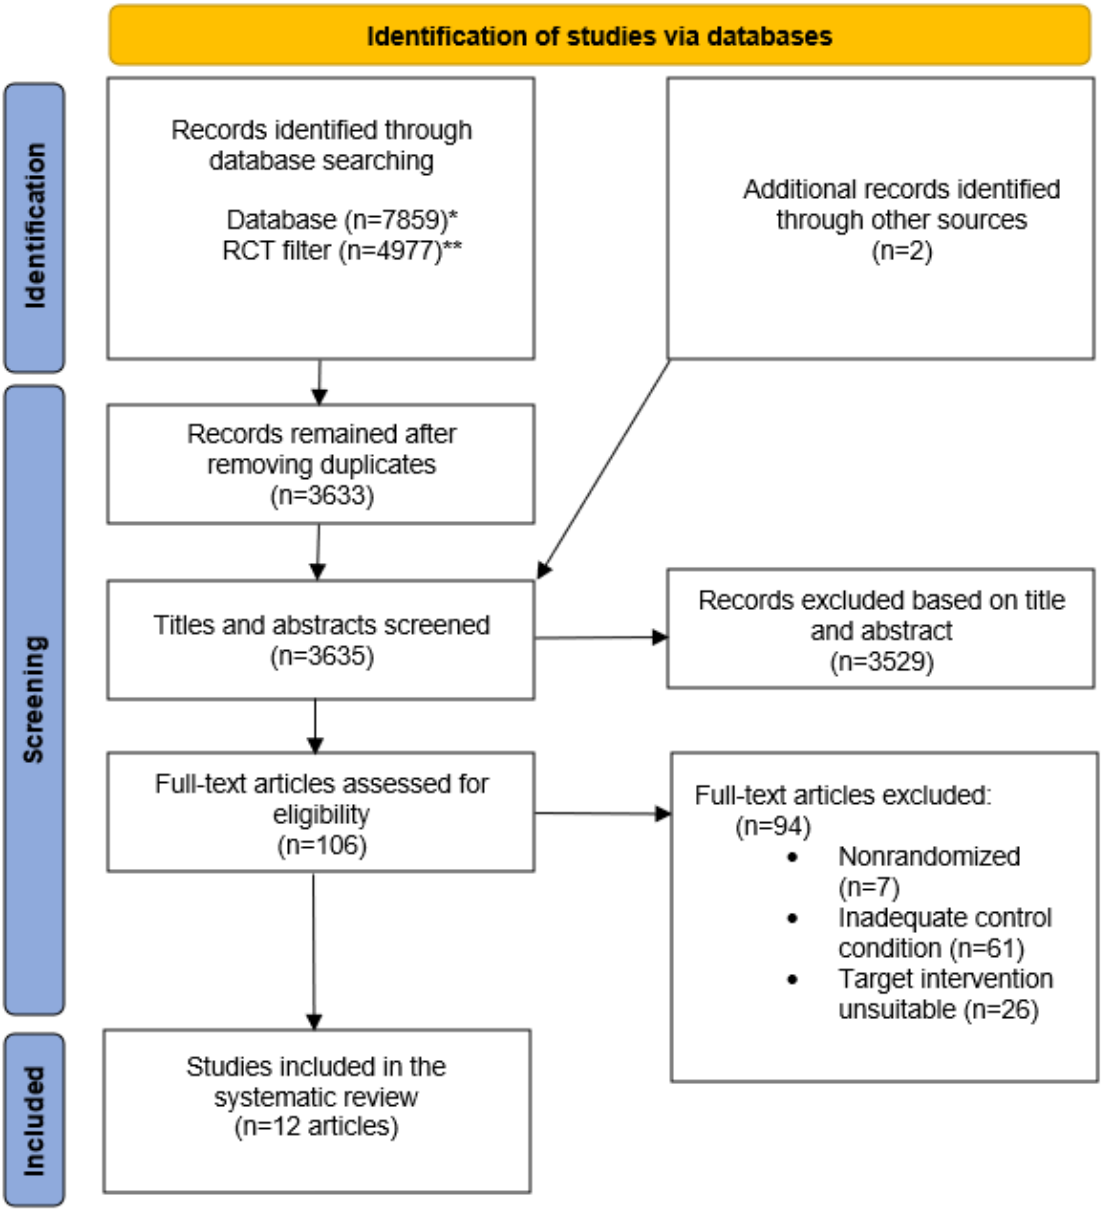
(Multimedia Appendix 5 [29,30,33,56-59]). Discrepancies were resolved through discussion.

Risk of Bias

The authors (PE and MB) independently assessed the risk of bias (RoB) using the revised Cochrane Risk of Bias (version 2) tool for randomized trials [60] and following the process outlined in chapter 8 of the Cochrane handbook [55]. Discrepancies were resolved through discussion. RoB figures were created using *robvis* [61].

Data Synthesis and Analysis

We used RevMan (version 5.4) [62] to create forest plots and calculate, depending on the variable type and type of analysis, mean differences (MDs), standardized MDs, risk ratios, and associated CIs at the 95% level. Where possible, we calculated missing SDs using the Cochrane collaboration RevMan calculator [62]. We conducted meta-analyses only in cases of acceptable levels of clinical and methodological diversity and where sufficient data were available [63]. We conducted meta-analyses using random effects models as we expected heterogeneity across articles to be high. Statistical heterogeneity was assessed using the I^2 statistic. MDs and CIs were calculated where meta-analytic analysis was not possible, but nonaggregated analysis was still deemed appropriate. This was to increase qualitative comparability across studies with nonnegligible heterogeneity in statistical approaches and reported results. All relevant reported results are listed in Multimedia Appendix 6 [29,30,33,56-59,64-68]. We grouped MDs of outcomes according to their CIs into (1) fully located within the range from –0.20 to 0.20 (*equivalence*), (2) fully located outside this range (*superiority*), or (3) partially located within and partially located outside this range (*neither equivalence nor superiority*). In the absence of an established a priori minimal important difference, we accept Cohen *d* cutoff of 0.2 (small effect) as the defined range from –0.20 to 0.20 to indicate equivalence [69]. We interpreted a CI of an MD falling within, but not exceeding, this range as evidence for equivalence, a CI of an MD falling entirely outside this range as evidence for nonequivalence or superiority of one delivery modality, and a CI falling within and exceeding this range as insufficient evidence to determine equivalence or nonequivalence on the respective measure. Where calculating MDs and CIs was impossible due to missing information, reported results on differences between digital and face-to-face delivery modalities were provided (Multimedia Appendix 6). Study authors were contacted to provide missing information. A funnel plot was not created because we identified <10 trials [70].



Results

Search Results

A flowchart of our search and screening process is depicted in Figure 1 [35]. The primary search for this study retrieved 4977 references and 3633 after removal of duplicates. Additional references (n=2) were identified through complimentary searches. The resulting 3635 references were screened at the title and abstract level. On the basis of our inclusion and exclusion criteria, 97.1% (3529/3635) articles were excluded during the title and abstract screening, and 2.9% (106/3635) articles were screened at the full-text screening stage. Overall, 0.3% (12/3633) of the initially identified articles reporting on 4 trials were included in this systematic review. Some (3/12, 25%) of the articles reporting on 2 trials [29,56,57] are only reported in Table 1 and Multimedia Appendix 6, as they could not be included in further meta-analytic aggregation or discrete analysis of MDs and CIs.

Characteristics of Included Articles

Number of Trials, Articles, and Sample Size

A total of 12 articles reporting on 4 trials were identified. One trial was reported on by a single article [64] (Supporting Carers of Children and Adolescents with Eating Disorders in Austria [SUCCEAT] trial), while the remaining 92% (11/12) of articles reported on a total of 3 trials. Of all 12 articles, 58% (n=7) of articles provided trial registration numbers, allowing for formally confirmed identification of the reported trial.

For the purposes of this study, the 4 trials are abbreviated according to their respective intervention names as follows: Behavioral Family Systems Therapy-Diabetes (BFST-D) trial [29,33,57,58], Family Problem-Solving Therapy (F-PST) trial [65-68], Pathways for African American Success (PAAS) trial [30,56,59], and the SUCCEAT trial [64].

As articles reporting on the BFST-D trial and articles reporting on the PAAS trial varied with regard to sample sizes (Table 1 and Multimedia Appendix 6), the total number of randomized participants across all trials could not be unambiguously determined. Given that for both trials, only 1 article each reported a different sample size as compared to all other articles reporting on the same trial, we reported the mode sample size for the total number of participants randomized to all conditions in all trials, including a control condition (N=754), and for the total number of participants randomized to face-to-face and digital delivery conditions (n=617). The same principle was applied for all reported participant characteristics, which varied in terms of proportions and absolute numbers depending on variation in reported sample sizes.

Participants

Some (4/12, 33%) articles reported on interventions delivered to youths with poorly controlled type 1 diabetes and their parents (BFST-D trial), 25% (n=3) articles reported on interventions delivered to parents, siblings, and youths identified as being at disproportionate risk for contracting HIV and sexually transmitted infections, teen parenthood, and substance use (PAAS trial). Moreover, 33% (4/12) articles reported on interventions delivered to youths with traumatic brain injury and their parents and other family members (F-PST trial), and 8% (1/12) articles reported on interventions delivered to parents of youths with anorexia nervosa (SUCCEAT trial). As there is inconsistent terminology between and within articles, the term *parent* is used here and throughout this paper to refer to parents, grandparents, legal guardians, and caregivers included in the respective articles. All identified interventions either involved families in intervention delivery (BFST-D, PAAS, and F-PST trials) or in terms of interpersonal target outcomes (SUCCEAT trial). Additional participant information is provided in Table 1 and Multimedia Appendix 7 [29,30,33,56-59,64-68]. Participant characteristics were reported to be similar across conditions in all articles, with the exception of the F-PST trial, which included a lower proportion of White participants in the face-to-face delivery condition, probably linked to quasi-randomization involving place of residence in the allocation procedure.

Face-to-Face and Digital Interventions and Delivery Format

Interventions were provided by health professionals in 75% (9/12) of articles (BFST-D, F-PST, and SUCCEAT trials) and by trained community leaders in 25% (3/12) articles (PAAS trial). Intervention content was similar across delivery modalities for all trials, with all articles explicitly mentioning the same intervention being delivered across conditions and all CPPs of interventions being delivered in both conditions (Table 1 and Multimedia Appendix 2).

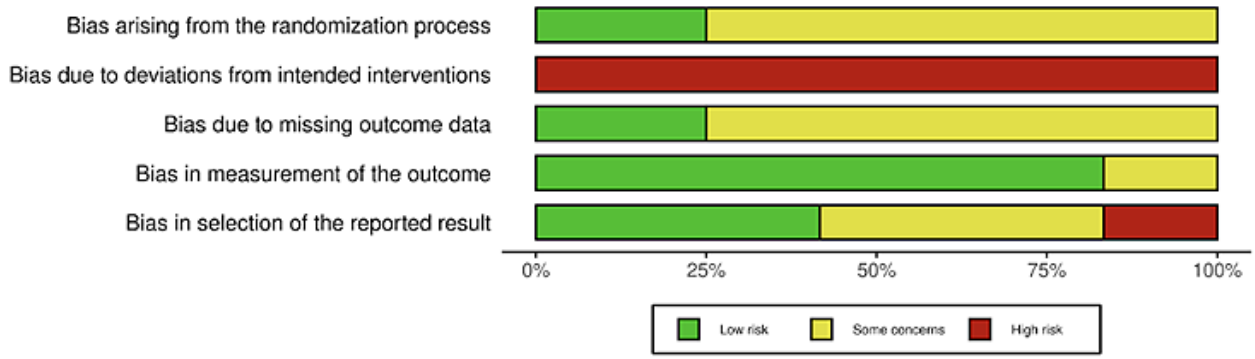
All therapist-guided digital delivery was provided via videoconferencing software. Self-guided intervention delivery was provided via access to web-based modules for 33% (4/12) of the articles (F-PST trial) and for 25% (3/12) of the articles (PAAS trial) via an interactive interface visually representing users through avatars in a virtual environment. Face-to-face delivery was reported as individual in-clinic sessions for 67% (8/12) of the articles (BFST-D and F-PST trials), as group sessions at community centers for 25% (3/12) of the articles (PAAS trial), and in-clinic workshops for multiple individuals for 8% (1/12) of the articles (SUCCEAT trial).

Outcomes

Across all 12 articles, 56 outcome measures (ie, dependent variables) were reported, including cases of parent-report and youth-report measures of the same construct. Primary outcomes (8/56, 14%), 71% (40/56) secondary outcomes, and 14% (8/56) further, dropout, or attrition outcomes were identified. We have provided an overview of all identified outcomes in Multimedia Appendix 8 [29,33,56-59,64-68].

We summarized and structured data along three domains: (1) outcome type (ie, youth, parent, family functioning, and dropout, attrition, or further), (2) delivery modality type (face-to-face, therapist-guided digital, and self-guided digital), and (3) measurement time point (postintervention test and follow up test) to reduce clinical and methodological diversity within outcome data categories. We provide a more detailed overview of delivery modality types (eg, videoconferencing or in-clinic sessions) in Table 1, an overview of outcome measures (ie, dependent variables) in Multimedia Appendix 8, and measurement time points in Multimedia Appendix 6.

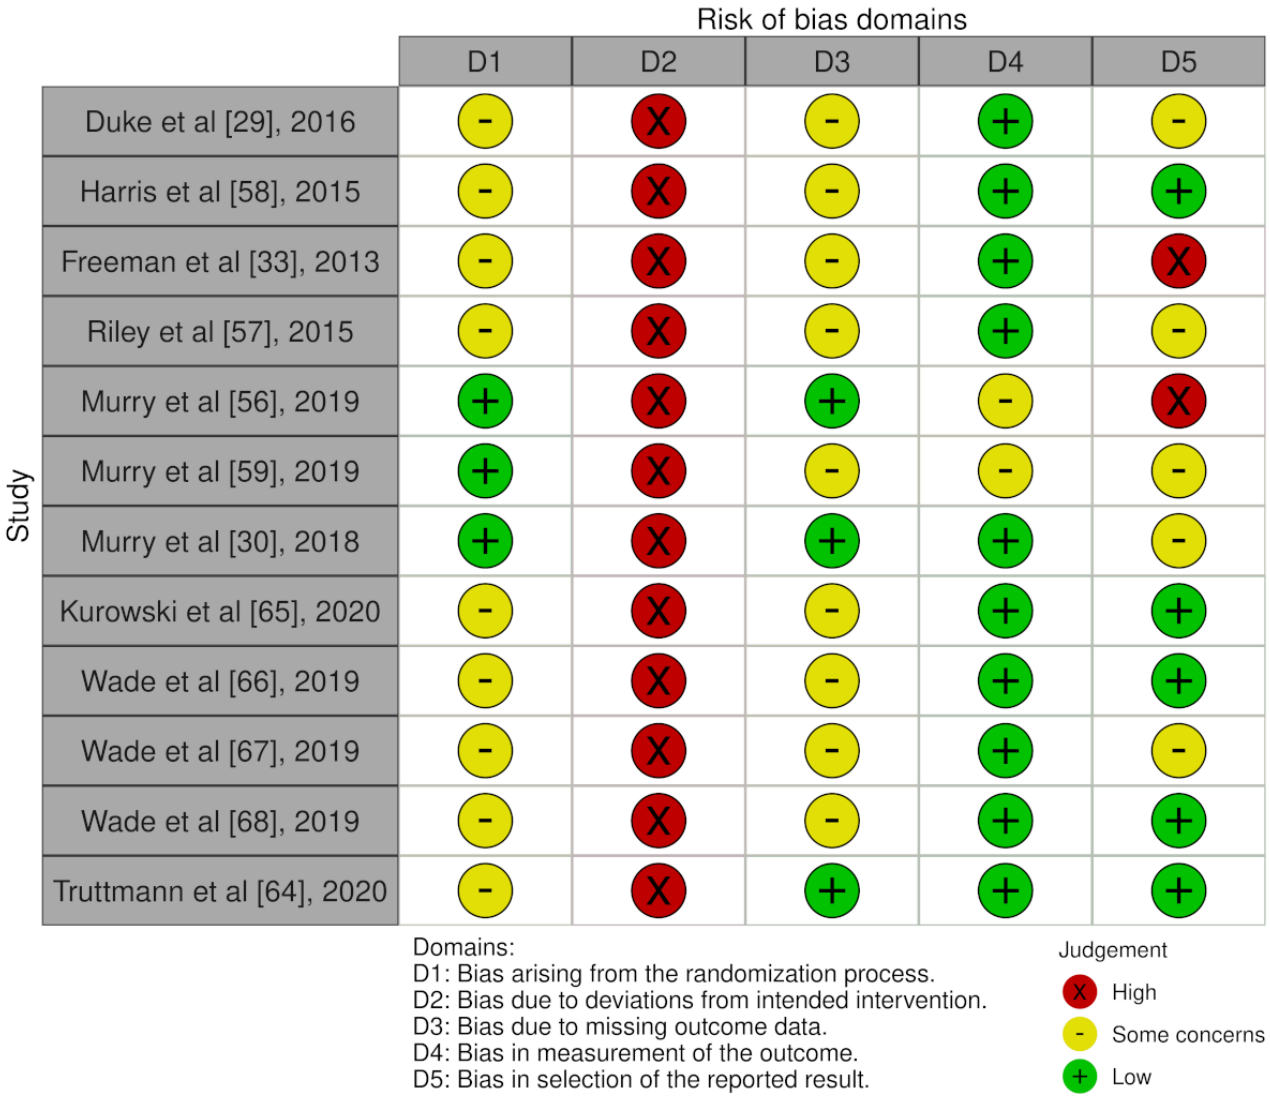
XSL•FO
RenderX



The application of these 3 domains to the categorization of data yielded 16 potential outcome categories: youth (Multimedia Appendix 9 [58,59,64-67]); parent (Multimedia Appendix 9); family functioning (Multimedia Appendix 10 [59]); and adherence, attrition, and further outcomes (Multimedia Appendix 11 [30,33,62,65,68]) for either therapist-guided digital versus face-to-face delivery (Multimedia Appendix 9) or self-guided digital versus face-to-face delivery modalities (Multimedia Appendices 9 and 10) at either posttest (Multimedia Appendices 9 and 10) or follow-up test (Multimedia Appendix 11) time points.

Risk of Bias

Overview



The 12 articles were rated as high risk for allocation concealment. For sequence generation, 75% (9/12) articles were rated as having some concerns. For randomization, 2 of the 4 trials used quasi-randomization. Some (9/12, 75%) articles were rated as having some concerns in terms of missing data. Overall proportions of RoB levels across articles are presented in Figure 2; individual RoB assessments at the article level are presented in Figure 3 [29,30,33,56-59,64-68]. Moreover, 92% (11/12) articles reported on 3 trials, with inconsistent reporting at times, which constituted a challenge for assessing the RoB, particularly for the domain of selective outcome reporting, as multiple articles reporting on the same trial were found to simultaneously overlap in some reported outcomes and diverge for other outcomes (eg, inconsistent reporting of the Diabetes Family Conflict Scale across articles reporting on the BFST-D trial).

Figure 2. Total proportions of articles' risk of bias assessments by assessment domain.

XSL•FO
RenderX

Figure 3. Risk of bias assessments of all included articles. D1: bias arising from the randomization process; D2: bias due to deviations from intended intervention; D3: bias due to missing outcome data; D4: bias in measurement of the outcome; D5: bias in selection of the reported result.

Sequence Generation

Of all 12 articles, 8% (n=1) reported a quasi-randomization temporal sequencing design (SUCCEAT trial); 33% (n=4) reported a quasi-randomized, multicenter RCT design (F-PST trial), in which participants were unequally allocated to the digital and face-to-face delivery conditions based on their place of residence (all participants who lived outside a 40-kilometer radius from the site were randomly allocated to the digital delivery conditions, and participants within the radius were randomly allocated to all conditions, favoring the face-to-face delivery condition by a ratio of 2:1); and 58% (n=7) reported randomized controlled trials (BFST-D and PAAS trials). Of those 7 articles, 57% (n=4) reported block randomization without providing information on allocation sequence concealment, increasing the RoB from sequence generation (BFST-D trial). Overall, 25% (3/12) of the included articles were rated low RoB arising from the randomization, while 75% (9/12) were rated as giving rise to some concerns.

Allocation Concealment

The question of adequate allocation blinding procedures (for participants and intervention providers) is a common concern in psychotherapy outcome research [71]. This also applies to the articles included in this review. Given the absence of a universally agreed-upon alternative approach [71], all articles were rated as high RoB in this domain.

Handling of Incomplete Data

For any of the 12 articles, not all outcome data were available. Some (2/12, 17%) of the articles provided evidence of data missing at random [56] or treated attrition as an outcome variable [30] and were rated as having low RoB. Most (9/12, 75%) articles did not adequately analyze if missing outcome data did not potentially bias the results and were rated as giving rise to some concerns.

XSL•FO
RenderX

Outcome Assessment

RoB arising from the measurement of the outcome variables was rated *low risk* for 83% (10/12) of the articles and with *some concerns* for 17% (2/12) of the articles that used a large proportion of outcome measures for which judgments regarding validity and reliability could not be made [56,59] (Multimedia Appendix 8).

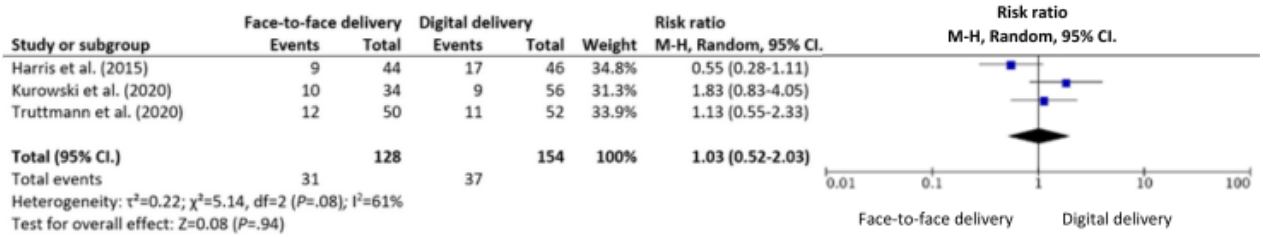
Selective Reporting

As indicated earlier, RoB from selective reporting was challenging to assess given the interaction of multiple articles reporting on the same trial and inconsistencies across articles on the same trials. This was further exacerbated in the case of a trial for which no preregistration could be identified (PAAS trial) and of an article exclusively reporting on unregistered outcomes of a preregistered trial [33]. Some (5/12, 42%) articles were rated as giving rise to some concerns, 9% (5/12) were rated as having low RoB, and 17% (2/12) of the articles were rated as having high RoB.

Appropriateness of a Meta-Analysis to Determine the Efficacy of Delivery Modalities, Adherence, and Attrition

Meta-analytic aggregation was deemed inappropriate for all delivery modality comparisons of youth, parent, and family functioning outcomes due to the relatively low number of trials within the respective outcome categories, combined with the presence of substantial clinical and methodological diversity across trials [63]. Meta-analytic aggregation of the number of sessions attended and attrition was conducted because heterogeneity was lower and the number of eligible trials was higher for these outcomes as compared to the other outcome measures reported and included (Figure 4 [58,64,65] and Figure 5 [58,64,65]). The substantial clinical and methodological diversity across trials remains problematic for drawing meaningful conclusions using meta-analytic aggregations. However, a preliminary quantitative synthesis was included as it still serves as a starting point for discussion and future research.

Figure 4. Meta-analysis of number of sessions attended in face-to-face versus digital delivery modality comparison.



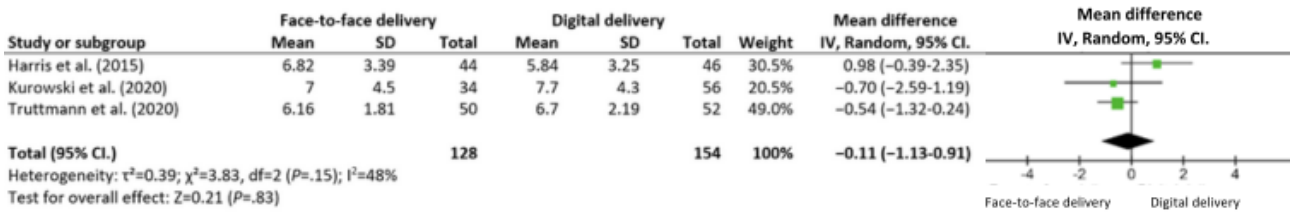


Figure 5. Meta-analysis of drop-out (event) risk ratio in face-to-face versus digital delivery modality comparison.

Nonaggregated Analyses for Face-to-Face and Digital Delivery Modalities

Of all 56 reported outcomes (ie, dependent variables) across all trials and articles, 25% (n=14) outcomes from 2 trials (13/14, 93% in the F-PST trial and 1/14, 7% in the SUCCEAT trial) showed MDs with corresponding CIs falling either (1) fully within our predefined range of minimal important difference of –0.20 to 0.20 or (2) fully outside of this range. These outcomes are reported in Table 2 and Multimedia Appendix 12. All remaining 75% (42/56) outcomes showed MDs with corresponding CIs partially located within and partially located outside this range. Among these, 4% (2/56) further outcomes, 2% (1/56) family functioning outcome, and 2% (1/56) youth outcome were reported as substantially different between delivery modalities in the original articles while still including our range for the minimal important difference. Multimedia Appendix 9 shows a full list of all MDs and CIs of outcomes.

[i]BSI: Brief Symptom Inventory.

[j]SUCCEAT: Supporting Carers of Children and Adolescents with Eating Disorders in Austria.

[k]SCL: Symptom Checklist 90-Revised Global Severity Index.

[l]P-PE: Parent Rated Program Evaluation.

Of the 14 outcomes falling fully within or fully outside the minimal important difference range, superiority of the digital delivery condition was found for 71% (n=10) outcomes. Of these 10 outcomes, 60% (n=6) were youth outcomes and 40% (n=4) were parent outcomes. The quality of life of youths, reported by parents (Pediatric Quality of Life Inventory, parent report) at post intervention test, was substantially higher for both therapist-guided and self-guided digital delivery modalities compared to face-to-face delivery modalities and remained substantially higher for the self-guided digital delivery condition at follow-up. Somatic symptoms of youths, reported by them (Health and Behaviour Inventory somatic, youth report) at follow-up, were substantially higher in the face-to-face delivery condition compared to both therapist-guided and self-guided digital delivery conditions. In addition, cognitive symptoms of youths, reported by parents (Health and Behaviour Inventory cognitive, parent report) at follow-up, were substantially higher in the face-to-face delivery condition compared to the self-guided digital delivery condition. Depressive symptoms of parents (Center for Epidemiological Studies Depression Scale) at post intervention test were substantially higher in the face-to-face delivery condition compared to both therapist-guided and self-guided digital delivery conditions. Similarly, mental symptoms of parents (Brief Symptom Inventor) at post intervention measurement were substantially higher in the face-to-face delivery condition compared to both therapist-guided and self-guided digital delivery conditions.

Superiority of the face-to-face delivery condition was found for 3 outcomes. All of these outcomes were parent outcomes from the F-PST trial at follow-up. In contrast to comparisons at post intervention measurement, depressive symptoms of parents (Center for Epidemiological Studies Depression Scale) at follow-up were substantially higher in the self-guided digital delivery condition compared to the face-to-face delivery condition. Similarly, contrasting with comparisons at post intervention measurement, mental symptoms of parents (Brief Symptom Inventory) at follow-up were substantially higher in the therapist-guided digital delivery condition compared to the face-to-face delivery condition. Program evaluation by parents was more favorable in the face-to-face delivery condition compared to the therapist-guided digital delivery condition.

Only 2% (1/56) of outcomes fell fully within the minimal important difference range. In the SUCCEAT trial, psychopathological symptoms of parents (Symptom Checklist 90-Revised Global Severity Index) at post intervention test were equal between therapist-guided digital and face-to-face delivery conditions.

Meta-Analytic Aggregation of Adherence and Attrition

A total of 9 articles reporting on all 4 trials (BFST-D trial [29,57,58], PAAS trial [59], F-PST trial, and SUCCEAT trial) reported on the number of sessions attended, and all (11/12, 92%) articles, except for 1 (PAAS trial [57]), reporting on all trials reported on attrition. The number of sessions attended and attrition were meta-analyzed, and the meta-analytic aggregations are reported in Figures 4 and 5. The heterogeneity between trials was moderate (I^2=48% for number of sessions attended) to high (I^2=61% for attrition), and given the low number of included trials, this heterogeneity estimate might be inaccurate [72], and conclusions from the meta-analyses should thus be interpreted with caution.

Discussion

Principal Findings

We identified 12 articles reporting on 4 trials from which data were extracted (Multimedia Appendix 5). Of note, despite broad inclusion criteria for participants, participants included only youths or parents of youths. Recipients of interventions were youths with poor diabetic control, traumatic brain injuries, increased risk behavior likelihood, and parents of youths with anorexia nervosa. A total of 56 relevant outcomes were identified. Two trials provided digital intervention delivery via videoconferencing, one via an interactive graphic interface, and the other via a web-based program. RoB judgments varied substantially across domains and articles, with largely *some concerns* judgments for randomization, missing outcome data, and selective reporting. Applying a minimal important difference criterion to indicate equivalence or superiority, nonaggregated analyses of MDs and CIs between delivery modalities yielded varying types of comparative outcomes across the included studies: superiority of the digital delivery modality and superiority of the face-to-face delivery modality (CIs falling fully outside the range of the minimal important difference) and equivalence between delivery modalities (CIs falling fully inside the range of the minimal important difference), with most comparative outcomes, indicating neither superiority of one modality nor equivalence between delivery modalities (CIs falling within and outside the range of the minimal important difference). Overall, our analyses did not reveal any strong evidence for the superiority of face-to-face compared to digital delivery conditions and might tentatively instead indicate a higher proportion of favorable effects of digital delivery modalities for certain outcomes and certain contexts. Due to the qualitative nature of this analysis, the limited number of studies included in this review, and the large heterogeneity between studies, results need to be interpreted with caution. In addition, more research is needed to draw meaningful conclusions on the comparative efficacy of digital versus face-to-face delivery modalities of ST interventions.

We found a limited and insufficient amount of evidence to meta-analytically estimate the comparative efficacy of digital

XSL•FO
RenderX

versus face-to-face delivery modalities of ST interventions with regard to most psychological, somatic, and behavioral parent and youth outcomes, as well as family functioning and further outcomes at either postintervention test or follow-up test. Meta-analytic analysis was deemed appropriate only for attrition and the number of sessions attended. We compared digital versus face-to-face delivery modalities for attrition and the number of sessions attended, showing no evidence for the superiority of either delivery modality in these domains.

Comparison With Prior Work

Our findings are largely consistent with related findings from a recent meta-analysis on family therapy, including 3 trials reporting no evidence for a difference at postintervention test between therapist-guided digital versus face-to-face delivery of interventions for youth outcomes and parent outcomes [6]. Similarly, our findings are consistent with findings from a recent meta-analysis on therapist-guided digital parenting interventions that included 4 trials reporting no evidence for a difference at posttest for youth outcomes between therapist-guided digital and face-to-face delivery conditions [7]. None of this prior work, including ours, either strongly supports the superiority of face-to-face over digital delivery conditions or vice versa.

This study adds to research as the first to contribute to the existing body of research from an ST standpoint comparing RCTs of digital and face-to-face delivery modalities of the same intervention. While showing considerable overlap with family therapy, couple therapy, and parenting interventions, ST interventions are characterized by a largely independent theoretical framework and set of therapeutic techniques. Recent reviews in related areas of research [6,7,10,47,73] include interventions with different conceptual backgrounds (eg, family-based cognitive behavioral therapy and the integrated family intervention for child conduct problems [6]) under umbrella terms, such as family therapy or parenting interventions. The theory-driven approach we adopted for this systematic review helps to increase granularity by only including interventions based on ST content and conceptual background.

Strengths and Limitations

Our systematic review has several strengths. First, we applied rigorous methodology, which was preregistered and followed PRISMA guidelines [26]. Second, we applied a search strategy designed for high sensitivity to 6 databases, with an extensive range of complimentary searches coupled with consistent application of inclusion criteria on study design, intervention type, and delivery modalities, which enabled the descriptive synthesis of published evidence based on diverse target populations, different contexts, and different digital delivery modalities. Third, including ST interventions by identifying CPPs and testing them against our definition criteria ensured high levels of reproducibility and validity.

However, there are also limitations to be considered when interpreting the findings of this study. First, the definition of ST applied here is an adapted version of one of several, at times inconsistent, definitions of ST currently used [74,75]. However, our definition is based on the widely accepted definition by von Sydow et al [19], which has also been used as the basis for large-scale public policy and insurance regulations. Second, the operationalized definition criteria were only applied to identified CPPs of the interventions and for criterion 1 (namely, “perceives behavior and mental symptoms within the context of the social systems people live in”), conceptual background to make inclusion or exclusion judgments during screening. This approach may have excluded additional potentially relevant information about the interventions not provided as part of the description of the intervention itself (eg, the information provided in cited articles). However, we judged this approach to be the most beneficial to this study’s replicability by reducing the arbitrary selection of intervention features as much as possible. Third, given that this study was, to our knowledge, the first to investigate digital versus face-to-face delivery modalities for ST interventions, no a priori categorical constraints were defined with regard to participants, outcomes, or contexts. Instead, constraints were defined post hoc, with the goal of maximizing diversity between and minimizing diversity within subgroups. Of note, despite a few constraints regarding the type of participant population, the sample from which participants were recruited was found to be comparatively narrowly defined (youths or parents of youths). Fourth, while our definition of the minimal important difference is in line with current guidelines [19] and current research in related fields [69], also based on Cohen *d* cutoff of 0.2 for a small effect, there are other approaches, such as anchor-based estimates [76], which might yield different ranges for the minimal important differences for the scales included in this study. However, given the fact that the required data for other approaches toward defining the minimally important differences, such as anchors or expert ratings, are currently not available for all identified outcome measures, our approach based on a Cohen *d* cut-off is acceptable and feasible.

Generalizability

Some factors limit the generalizability of our findings. First, while the identification of a low number of trials constitutes a finding in its own right, it limits the appropriateness of meta-analytic aggregation. This was exacerbated by the fact that multiple articles with potentially relevant findings reporting on the same trial were identified and that some articles, in some cases, showed inconsistencies in reporting data (eg, on sample size). Second, despite post hoc introduction of categories, diversity within these categories remained substantial (eg, in terms of participants’ race, differences in face-to-face delivery formats, or different outcome domains), further limiting the appropriateness of meta-analytic aggregation. The differential impact of the type of digital modality used in each trial further limits the results of our study, and due to the low number of trials, it was not possible to analyze these tools separately. Third, the high diversity between trials (eg, in terms of delivery modalities, patient features, outcomes, and contexts) combined with the low overall number of trials limits the generalizability of this study’s findings to other populations and delivery contexts. Fourth, the low number of identified trials did not allow for subgroup analyses based on RoB judgments. Fifth, 3 of the 4 trials were conducted in the United States, and 3 of the 4 trials recruited a substantial majority of White participants, further limiting generalizability to other contexts and target

XSL•FO
RenderX

populations. Sixth, the influence of factors such as paraverbal communication, subject of discussion, and client-practitioner dynamics is crucial for understanding psychotherapeutic processes. Although RCTs are seen as the gold standard in evidence-based medicine, they may not adequately represent these factors, and the same applies to our study by extension.

Clinical and Research Implications

This review has some important clinical and research implications. Before digital interventions can be accepted unanimously and unambiguously, solid evidence is needed to be built on specific criteria for evaluating the appropriateness of digital modes of delivering ST interventions. Digital delivery is rapidly increasing despite insufficient evidence on the comparative efficacy of digital and face-to-face delivery modalities of ST. This might explain some of the reported clinicians' resistance to implementing digital interventions in their practices [77] and should caution against replacing face-to-face with digital delivery modalities without careful consideration. At the same time, given the evidence base supporting the efficacy of digitally delivered systemic psychotherapy (though currently still not as broad as that for face-to-face delivery), the largely inconclusive evidence regarding the comparative efficacy of delivery modalities paired with some indicators for the superiority of digital delivery modalities of ST for certain populations and contexts could also be interpreted as a caution against adopting face-to-face delivery of ST interventions as the clinical default. Our study might serve as a first tentative indicator that different populations benefit differently from different delivery modalities. One could, for instance, look at differences between significant outcomes from the included trials in our study and speculate if parents might be more likely to benefit from face-to-face delivery than youths who, in turn, might be more likely to benefit from digital delivery modalities. Potential avenues for future research in this regard could, for instance, investigate the impact of the parents' role as facilitators of self-guided group interventions. At this point, these points of departure for future research remain speculative, given the current lack of clear evidence regarding the comparative efficacy of digital and face-to-face delivery modalities of ST. To that end, more studies with equivalence design are required.

According to Greene et al [78], equivalence studies should include 4 key aspects in their design: an active comparator condition, identifying appropriate equivalence margins, calculating adequate sample size estimations, and doing appropriate statistical analysis [78]. Our review highlights the need for research implementing all these key aspects. Furthermore, future research should explore subgroups or conduct sensitivity analyses to understand the limitations and the differential advantages of digital and face-to-face delivery modalities. The questions, such as how different types of digital interventions compare to face-to-face interventions and which intervention is efficacious for target populations, specific contexts, and various modes of digital interventions, including therapist-guided, self-guided, videoconferencing, virtual augmented reality, and smartphone apps, remain unanswered. Moreover, research on digital apps and interventions that, even if not directly involved in therapy, may provide several benefits in supporting those delivering and receiving mental health interventions is required. There is a need to investigate digital modes of delivery that could potentially complement face-to-face interventions through blended forms of care (refer to the study by Erbe et al [79]), specifically in the context of ST. Overall, more high-quality controlled trials using similar outcome measures as well as systematic reviews and meta-analyses are required to scrutinize under what circumstances digital ST interventions work best, especially given the increasing amount of available modes of delivery and the increase in digital delivery of mental health care in general.

Conclusions

Taken together, our systematic review indicated that the current evidence regarding the comparative efficacy of digital and face-to-face delivery modalities of ST interventions does not allow conclusions to be drawn regarding equivalence or superiority for youth, parent, family functioning, adherence, attrition, or further outcomes. There is a dearth of RCTs comparing the efficacy of comparable ST interventions delivered via both digital and face-to-face delivery modalities. The low number of trials combined with high clinical and methodological diversity between trials did not permit drawing meaningful conclusions from meta-analytic aggregation, and neither equivalence nor superiority of one modality can be excluded at this point. Nonaggregated analyses of MDs and CIs between delivery modalities indicated that neither equivalence nor superiority of either modality can be excluded at this stage for most outcomes, target populations, and contexts. As digital delivery of ST interventions is becoming increasingly ubiquitous, more research is urgently required to investigate how digital delivery of ST interventions compares to face-to-face delivery of the same interventions. There is a need for more research with a particular focus on different types of digital delivery modalities, including blended forms of mental health care, investigating potential variation in efficacy across different settings, populations, outcomes, and contexts.

Acknowledgments

GM received funding from the Stanley Thomas Johnson Stiftung and Gottfried und Julia Bangerter-Rhyner-Stiftung (PC 28/17 and PC 05/18), from Gesundheitsförderung Schweiz (18.191/K50001), from the Swiss Heart Foundation (FF21101), from the Research Foundation of the International Psychoanalytic University Berlin (5087), from the Swiss National Science Foundation (100014_135328), from the Hasler Foundation (23004), in the context of a Horizon Europe project from the Swiss State Secretariat for Education, Research and Innovation contract 22.00094, and from Wings Health in the context of a proof-of-concept study. GM and LK received funding from the German Federal Ministry of Education and Research (budget item 68606). GM and MB

received funding from the Research Foundation of the International Psychoanalytic University Berlin (5217). The article was funded and supported by the Open Access Fund of Universität Trier and by the German Research Foundation (DFG).

Data Availability

The datasets generated and analyzed during this study are available from the corresponding author on reasonable request. A list of articles excluded with respective justifications for exclusions at the full-text screening stage can be made available upon request.

Authors' Contributions

PE and MB conceptualized the study, conducted data analysis and interpretation, and wrote the manuscript draft. PE, MB, and JB contributed to data collection. PE, MB, GM, LK, and JB revised the manuscript. PE, MB, GM, LK, and JB contributed to the final approval of the manuscript for publication.

Conflicts of Interest

GM is the cofounder and holds stock in Therayou AG, which is active in the field of digital and blended mental health care. GM receives royalties from publishing companies as an author, including a book published by Springer, and an honorarium from Lundbeck for speaking at a symposium. Furthermore, GM is compensated for providing psychotherapy to patients, acting as a supervisor, serving as a self-experience facilitator (“Selbsterfahrungsleiter”), and for postgraduate training of psychotherapists, psychosomatic specialists, and supervisors. Other authors do not declare any conflicts.

Abstract

Background: The rapid implementation of telemedicine during the early stages of the COVID-19 pandemic raises questions about the sustainability of this intervention at the global level.

Objective: This research examines the patient experience, health inequalities, and clinician-patient relationship in telemedicine during the COVID-19 pandemic's first 2 years, aiming to identify sustainability factors.

Methods: This study was based on a prepublished protocol using the Joanna Briggs Institute (JBI) methodology for scoping reviews. We included academic and gray literature published between March 2020 and March 2022 according to these criteria: (1) population (any group); (2) concepts (patient experience, clinician-patient relationship, health inequalities); (3) context (telemedicine in primary and outpatient care); (4) excluding studies pertaining to surgery, oncology, and (inpatient) psychiatry. We searched Ovid Medline/PubMed (January 1, 2022), Web of Science (March 19, 2022), Google/Google Scholar (February and March 2022), and others. The risk of bias was not assessed as per guidance. We used an analysis table for the studies and color-coded tabular mapping against a health care technology adoption framework to identify sustainability (using double-blind extraction).

Results: Of the 134 studies that met our criteria, 49.3% (66/134) reported no specific population group. Regarding the concepts, 41.8% (56/134) combined 2 of the concepts studied. The context analysis identified that 56.0% (75/134) of the studies referred to, according to the definition in the United Kingdom, an outpatient (ambulatory care) setting, and 34.3% (46/134) referred to primary care. The patient experience analysis reflected positive satisfaction and sustained access during lockdowns. The clinician-patient relationship impacts were nuanced, affecting interaction and encounter quality. When mapping to the nonadoption, abandonment, scale-up, spread, and sustainability (NASSS) framework, 81.3% (109/134) of the studies referenced the innovation's

XSL•FO
RenderX

sustainability. Although positive overall, there were some concerns about sustainability based on quality, eHealth literacy, and access to health care for vulnerable migrants and the uninsured.

Conclusions: We identified confusion between the concepts of patient experience and patient satisfaction; therefore, future research could focus on established frameworks to qualify the patient experience across the whole pathway and not just the remote encounter. As expected, our research found mainly descriptive analyses, so there is a need for more robust evidence methods identifying impacts of changes in treatment pathways. This study illustrates modern methods to decolonize academic research by using gray literature extracts in other languages. We acknowledge that the use of Google to identify gray literature at the global level and in other languages has implications on reproducibility. We did not consider synchronous text-based communication.

KEYWORDS

pandemic; primary care; outpatients; telemedicine; ambulatory care; global health; patient experience; NASSS; clinician-patient relationship; health inequalities; gray literature; PRISMA

Introduction

Following the World Health Organization (WHO) announcement declaring COVID-19 a pandemic on March 11, 2020, the organization recommended telemedicine as one of the first critical interventions to minimize demands on stretched supplies of personal protective equipment [1,2]. Although telehealth was not new as a delivery mode, there were great expectations particularly around the use of video consultations in this context. In Africa, telemedicine held promise, as it rationalized human resources allowing national or international experts to relay advice to other clinicians [3]; in the United Kingdom, the pandemic was deemed a "burning platform" to propel the UK National Health Service (NHS) toward widespread adoption of video consultations [4]. Most medical specialties responded to the WHO recommendation with rapid changes in service delivery toward telemedicine (both telephone and a new medium—video consultations) in primary and secondary care across the globe.

In the United Kingdom, 15 months into the pandemic, the academic community and political groups raised questions around the sustainability and impacts of the move toward telemedicine, building upon the learning of the past year toward a "new normal," particularly as social distancing and lockdown measures were removed [5]. A 2021 report by the UK Health and Social Care Committee defined telemedicine as a "welcomed and positive innovation" overall while highlighting concerns by various national organizations on its impact on health inequalities in terms of exclusion (lack of access), quality, and patient safety. The committee reported important consensus from recognized local institutions such as the Health Foundation and the Kings Fund and patient organizations such as National Voices and Healthwatch on the need for additional research to assess the future of telemedicine in a patient-centered way [6].

In previous protocols [7,8], we relayed how prepandemic evidence synthesis identified several barriers and objections that hindered telemedicine uptake, including technology, workload, and confidentiality [9], as well as concerns regarding appropriateness [10]. However, at the outset of the pandemic, these objections were rapidly overcome, supported by major regulatory and financial enablers [11,12]. Given the considerable incentives and support toward the implementation of telemedicine, there are concerns about the risks of losing some of the advantages of this mode of delivery in a postpandemic future [13], particularly once incentives are no longer in place [14,15]. These concerns apply to not only the United Kingdom, Canada, or the United States but also sub-Saharan Africa [16] and Latin America [17] where considerable barriers persist and there has been more limited evidence of uptake.

The purpose of this scoping review was to explore the global evidence (both academic and nonacademic) surrounding the rapid adoption of telemedicine in outpatient and primary care settings during the first 2 years of the COVID-19 pandemic to identify how elements related to patient experience, clinician-patient relationship, and health inequalities support (or take away from) the sustainability of this delivery model.

Methods

Protocol

This review was conducted according to an a priori published protocol [8] following the Joanna Briggs Institute (JBI) methodology for scoping reviews, updated guidance, and data extraction guidance [18-20]. This last guidance clarifies that a review can focus on the most relevant section of a document for analysis, without having to review whole studies in scoping reviews [20]. We outlined deviations from the original protocol and the methodology in Multimedia Appendix 1. A key contribution of this study hinges on the methods used to search and extract gray literature across a wider set of countries as to achieve truly global representation.

Inclusion Criteria

Population, Concept, Context Principle

The inclusion criteria used the Population, Concept, Context (PCC) principle. We classified each article against the PCC framework. Namely, for each document, we sought to identify (1) the population group (if any) to which the document referred, (2) the concept to which it referred (patient experience, clinician-patient relationship, health inequalities, or a combination of these), and (3) in which (clinical) context telemedicine was being used (outpatient, primary care, or particular specialties).

XSL•FO
RenderX

Population

The review focused on primary care services offered to the general population. Studies focusing on specific population groups or those with particular conditions within a particular country or geographical area were included.

Concept

Although the key concept under consideration was the adoption of "telemedicine," as defined in the Introduction, we narrowed our inclusion criteria to the sustainability of the interventions, focusing on patient experience, health inequalities, and clinician-patient relationship. Telemedicine has been defined as per our protocol [8] using academic literature [21] and the WHO [22], which defines it as "The delivery of health care services, where distance is a critical factor, by all health care professionals using information and communication technologies [...]." Although we focused on telephone and video as communication technologies, we thank an anonymous peer reviewer who identified that text messaging also falls in this category (albeit not included in our review).

Context

The context was primary care services provided during the COVID-19 pandemic in any setting or country during the first 2 years of the pandemic (March 2020-March 2022).

Types of Sources

This scoping review considered quantitative, qualitative, and mixed methods study designs for inclusion. In addition, systematic reviews, protocols, other documents, and commentaries or opinions were considered for inclusion in the proposed scoping review. These commentaries or other documents might have appeared in peer-reviewed journals or other gray literature such as industry magazines or reports [23,24].

Search Strategy

This section summarizes our prepublished protocol [8]. We structured this section by first explaining the selection and identification of search terms (both in English and other languages), then how we used those terms to search for academic and gray literature. To note, the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) [25] was used to structure our review protocol [8].

Identifying Search Terms

Our search terms, which were in English, centered around telemedicine, primary care, and COVID-19 and were expanded through a limited search on Ovid Medline and Web of Science. We also sought guidance from University of Warwick librarians, who identified COVID-19 search terms from the National Institute for Health and Care Excellence (NICE) [26]. Additionally, we examined previous telemedicine protocols in general practice [27] and Primary Care Cochrane Library Protocols. For search terms in other languages, we used a 2-step process to identify relevant terms for the included non-English search results. We used Google Translate and engaged in discussions with native speakers to ensure these were accurate translations.

Search Approaches

We had 2 distinct approaches depending on whether we were searching for academic or gray literature. With the aforementioned terms, we searched the following academic databases: Ovid Medline (equivalent to PubMed [28]), Web of Science, and Google Scholar. PROSPERO and Cochrane Library were used to inform our design. PROSPERO in particular was used to check whether there was any ongoing review on the topic. All identified search terms and examples of the searches (for academic and gray literature) can be found in Multimedia Appendix 2, as per our previously published protocol [8].

We searched Ovid Medline/PubMed (January 13, 2022), Web of Science (March 19, 2022), Livivo (March 15, 2022), Scopus (March 19, 2022), PROSPERO (January 12, 2022), Cochrane Library (January 12, 2022), and Google/Google Scholar (February 2022 and March 2022).

As shown in Multimedia Appendix 2, to identify relevant gray literature published at the time of the pandemic, we used advanced Google search criteria with simplified search terms. We combined the terms telemedicine, "Primary Care," and COVID-19 with (1) "patient experience," (2) "health inequalities," or (3) "patient-clinician interaction" and asked the search engine to provide pdf-only results within the years 2020 through 2022. Although we recognize it is not fully possible to reproduce Google searches, the selection of pdf documents was aimed at identifying the most retrievable and credible gray literature [8] while, at the same time, supporting reproducibility of the analysis [23,24].

We undertook these searches in English, Chinese, Spanish, Arabic, Portuguese, Hindi, and Indonesian. To improve representation of African countries due to difficulties searching in Urdu, we undertook additional Google searches in English including country-specific results for the 5 largest African countries by population (Nigeria, Ethiopia, Democratic Republic of Congo, Egypt, and South Africa [29]). For Google searches, we selected the first 30 results by relevance, and for English-based results, we selected the top 10 results by country. We selected the first 30 results based on the literature [30-33], timeline, and budget. Further, as can be seen in the example for a failed search for Pakistan in Multimedia Appendix 2, Google searches only provided less than a handful of results when restricting by country of publication.

We followed established guidelines for analyzing non-English text [34]. We used machine translation via Google Translate to translate at least 3 paragraphs containing the key search terms (telemedicine, primary care, and any of the combinations of patient experience, clinician-patient relationship, and health inequalities). We selected 3 paragraphs that were roughly equivalent in the number of words to that of an abstract.

Screening

The authors used a single-phase, double-blind screening of abstracts and extracts based on the eligibility criteria. Screening instructions were tested by 4 authors across a sample of 50

XSL•FO
RenderX

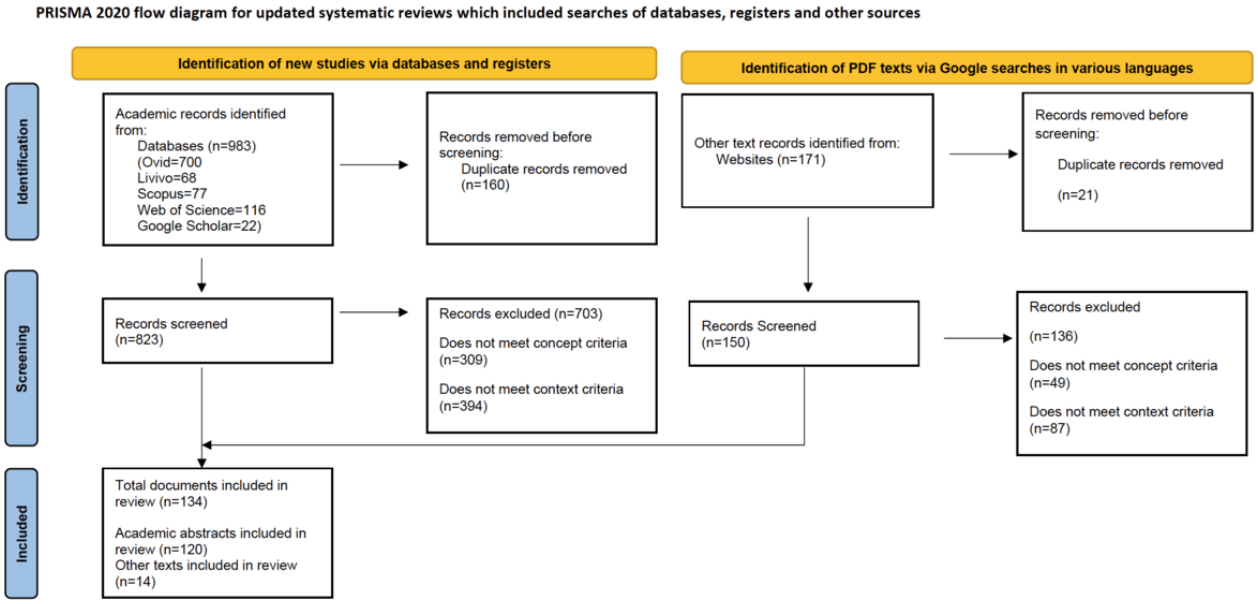
abstracts to verify the instructions had been properly understood. The remaining articles were allocated across several combinations of pairs of authors using double-blind screening and Rayyan [35] as an aid. Any discrepancies were resolved by the pair of authors themselves and verified by the lead author before data extraction. Given the extended scope of our review, and in agreement with the prepublished protocol and the latest JBI guidance [20], there was no full-text screening as the abstracts and extracts were our main data source. Abstracts and extracts have been made available in Multimedia Appendix 3.

Data Extraction

The authors used double-blind extraction of data using an Excel table template as outlined in Multimedia Appendix 4. Following the latest JBI guidance for scoping reviews [20], we chose to focus data extraction on abstracts and extracts only, reflecting the wide research design that allowed us to accommodate the breadth of the review in terms of (1) themes; (2) a worldwide, multilanguage approach; and (3) sources. Using a data extraction tool shared in Multimedia Appendix 4, we mapped the text in tabular form against the NASSS framework [36] domains, noting some of the document sections might touch upon 1 or more domains.

Data Analysis and Presentation

In agreement with the latest JBI methodological guidance [18-20], no critical appraisal was undertaken, and the final presentation of results consisted of the following. In the first section, the results of the search were presented in a PRISMA-ScR flow diagram [25], including a flowchart and a checklist, and we conducted a table analysis of more detailed characteristics of the included documents (Table S1 in Multimedia Appendix 5). We captured the number of articles that included certain data against the PCC framework. Understandably, in the “population” label, the numbers do not add up to the total as some categories are not mutually exclusive. A color-coded (heat map) mapping was created in tabular form against the NASSS framework’s [36] domains: (1) the condition, (2) the technology, (3) the value proposition, (4) adopters, (5) organizations, (6) wider system, and (7) embedding and adaptation over time. The heat map shows graphically the maximum and minimum numbers of references for each domain (using the average counts for double-blind data extraction and mapping). We performed a narrative analysis (including sentiment analysis) of references to the sustainability of video consultations outside of social distancing restrictions brought about by the pandemic. The results are discussed from the point of view of sociotechnical grounded theory, providing strengths and limitations of the sources and the review method itself. We included a statement of positionality in our conclusions, as well as recommendations for research and practice. We believe that reflexivity through researcher positionality is fundamental to decolonizing global health research that seeks to include voices and perspectives usually marginalized from the academic discourse [37-39].



Results

PRISMA Study Inclusion

Academic database searches identified 983 records, and 171 additional records were identified through Google searches for various languages and countries. For Google Arabic and Google Pakistan, there were no results that matched the search criteria. Of the total 1154 articles, 181 were identified as duplicates and were removed: 160 duplicates were academic articles, and 21 duplicates were identified among the nonacademic articles. After the removal of duplicates, there were 973 articles to be screened. Of these 973 articles, 823 articles were from academic databases, and 150 were from nonacademic databases. After the abstract screening and before data extraction, 703 academic and 136 nonacademic articles were excluded, leaving a total of 134 documents [29,40-171] for data extraction including 120 academic articles and 14 extracts from gray literature searches. See the PRISMA-ScR [25] flowchart (Figure 1).

XSL•FO
RenderX

Figure 1. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) flowchart outlining the process of identification, screening, and final inclusion across various types of data sources.

Summary of Document Types

We separated the academic studies (which we identified as those having a clearly labelled abstract with introduction, aims, methods, results, and discussion sections) from the other documents (or gray literature) and found that these other documents represented 27.6% (37/134) of the selected documents. Searches in academic databases and journals provided a small group of gray literature in the form of commentaries or guidelines. Conversely, general internet searches also identified a minority of academic documents.

The document pool achieved global representation, with documents from all continents, including South America [46,110,166] and Africa [116,121]. There was, however, overrepresentation from North America (58/134, 43%), with a large proportion of documents from the United States.

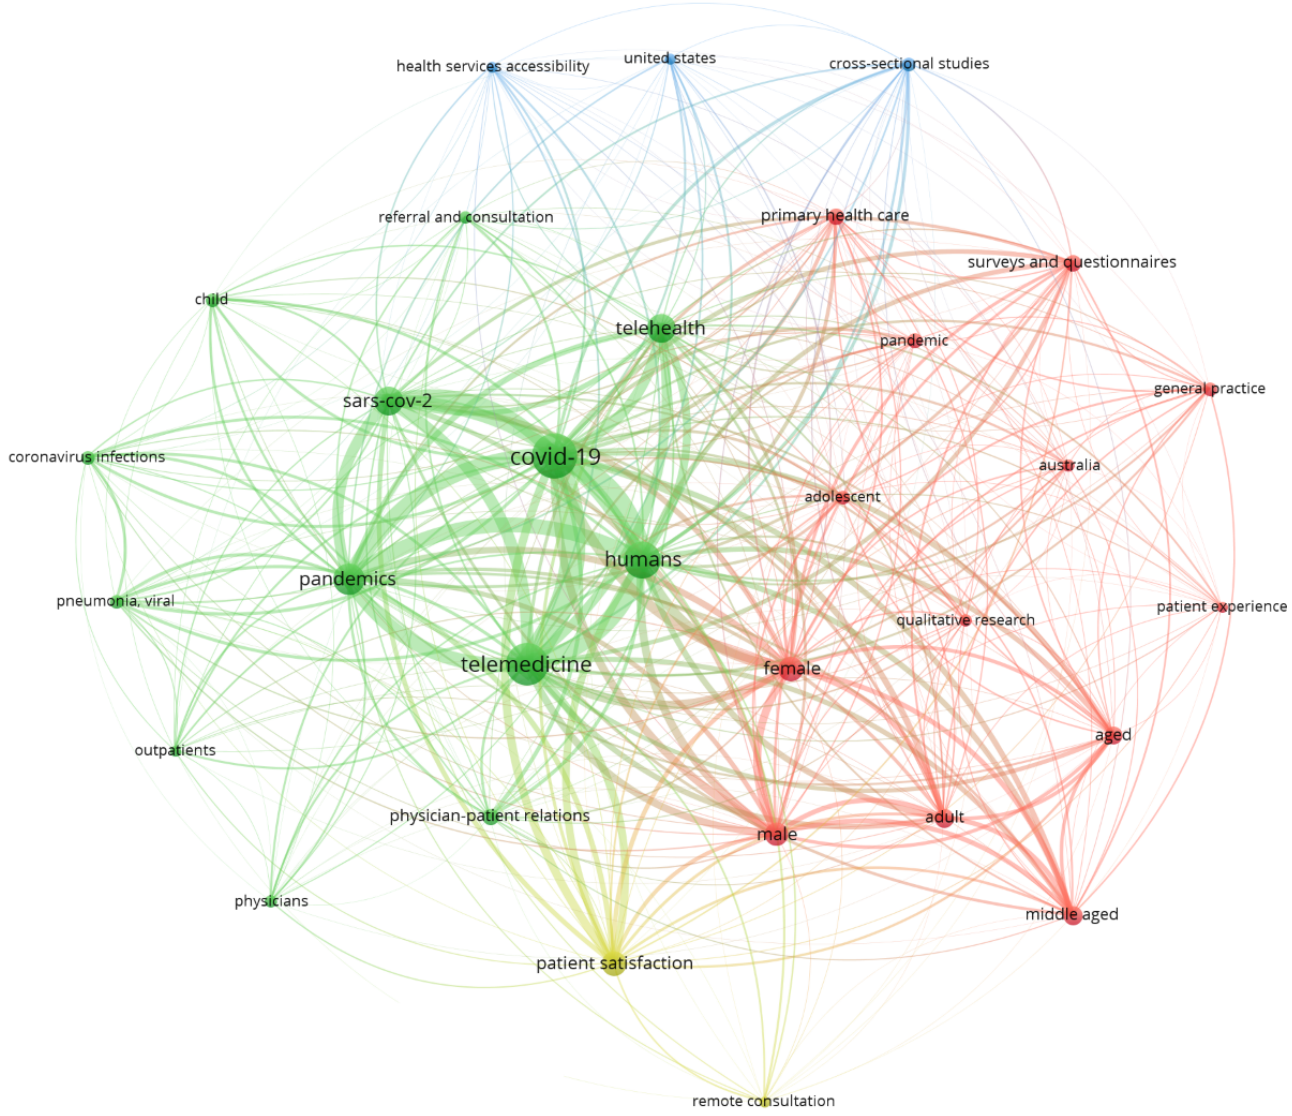
In terms of the methodology in the selected documents, over 72% (96/134) of the documents used surveys, questionnaires, or interviews. The use of surveys and questionnaires was closely related to the type of design observed, with most studies being cross-sectional (96/134, 72%). Finally, regarding the telemedicine medium, the documents did not specify the medium by generally referring to “telemedicine” in 57% (77/134) of documents. More details are provided in Table S2 in Multimedia Appendix 5.

Quantitative Classification Against the PCC Framework

Table S3 in Multimedia Appendix 5 includes the characteristics of the 134 documents against the protocol’s PCC. We follow with a short commentary highlighting any documents that exemplify these findings. Table 1 shows how the documents related to the various key concepts explored (clinician-patient relationship, health inequalities, and patient experience), and the following paragraphs summarize the key findings. In addition, Figure 2 shows the results of the bibliographic keyword analysis.

In terms of population groups, a large subset of abstracts and extracts (66/134, 49.3%) reported no specific demographics nor patient characteristics (see, for example, the extract from the board report from the East Kent Hospitals NHS Foundation Trust [64] or Karacabeyli et al [95]). The main demographic characteristics reported in abstracts and extracts were age (39/134, 29.1%) and sex (20/134, 14.9%), with studies also considering sociodemographic factors. It is important to note that a particular document might have tracked more than one characteristic; see, for example, Manski-Nankervis et al [113], which tracked education status, gender, age, and whether patients spoke English at home.

In terms of the concepts studied**,** the most popular concept was the clinician-patient relationship, reported in 28 abstracts. The majority of documents (69/134, 51.5%) combined 2 or 3 concepts. In the following paragraphs, we provide a brief summary of results across the various concepts.



Regarding patient experience, we found 26 studies solely focused on this concept. Patient experience was mostly equated with patient satisfaction and access. There were positive levels of satisfaction overall [99,121,149] and sustained access at the time of lockdowns [48,53].

XSL•FO
RenderX

Table 1. Classification of the documents against the key concepts.

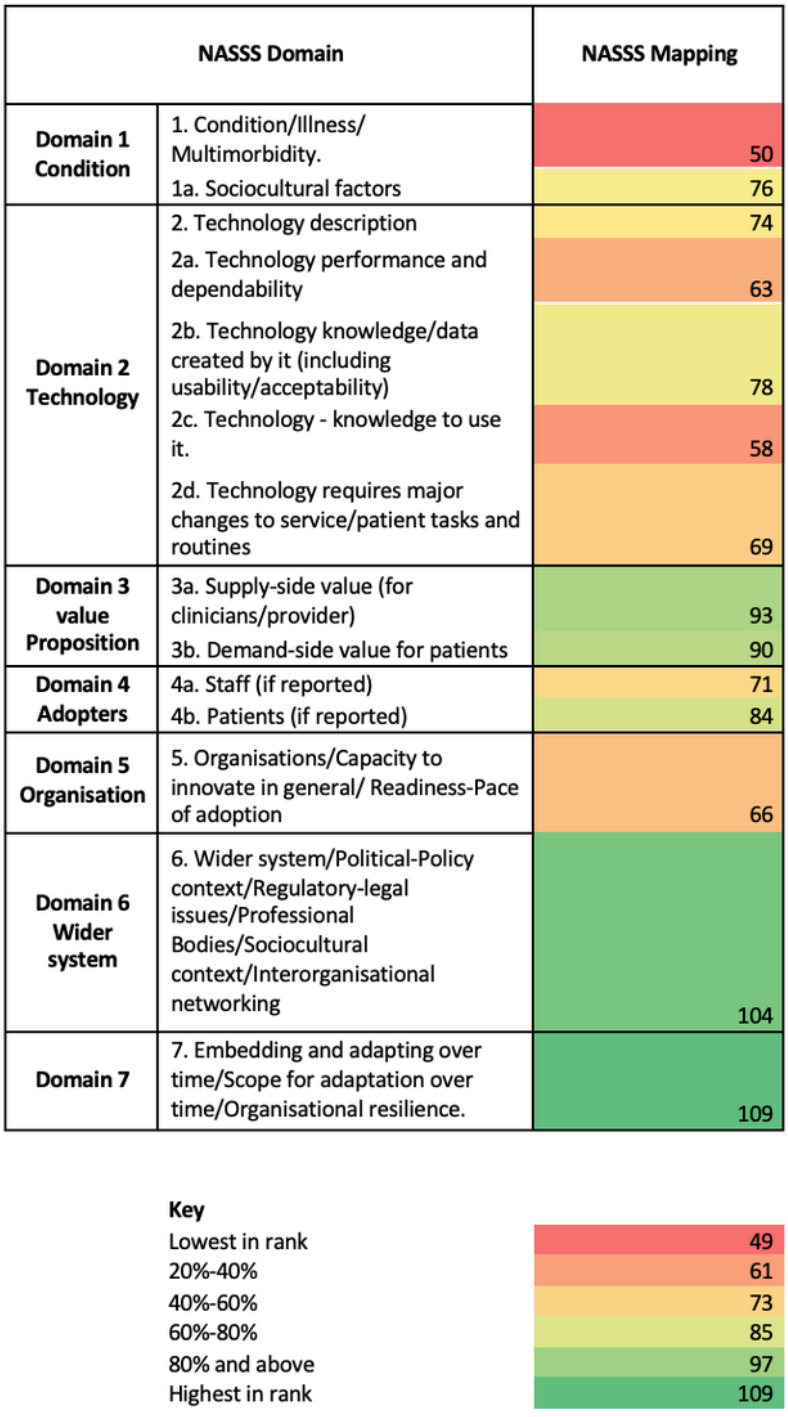
Concept	Documents, n
1 concept	
Clinician-patient relationship	28
Health inequalities	11
Patient experience	26
2 concepts	
Clinician-patient relationship, health inequalities	11
Clinician-patient relationship, patient experience	29
Health inequalities, patient experience	16
All 3 concepts	
Clinician-patient relationship, patient experience, health inequalities	13

Figure 2. Bibliographic keyword analysis.

Regarding health inequalities, there were only 11 studies solely focused on this concept. We found gaps in evidence that made it difficult to pinpoint the impacts on health inequalities of specific groups, with some evidence of health inequality exacerbation for those considered to be at the fringe of the economic and health system (such as vulnerable migrants, families with high levels of economic deprivation or health care insurance exclusion, or rural communities with limited access to technology) [74,116,140].

XSL•FO
RenderX

Regarding the clinician-patient relationship, there were 28 documents solely focused on this concept, mainly on the clinician-patient interaction and quality of the encounter. There was no consensus regarding whether the impact of telemedicine on the interaction had been positive, neutral, or negative [43,56,70], while there was consensus on the added value of the quality of the remote encounter for triage, follow-up consultations, or chronic condition management [128,133,155].



Finally, concerning the context, we identified 46 documents focused solely on primary care, general outpatient care featured in 19 documents, and various outpatient specialties were featured in 56 extracts.

Mapping Against the NASSS Framework

As shown in Figure 3, there was considerable variability in evidence across the NASSS [36] domains and subdomains. Domains 6 (wider system), 7 (time domain), and 3 (value proposition) had the most information. For domain 6, documents referenced the pandemic or pandemic-related lockdowns and infection control measures coupled with regulatory enablers or recommendations (such as mandatory online triage in primary care, parity in payments between face-to-face and telemedicine appointments). There was lower density of information about specific conditions that were being managed with telemedicine (subdomain 1a), knowledge needed to use telemedicine (subdomain 2c), and organizational or implementation aspects (domain 5).

XSL•FO
RenderX

Figure 3. Heat map against each of the nonadoption, abandonment, scale-up, spread, and sustainability (NASSS) domains.

Narrative Analysis of Sustainability

Roughly over one-half of the documents (75/134, 56%) identified challenges in terms of sustainability or made recommendations on how to address them. Among these, sentiment was mixed or neutral in 40 documents and positive in 31 documents, with only a small subgroup [68,89,141,148] viewing such challenges negatively as barriers to further planning and progress. Challenges and areas of consideration included general planning such as workforce training, digital resources, patient experience, and ethical issues [92] or a more focused look at the technology itself such as more effective digital platforms and increased use of home medical equipment [43]. Other issues such as patient selection were also noted with consideration to disease progression, language and cognitive ability, health literacy, and technology access [40]. The systematic review by Mbunge et al [116] of the digital technologies deployed in South Africa during the pandemic

XSL•FO
RenderX

identified a "digital divide" barrier in rural areas and advocated for better networks.

Almost one-third (38/134, 28%) of the documents set out plans for sustainable growth and further embedding, with generally positive sentiment. The report by the East Kent Hospitals NHS Foundation Trust in 2021 [64] mentioned an enhanced engagement plan to meet ambitious targets set by health care authorities for the delivery of telemedicine appointments. Tulupova et al [162] referred to plans for the creation of telemedicine guidelines and an educational program on communications in health care using digital technologies for patients to improve digital health literacy. The remaining documents either did not address the area of sustainability [42,44,49,66,95,101,106,110,111,122,132,143,153,167] or had a generally negative view on the sustainability of the intervention [63,74,80,112,169]. The negative commentary was based on concerns about quality (ie, treating musculoskeletal conditions), eHealth literacy, and access to health care for those at the fringe of the health care system coverage (such as vulnerable migrants and the uninsured).

Discussion

This section includes 4 main areas: (1) a summary of our findings, (2) a sociotechnical grounded theory research interpretation of the findings (based on Hoda [172]), (3) positioning against the wider and recent literature, and (4) strengths and limitations of our study. The section finalizes with a short conclusion.

Summary of Findings

Concerning the protocol's PCC, 49% (66/134) of the documents reported no specific population group targeted by the study (population); according to the UK definition, 55% (74/134) of the studies referred to an outpatient (ambulatory care) setting, and 34% (46/134) referred to primary care (context); and 49% (66/134) of the studies referred to only 1 of the concepts studied (concept).

Mapping to the NASSS framework [36] identified that 93% (125/134) of the studies referenced the sustainability of telemedicine with moderately positive comments.

Global Representation

We found 134 studies meeting our criteria and achieved global representation. We highlight some of the global results from limited-resource countries here.

Despite the limited evidence for African countries (2 studies [116,121]), our findings were aligned with other African reviews around insufficient evidence of use due to considerable barriers in this region [16] and a lack of "meaningful investment" in this area [173]. We concurred with Nittari et al [174] that several barriers are still present that risk the sustainability of this delivery mode beyond the pandemic.

Studies in South America [46,110,166] provide examples of effective use in outpatient settings (specifically speech and language therapy [46]), as well as reflections on how this new delivery mode in the context of the wider pandemic might have generated an element of mistrust and fear in the clinician-patient relationship [166].

Results from Middle Eastern and Asian countries [41,97,104,105] provide perspectives on the use of telemedicine in orthopedics and hematology while indicating the equivalence of audio and video consultations, an important point to inform telemedicine programs in low-income countries as a way of increasing access to health services.

Positioning Against the Wider and Recent Literature

This review can be positioned in the emerging literature of reviews around telemedicine during the pandemic period [175-183].

A key finding of our study is how patient experience was generally equated with patient satisfaction. Other studies have found these are often used interchangeably [184-186]. However, accepted definitions of patient experience go beyond satisfaction and "focus on individualized care and tailoring of services to meet patients' needs" [187]. This is related to another finding, as the studies are mainly observational with no reference to patient experience frameworks, let alone to some emerging frameworks specific to the digital patient experience [173,188]. Our findings on patient experience are aligned with another recently published review focused on the COVID-19 pandemic, with similar categories and findings [178]. In terms of the clinician-patient relationship, our findings were mixed, but recent reviews found that the relationship was "troubled" telemedicine given both patient and clinician reluctance to use [177]. However, others found the tool useful [106].

de Oliveira Andrade et al [175] focused on the role of legislation in the widespread utilization of telemedicine during the pandemic, finding that regulatory frameworks enabled telemedicine spread in areas related to ethics, reimbursement, data safety, and pandemic-related regulatory relaxation (in the United States, for instance, relaxation of interstate practice was particularly relevant [183]). We found a lack of consensus in terms of sustainability as these financial and regulatory incentives dissipated; however, supportive regulation would be a defining factor in its sustainability. Our evidence seems more nuanced than other recent reviews [177,189]. We are aware specialties like family medicine and general practice seem to have a preference for a particular medium, such as telephone instead of video [190], with more work being undertaken regarding the impacts on quality [191] or equivalence between face-to-face and remote consultations [183].

Regarding the impact on health inequalities, another review identified emerging literature on the opinions of vulnerable populations regarding telemedicine [180]. We saw references [192-195] to an emerging framework for digital health equity [196], which we expect will help address the gaps we identified in the design and evaluation of inclusive digital health care services to address the "self-reinforcing effect of digital and social exclusion" [197] and its impact on health care inequalities in access and experience. Our concerns about implications on health inequality resonate with other similar reviews for telemedicine [179].

Strengths and Limitations

Strengths

We mapped the emerging literature (gray and academic) on telemedicine during the pandemic to a well-established framework using 3 lenses (patient experience, health inequalities, and clinician-patient relationship). We identified this as the only systematic review of its kind. Only 1 other review mapped academic literature on video consultations to the NASSS framework [36] but outside the context of the pandemic [37]. Notably, we effectively reflected the experiences of non–English-speaking countries with literature across the 5 continents, so it is truly global health–oriented, with the added values and perspectives of a diverse, multidisciplinary research team.

When identifying the limited literature at the intersection of health inequalities and telemedicine, we provided a brief taxonomy of potential groups impacted differently. Recognizing the multidimensionality and intersectionality of social exclusion, we show that demographic characteristics such as age, sex, and socioeconomic factors have received some attention, but there is still very limited information and not enough to draw solid conclusions on impacts.

From a methodological standpoint, we provided additional insight on how to integrate effectively other documents and nontraditional voices and experiences into academic research with a reproducible approach.

Limitations of the Sources

The authors sought gray literature directly via Google to ensure a unified source and methodology to identify and capture experiences from non–English-speaking countries. This is a method with limited reproducibility. Researchers interested in gray literature information in English can consult the UK National Grey Literature Collection Funded by Health Education England. We are aware of additional databases with non-English literature that could be used [198]. Emerging literature has covered mostly single-center survey studies with limited sample sizes, reflective of the immediate experiences arising in the context of the pandemic.

Limitations of the Review

We have limited the depth of analysis to accommodate for the extensive scope, in accordance with the JBI guidelines for data extraction [199]. The use of document extracts using the "surrounding keyword" approach needs further development and testing, as we recognize slightly longer extracts are better at conveying enough information to support screening and analysis. We did not consider synchronous text-based communication. The methodology of scoping reviews is still skewed toward evidence from academic publications, which are biased toward researchers from North America and Europe. Although not specified in the current guidance, capping the number of results from traditional academic databases provides a more balanced representation and could reduce duplication while having limited effects on how comprehensive the findings are.

In conclusion, our discussion section has highlighted considerable variation in the emerging literature during the pandemic regarding changes in pathways toward telemedicine. We highlighted the different focus of studies focused on health inequality or outpatient care and the global representation of the studies included (which is a key strength). Of note is the finding equating patient experience with satisfaction, which reflects a potentially limited understanding of sociotechnical views of human-computer interaction and human factors in traditional health service research.

Conclusions

This section is divided into 3 parts comprising a reflection of our positionality as researchers in analyzing these themes as well as further recommendations for research and practice.

Statement of Positionality

Following the method by Pant et al [37], we frame some of our conclusions in the context of our positionality and our aims. We are a diverse group of researchers (with roots in Latin America, the Middle East, Asia, and Africa and with supervisors from the United Kingdom), but our gaze is colonially influenced by our education and current positionality in this country.

By opening our search criteria to non-English documents and gray literature, we succeeded in capturing immediate, emerging experiences at the global level, with 27.6% (37/134) of our documents having no structured abstract and classified as gray literature, with 5 documents from South America and Africa and 13 documents from Asia. The balance, however, is still very skewed toward the United States and English-speaking countries.

Our positionality and knowledge of the UK health system and legislation meant it was difficult to translate these categories to other systems, and we had to modify our parameters and analysis. For instance, although our choice of the UK diversity legislation ("protected characteristics") as a framework for categorizing health inequalities was helpful, the UK definition of "primary care" was not helpful due to its contrast with the definition set out by the WHO (for example in the work by Dimer et al [46] in Brazil, classifying speech and language therapy services as a "primary health care service," which are not available in the United Kingdom in this setting).

Recommendations for Research

From a methodological standpoint, we urge researchers looking to decolonize academic research to test and evaluate further our approach to using gray literature extracts in other languages, particularly in scoping reviews, as it provides that additional level of immediacy with the phenomenon of study. We noticed confusion on the use of patient satisfaction and patient experience, so research should focus on more robust frameworks reviewing the overall patient pathway (away from the evaluation of a remote encounter [184-186]). As expected, our research found mainly descriptive documents, so future research should focus on robust evaluation of clinical outcomes arising from changes in diagnostic and treatment pathways away from face-to-face settings. We recommend future research with a narrower approach to specific population groups and more

XSL•FO
RenderX

focused on access and outcomes (Table S1 in Multimedia Appendix 5). From a sociotechnical research perspective, we recommend future research using modern techniques (natural language processing, data mining, and sentiment analysis) focusing on categories with closer links to human-computer interaction. Following publication, we will publish our data on Open Science Framework [200].

Recommendations for Practice

The impact of telemedicine on patient safety is critical to determine the sustainability of this intervention when contrasting it with the under- or overutilization of resources [201]. If not ruling out the continued use of telemedicine, the authors outlined the importance of further research and refinements to the intervention itself. We found that models such as the Dynamic Sustainability Framework [75] might be useful to support learning and adaptation with care toward the potential disenfranchisement of some patient groups.

Acknowledgments

ChatGPT and Grammarly were used to edit the final draft. Many thanks to Cee MacDonald at Paperaid for the assistance with extract retrieval and text formatting.

This research did not receive any external funding and was undertaken as part of DV's self-funded PhD studies.

Authors' Contributions

These contributions use Contributor Roles Taxonomy (CRediT) guidelines. As this article is also a pedagogic exercise related to various individuals' studies, it was agreed that all voluntary contributors would be set as co-authors regardless of the degree of contribution.

This article contributes to DV's PhD studies at the University of Warwick, and DV contributed to the study conceptualization, data curation (lead), formal analysis (lead), investigation (lead), methodology (lead), project administration (lead), software, validation, visualization, writing of the original manuscript draft (lead), and manuscript review and editing. AS contributed to the data curation (lead), formal analysis (support), investigation (support), methodology (equal), project administration (support), software (support), visualization (support), writing of the original manuscript draft (support), and copyediting (lead). DOM and IL contributed to the data curation (support), investigation (support), and methodology (equal). GH and HZ contributed to the formal analysis (support), visualization (support), and writing of the original manuscript draft (support). TB contributed to the data curation (support), investigation (support), methodology (equal), and manuscript review and editing (support). SAI contributed to the data curation (support), formal analysis (support), and methodology (support). RP contributed to study supervision (lead), validation (lead), and manuscript review and editing (support). RS contributed to study supervision (support), manuscript review and editing (lead), and validation (lead). JD contributed to study supervision (support). AP contributed to validation of data extraction (support) and preparation of the final draft. LJM and KTK contributed to the data curation (support).

Conflicts of Interest

At the time of publication, DV, TB, and HZ worked in the UK National Health Service in the United Kingdom. The research was undertaken independently of DV's, TB's, and HZ's occupations and does not represent the views of their employers. The remaining authors declare no conflict of interest.

Abstract

Background: Major depressive disorder contributes to the global burden of mental illness. Therapeutic guidelines promote treatment self-management and support caregivers and family members in this process.

Objective: We aimed to identify therapeutic guidelines for the symptoms of major depressive disorder.

Methods: This scoping review followed the assumptions established by the Joanna Briggs Institute and the PRISMA-ScR (Preferred Reporting Items for Systematic reviews and Meta-Analyses extension for Scoping Reviews) protocol, carried out in 12 databases (LILACS, PubMed, SciELO, Scopus, Web of Science, b-on, BDENF, AgeLine, Cochrane, BVS, IBECS, and CINAHL) and 5 secondary gray literature sources (Google Scholar, Global ETD Search, EBSCO Open Dissertations, CAPES Catalog of Theses and Dissertations, and the Digital Library of Theses and Dissertations of the University of Sao Paulo). The eligibility criteria were based on the population, concept, and context framework: people diagnosed with major depressive disorder aged >18 years (population), therapeutic guidelines for self-management of major depressive disorder symptoms (concept), and symptoms of major depressive disorder (context). Data collection was carried out from March to July 2022 and updated in June 2024. The included studies were experimental, quasi-experimental, analytical observational, descriptive observational, qualitative, or quantitative studies; systematic reviews and meta-analyses; and scoping and literature reviews published in full without time restrictions in English, Spanish, or Portuguese. All the information, as well as the studies captured, was stored in a Microsoft Excel spreadsheet using Rayyan and the *JBI Manual for Evidence Synthesis*. The titles, abstracts, and full texts were carefully read and classified, extracting the results. After review by 2 independent researchers, 62 studies were selected. The results are presented descriptively, including characterization of the studies and mapping and categorization of groups and subgroups of therapeutic guidelines for self-management of major depressive disorder.

Results: In total, 62 studies published between 2011 and 2023 were included, where 44 (71%) came from indexed data sources and 18 (29%) were gray literature indexed on Google Scholar (13/62, 21%), doctoral theses (3/62, 5%), and master's dissertations (2/62, 3%). Among the therapeutic guidelines identified, mapped, and categorized, 7 major groups were identified for self-management: psychotherapy (32/62, 52%), adoption of healthy habits (25/62, 40%), integrative and complementary practices (17/62, 27%), relaxation techniques (9/62, 14%), consultation with a health professional (14/62, 22%), pharmacological therapy (9/62, 14%), and leisure or pleasurable activities (4/62, 6%).

XSL•FO
RenderX

Conclusions: It was possible to identify therapeutic guidelines to promote self-management of major depressive disorder in the adult population. Therapeutic guidance is an important resource for patients, their families, and the community, making patients the protagonists of their own health. For health professionals, therapeutic guidelines become tools that help develop skills and competencies for care among patients, thus ensuring their ability to self-manage major depressive disorder.

Introduction

Background

Major depressive disorder is one of the most prevalent mental disorders in the world, as well as one of the clinical conditions that contributes most to the global burden of mental illnesses [1]. The number of people presenting with symptoms suggestive of this disorder has shown a significant increase at an alarming and worrying rate, and it is estimated that it will be the world's first major disabling public health problem by 2030 [2].

It is a classic mental disorder that involves evident alterations in affect, cognition, and neurovegetative functions, affecting approximately 300 million people worldwide [2]. It is estimated that 3.8% of cases lead to functional incapacity and damage to physical and mental health, as well as professional losses and considerable morbidity and mortality due to suicide or association with other illnesses [3].

In addition to these impacts, it is difficult to diagnose major depressive disorder accurately and quickly as its classification and assessment are based on clinical findings and the patient's history [2]. Therapies for the treatment of major depressive disorder, such as psychobiosocial therapies, psychotherapy, and pharmacotherapy, have advanced and are used according to the severity of the symptoms and potential adverse events [4]. Considering that mental health care has undergone important transformations, such as the creation of an out-of-hospital network made up of substitute services that propose the rescue of the singularity or subjectivity of the person in psychological distress, respecting their integrality and existence [5], promoting their autonomy in the management of the illness or treatment means encouraging empowerment, the ability to make choices, and taking responsibility for themselves as a citizen and social being [6].

This knowledge and skills are important tools to prevent complications, control symptoms, self-manage treatment, and even avoid recurrences and hospitalizations [7]. Due to the complexity of the disease, some adaptive actions can be taken, including controlling destabilizing factors, preserving self-confidence, re-establishing important relationships, attempting to regain functioning, managing symptoms, negotiating the care environment, and maintaining satisfying relationships [7,8].

Society has been moving toward the construction and adoption of technological innovations using smartphones and computer applications. These resources can be of great value in the process of promoting people's skills in the mental health field [8]. In this sense, based on the results of this scoping review, a systematic set of therapeutic guidelines was developed based on clinical practice and scientific evidence. This set of therapeutic guidelines is capable of supporting a computational application, generating knowledge in the area of mental health, creating a connection with the patient, and supporting self-management of one's health remotely [8,9].

These therapeutic guidelines can be adopted with the aim of promoting and supporting self-management in the daily treatment of the patient and supporting the caregiver or family members in performing techniques safely and appropriately, completing therapeutic sessions, maintaining functionality, or preventing possible complications of the disorder [9]. It should be emphasized that, although it is important to encourage self-management by the individual and the family, it is also essential that the care provided by health professionals, including nurses, assists in the promotion and reorganization of the self, breaks and overcomes relationships of dependence, and levels the acquisition or development of knowledge and skills for self-management [7,9].

Given the extent of the symptomatology and the particularities of major depressive disorder, a scoping review allows for an exhaustive analysis of the studies available so that the patient has access to information that will allow them to develop attitudes, knowledge, and skills to self-manage based on the best scientific evidence.

Objectives

Similarly, a set of therapeutic guidelines will constitute an instrument for the clinical practice of nurses and of the multidisciplinary team as the deepening of specific skills will allow for the provision of individualized care that is more suited to the needs of the person with major depressive disorder. Therefore, this scoping review was carried out with the aim of identifying therapeutic guidelines in scientific production for the self-management of major depressive disorder symptoms.

Methods

Overview

A scoping review is used to map key concepts, examine existing evidence before conducting a systematic review, and clarify and define conceptual boundaries. This scoping review was prepared in accordance with the methodological proposal of the Joanna Briggs Institute (JBI) in 2020, supported by the PRISMA (Preferred Reporting Items for Systematic reviews and Meta-Analyses) [10] and PRISMA extension for Scoping Reviews (PRISMA-ScR) [11] guidelines based on the following steps: formulation of the research question, identification of

XSL•FO
RenderX

relevant studies, selection of studies, extraction and analysis of data, and synthesis and construction of the report. The PRISMA-ScR checklist is available in Multimedia Appendix 1. This review protocol was registered in the Open Science Framework platform [12] on November 11, 2023, and was modified on February 19, 2025. There was no deviation from the protocol registered on the Open Science Framework platform.

Research Question

To formulate the guiding research question and guide data collection, the population, concept, and context (PCC) framework was used. The PCC strategy was adopted to drive the research question of this scoping review. In this study, *population* refers to people diagnosed with major depressive disorder aged >18 years, *concept* refers to therapeutic guidelines for self-management of major depressive disorder symptoms, and *context* refers to major depressive disorder symptoms (eg, changes in weight, appetite, and sleep; feelings of guilt; irritability or bad mood; anhedonia; fatigue; and low self-esteem).

Therefore, the following guiding question was defined: "What therapeutic guidelines support self-management of changes in weight, appetite, sleep, feelings of guilt, irritability or bad mood, anhedonia, fatigue and low self-esteem?"

Study Design and Eligibility Criteria

The data search was carried out in 12 information sources (LILACS, PubMed, SciELO, Scopus, Web of Science, b-on, BDENF, AgeLine, Cochrane, BVS, IBECS, and CINAHL) and 5 secondary information sources of gray literature (Google Scholar, Global ETD Search, EBSCO Open Dissertations, CAPES Catalog of Theses and Dissertations, and the Digital Library of Theses and Dissertations of the University of Sao Paulo).

The search strategy was developed using the controlled and noncontrolled descriptors obtained in the initial search plus the Boolean operators "OR," "NOT," and "AND," as well as keywords found in the Health Sciences Descriptors and Medical Subject Headings of the US National Library of Medicine combined with each other according to each database. The strategies used and how they were combined are available in Multimedia Appendix 2.

The search followed five distinct phases according to the JBI methodology, and a team of 5 researchers was assembled for this scoping review: (1) initial search in the selected databases to identify articles on the topic and, from there, select words and indexing terms contained in these publications to develop the full search strategy; (2) use of the keywords and indexing terms identified to search all the databases included; (3) definition of the study design and eligibility criteria, including the determination of the type of study, target population, interventions and outcomes analyzed. In addition, inclusion and exclusion criteria were established for the selection of studies; (4) identification and selection of studies, including the systematic search in databases and sources of gray literature, application of filters and search strategies to ensure the identification of relevant studies and screening of relevant articles (reading of titles, abstracts and, when necessary, the full text); and (5) data extraction and analysis, including the collection of information from the selected studies, the assessment of methodological quality and the synthesis of findings.

The eligibility criteria are described in Textbox 1, and the studies found were refined based on the PCC acronym, type of study, year of publication, language, and results. The search was carried out from March 2022 to July 2022 and updated in June 2024.

XSL•FO
RenderX

Textbox 1. Eligibility criteria.

Inclusion criteria

- Population: people diagnosed with major depressive disorder aged >18 years
- Concept: therapeutic guidelines for the self-management of symptoms of major depressive disorder
- Context: symptoms of major depressive disorder, such as changes in weight, appetite, and sleep; feelings of guilt; irritability or bad mood; anhedonia; fatigue; and low self-esteem
- Type of study: experimental and quasi-experimental studies (randomized and nonrandomized controlled trials), analytical observational studies (prospective and retrospective cohort studies, case-control studies, and analytical cross-sectional studies), descriptive observational studies (case series, individual case reports, and descriptive cross-sectional studies), qualitative and quantitative studies, systematic reviews, meta-analyses, scoping reviews, and literature reviews; due to the scarcity of publications found in the databases, it was also decided to include gray literature (course completion studies, dissertations, and theses)
- Year: there were no restrictions on the search period as the first search strategies developed yielded few studies on the subject
- Language: English, Spanish, and Portuguese
- Results: publications whose objective addressed therapeutic guidelines to assist in the self-management of patients with active symptoms of major depressive disorder

Exclusion criteria

- Population, concept, and context: publications without information on the population, concept, and context of interest for this study
- Type of study: duplicate studies, opinion articles, letters to the editor, abstracts of conference proceedings, and studies with unavailable text
- Language: studies in languages other than those selected
- Results: publications that did not fit the objectives and did not contain information related to the population, concept, and context of this study

Study Identification and Selection

The process of identifying and selecting studies is one of the most important stages in the conduct of a scoping review. To minimize potential bias, the *JBI Manual for Evidence Synthesis* guidelines were used and explained in a meeting with 6 researchers to ensure that this process was clear to everyone.

Thus, to maintain the rigor of the screening process, the studies obtained from each of the databases based on the eligibility criteria were exported to a reference management software (EndNote; Clarivate Analytics), and duplicates were removed. The remaining studies were then imported into the Rayyan application (Qatar Computing Research Institute) for analysis and selection based on titles and abstracts.

The titles and abstracts were read and analyzed by 2 independent reviewers to identify those that were potentially eligible. After reading the titles and abstracts, the preselected studies were subjected to data analysis and mapping, which consisted of carefully reading and classifying the texts from which the results were extracted.

The selected studies were read in full by 2 additional reviewers (MdPSdSN and PdCT) to confirm their relevance to the research question. Any doubts about the inclusion of studies would be resolved through discussion with a third reviewer until a consensus was reached. It was not necessary to contact a third reviewer.

Data Extraction and Analysis

As recommended by the JBI, the authors developed a tool to extract the data for the scoping review. Those responsible for data extraction (MdPSdSN, PdCT, and PMM) read and carefully classified the texts. The data were documented in a Microsoft Excel (Microsoft Corp) spreadsheet for better data extraction and evaluation. The final studies were determined from this step. The following variables were extracted from the studies: symptoms, authors, year, reference, study title, objective, study design, and mapping of results.

The focuses of the studies were analyzed, and the results and discussion are presented descriptively and quantified as frequencies in tables. The Discussion section synthesizes the evidence found during the review to explore it and compare it with the existing literature.

The mapped results were categorized into 7 major groups and subgroups of therapeutic orientations for the self-management of major depressive disorder based on the similarities between them. For example, therapeutic orientations focused on physical activity or regular exercise and healthy eating were classified as adoption of healthy habits, whereas listening to music, watching movies, reading, painting, going out with friends, taking outdoor walks, and practicing spiritual and religious activities were grouped in the category of leisure or pleasurable activities. This was done for all the therapeutic orientations identified considering the objective of this scoping review.

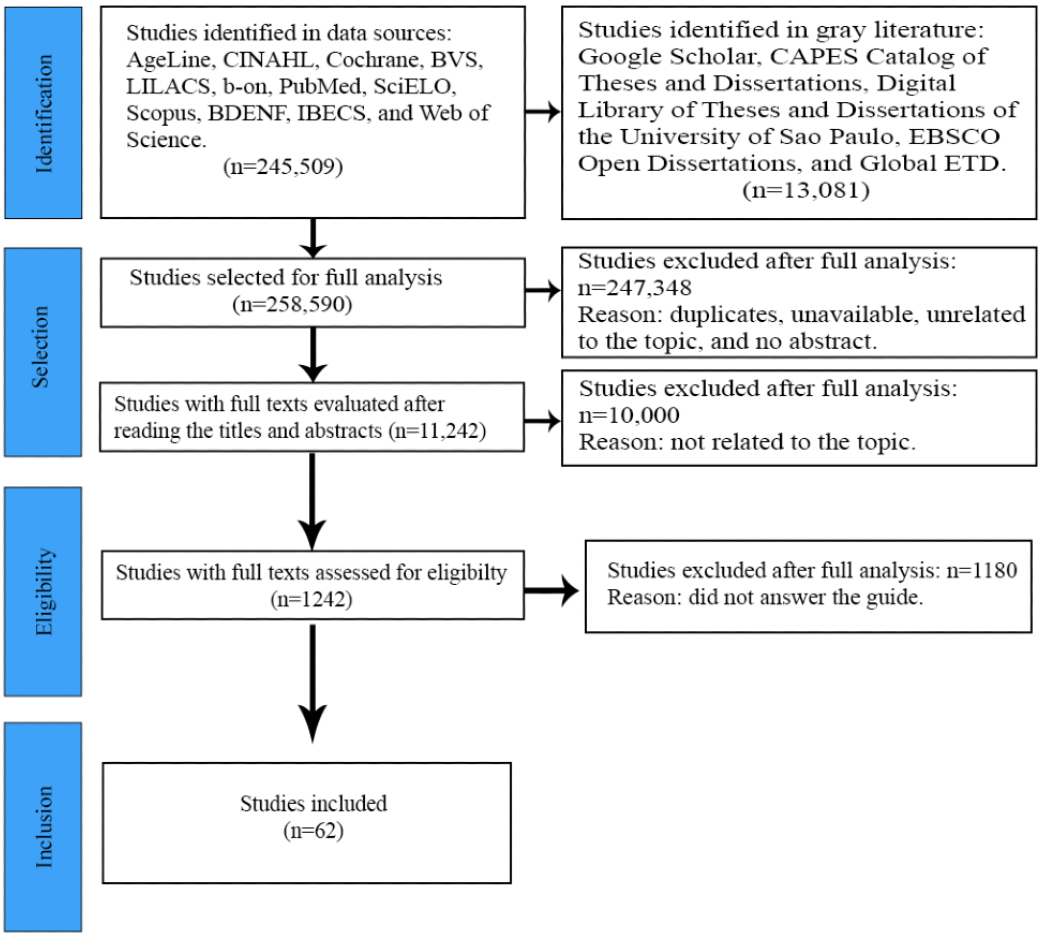
Regarding the methodological assessment (although it was not mandatory), each included study had its level of evidence identified based on the JBI appraisal tools [13] and the study design.

Thus, classification I was assigned to systematic reviews and meta-analyses of randomized clinical trials, classification II was assigned to randomized clinical trials, classification III was assigned to nonrandomized controlled trials, classification IV was assigned to case-control or cohort studies, classification V was assigned to systematic reviews of qualitative or descriptive

XSL•FO
RenderX

studies, classification VI was assigned to qualitative or descriptive studies, and classification VII was assigned to opinions of authorities or expert committee reports. This hierarchy classifies levels I and II as strong, levels III to V as moderate, and levels VI to VII as weak.

Results



Overview of the Studies Found

Initially, 258,509 potentially eligible publications were found in the databases and 13,081 publications in the gray literature sources, of which 1538 (0.63%) focused on sleep disorders, 8315 (3.39%) focused on appetite disorders, 6732 (2.74%) focused on weight disorders, 5814 (2.37%) focused on feelings of guilt, 2509 (1.02%) focused on irritable mood, 200,002 (81.46%) focused on low self-esteem, 1848 (0.75%) focused on anhedonia, and 31,832 (7.64%) focused on fatigue.

The inclusion and exclusion criteria were applied, and 247,348 duplicate studies were removed, leaving 11,242 (4.55%). Next, a new screening was carried out in search of available publications that had abstracts and dealt with therapeutic guidelines. Of the remaining 11,242 studies, 10,000 (88.95%) were excluded, leaving 1242 (11.05%).

Once the 1242 studies had been selected, the second full reading was carried out. Of the 1242 studies, 1180 (95.01%) were excluded because they did not answer the guiding question. Thus, 62 studies were included in the final sample of this review. Figure 1 shows the results using the PRISMA-ScR flow diagram.

Figure 1. Flow diagram of the search and selection of studies according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 model.

Characteristics of the Included Studies

Of the 62 studies dealing with therapeutic guidelines (Table 1), 71% (n=44) came from indexed data sources, and 29% (n=18) were gray literature indexed on Google Scholar (n=13, 21%), doctoral theses (n=3, 5%), and Master's dissertations (n=2, 3%).

It was found that the studies were published between 2011 and 2023, with a higher number of publications in the years 2018 to 2023 (40/62, 63%), demonstrating that the use of therapeutic guidelines is recently evolving. In terms of language, most publications were in English (North America—United States) and Portuguese (South America—Brazil), totaling 63% (40/62) of the publications (Table 1).

Regarding study design, the studies were clinical trials (30/62, 48%), systematic reviews (6/62, 10%), narrative literature reviews (7/62, 11%), systematic reviews and meta-analyses (6/62, 10%), qualitative studies (3/62, 5%), pilot studies (3/62, 5%), experimental studies (2/62, 3%), case reports (2/62, 3%), noncontrolled studies (1/62, 2%), cross-sectional studies (1/62, 2%), and scoping reviews (1/62, 2%; Table 1).

XSL•FO

Summary of the Extracted Variables

Table 2 presents the variables extracted from the studies: symptoms, authors, year of publication, reference, title of the study, objective, and study design. All 62 studies focused on people aged >18 years with a diagnosis of major depressive disorder and active symptoms, with a maximum age of 70 years. Of the 15 publications selected on the symptom of sleep disorders, 10 (67%) were published on PubMed [14-23], 1 (7%) was published on SciELO [24], 1 (7%) was published on AgeLine [25], and 3 (20%) were published as gray literature [26-28].

[a]CBT: cognitive behavioral therapy.

[b]CT: cognitive therapy.

For the symptom of anhedonia, 9 publications were selected: 3 (33%) published on BVS [32,52,72], 3 (33%) published on PubMed [53-55], 2 (22%) published on Scopus [31,56], and 1 (11%) published as gray literature [33]. Similarly, the symptom of low self-esteem was identified in 9 publications: 5 (56%) published in PubMed [34,37,49,50,71], 1 (11%) published on Scopus [58], and 3 (33%) published as gray literature [35,59,67]. Furthermore, 9 publications were also selected for the symptom of irritated mood: 4 (44%) published on PubMed [57,60,63,70] and 5 (56%) published as gray literature [39,43,48,66,69].

For the symptom of guilt, 8 publications were selected: 4 (50%) published on PubMed [40,41,65,68] and 4 (50%) published as gray literature [36,38,62,73]. Regarding the symptom of weight change, 6 publications were identified: 5 (83%) published on PubMed [42,44,46,47,75] and 1 (17%) published as gray

XSL•FO
RenderX

literature [51]. For the symptom of fatigue, 3 publications were selected: 2 (67%) published on PubMed [29,30] and 1 (33%) published on CINAHL [74]. Finally, for the symptom of appetite change, 3 publications were identified: 2 (67%) published on PubMed [45,61] and 1 (33%) published as gray literature [64]. Regarding the level of evidence, 48% (30/62) of the studies were level II, 34% (21/62) were level I, 8% (5/62) were level V, 6% (4/62) were level VI, and 3% (2/62) were level III.

Self-Management of Major Depressive Disorder

The evidence available from the included studies to promote self-management of the symptoms of major depressive disorder describes the characteristics, benefits, and applicability of therapeutic guidelines in everyday life, demonstrating that these guidelines can promote a safe space to share conversations on sensitive subjects such as stigma and prejudice, adverse drug events, diagnosis, and relapse [14-75].

The findings also point out that, to promote self-management through therapeutic guidelines, it is necessary to know the functionality of the patient or family, have access to community resources and a social support network, and monitor the participation of these individuals in their care [16,33,35,37,40]. The interdisciplinary team's online or face-to-face follow-up of patients with major depressive disorder involves monitoring the use of therapeutic guidelines and whether they are being carried out correctly and appropriately considering the individual's uniqueness, as well as monitoring changes in symptoms and problems with medication, providing social support, and identifying patients at high risk of relapse [23,41].

Another common point cited in the studies was the ability of health professionals to instruct patients with major depressive disorder on how to deal with symptoms and biosociopsychological demands [16,31-33]. Professionals require skills and good communication with patients when instructing them on the use of therapeutic guidelines for managing the disorder, since incorrect instructions or misunderstandings may make the application of therapeutic guidelines less efficient [23,35,37,40,67,70,74,75]. If the professional advises the patient to sunbathe (phototherapy) during the day, but does not specify the time, this may cause the patient to take this guidance at inappropriate times and be harmful to their health. Therefore, phototherapy would not be effective. The findings encourage a multidisciplinary approach to the applicability of therapeutic guidelines, focusing on the specificities of each person and collective actions, strengthening the patient's ability to self-manage.

Therapeutic Guidelines for Self-Management

The analysis of the studies, as described previously, resulted in the mapping and categorization of 7 large groups of therapeutic guidelines for the self-management of major depressive disorder. These guidelines are made up of a set of actions or activities (n=40), which have been called subinterventions based on the similarities between them (Table 3).

In total, 52% (32/62) of the therapeutic guidelines identified fell into the category of psychotherapy, which helps monitor and plan activities with the person (in the context of their symptoms), manage adverse experiences, and develop social skills [14,16,17,22,23,26,28,29,31,36-38,46,56,58-72,74,75]. Adoption of healthy habits (25/62, 40%) and integrative and complementary practices (17/62, 27%) were the second and third most observed categories. The process of adopting integrative and complementary practices [17,19,20,24-26,29-40], together with healthy habits such as eating a balanced diet and exercising frequently and for the right duration, showed a good response in improving depressive conditions, as well as being an important factor in preventing relapses of major depressive disorder [21,26,27,29,30,33,37,38,41-57].

Finally, relaxation techniques (9/62, 14%), consultation with a health professional (14/62, 22%), pharmacological therapy (9/62, 14%), and leisure or pleasurable activities (4/62, 6%) were the least observed therapeutic guidelines in the studies. However, they offered promising insights into self-management of the disorder and underscored the importance of a multifaceted approach to managing this complex condition [16,20,23,26-30,33,36-38,41,50,57,66].

It is widely recognized that the concept of self-management is traditionally associated with approaches that the patient can carry out autonomously, such as adopting healthy habits, physical exercise, and relaxation techniques. However, it is crucial to emphasize that, in the context of major depressive disorder, self-management transcends these independent symptom management practices [37].

It involves empowering the patient to take active control and gain an in-depth understanding of their condition through the application of a variety of therapeutic interventions [35]. Patients with major depressive disorder may experience feelings of frustration and a range of negative thoughts, see everyday problems as major catastrophes, have difficulty recognizing efforts that awaken hope for life, and cope with the possible adverse events that psychiatric medications can cause [66].

For this reason, orientation toward psychotherapy and psychopharmaceuticals is justified as a self-management strategy as a way of coping with the adverse effects of medication and all the feelings of self-demand, excessive demands, and frustration caused by the disorder.

In relation to the population to which this study refers, the results show that patients with major depressive disorder have motivational, cognitive, and psychological deficits that can modify their ability to cope and reason [22,60,63,65].

In view of this, self-management of the signs and symptoms resulting from major depressive disorder needs to take place at the beginning of treatment, with the support of family or caregivers; friends; community organizations; and, most especially, the multi-professional health team to help with the correct use of therapeutic options until the person is able to self-manage independently [14-75]. Therefore, the therapeutic guidelines found in this review are not restricted to the professional-patient relationship; these relationships are broad and include families and the community.

XSL•FO
RenderX

Table 3. Mapping of the results regarding the therapeutic guidelines.

Therapeutic guideline	Subinterventions
Adopting healthy habits	• Physical activity or regular exercise [21,26,27,29,30,33,37,38,41-57] • Healthy eating [26,27,29,37,41-46]
Leisure or pleasurable activities	• Listening to music, watching movies, reading, painting, going out with friends, taking outdoor walks, and practicing spiritual and religious activities [37,38,41,50]
Relaxation techniques	• Progressive muscle relaxation [33,41,66] • Respiratory rehabilitation [16,26,27,29,30,36] • Stretching [16,26,27,29,41,66] • Warm baths [16] • Massages [29,41,66] • Meditation [30]
Pharmacological therapy	• Psychopharmacological therapy [16,20,26,28,29,36,38,41,57]
Consultation with a health professional	• Psychoeducation or professional counseling [16,20,23,26,27,29,36-38,41-43,57,66]
Psychotherapy	• Behavioral activation [69,73] • Cognitive behavioral psychotherapy [14,16,23,26,29,31,38,58,67-71] • Mindfulness [22,26,28,36-38,59-66] • Psychotherapy focused on problem-solving [29,38,74] • Competitive memory training psychotherapy [71] • Self-efficacy psychotherapy [46] • Guided self-help psychotherapy [23,72] • Interpersonal psychotherapy [17,23,56] • Therapy focused on acceptance, commitment [62], and emotion [75]
Integrative and complementary practices	• Acupuncture [19,26,29,39] • Music therapy [24,30-33] • Phytotherapy [26,29] • Phototherapy [26,29] • Aromatherapy [19] • Cryotherapy [29] • Thermotherapy [29] • Tai chi [17,29,38] • Reflexology [29] • Qigong [29] • Yoga [25,29,34-37] • Art therapy [40] • Chromotherapy [20]

Discussion

Principal Findings

From this review, it was possible to identify the therapeutic guidelines for the self-management of the symptoms of major depressive disorder in scientific production as psychotherapy, adoption of healthy habits, integrative and complementary practices, relaxation techniques, consultation with a health professional, pharmacological therapy, and leisure or pleasurable activities.

The selected studies show that knowledge on the subject significantly improves self-management of the symptoms of major depressive disorder through these therapeutic guidelines to promote behavior changes and awareness of the symptoms of the disorder, prevention of relapses, reduction of the perception of obstacles, and increased adherence to treatment.

A small number of articles published in journals on the subject were found for all the symptoms investigated, especially irritable mood, followed by fatigue, weight change, appetite change, sleep changes, and low self-esteem, necessitating the addition of secondary documents that considerably broadened the identification of other therapeutic guidelines.

Most of the studies originated in America (40/62, 63%), where the largest number of people with major depressive disorder is concentrated. Regarding the concept that triggered the research, the studies involved health professionals, students, and the general population, covering the definition, description, comparative analysis, efficiency, and applicability of therapeutic guidelines. These studies were included to increase the possibility of nurses playing a leading role in the self-management of symptoms of major depressive disorder [14-75].

The factors considered important for the self-application of therapeutic guidelines in the studies were cognition; level of education; environmental factors; and the functional capacity of the patient, caregivers, and family members. It should be emphasized that, for self-management, clients who are going

XSL•FO
RenderX

to follow these therapeutic guidelines should receive them in clear and objective language and format, with specificity and relevance for each symptom, enabling adherence to treatment and favoring the therapist–patient or caregiver bond [26]. These therapeutic guidelines are also considered low cost and easy to use, optimize rehabilitation and autonomy, and encourage self-care [26]. It is important to highlight the definitions of each of the therapeutic guidelines identified in this review.

Integrative and complementary practices, as therapeutic resources based on traditional knowledge, were the therapeutic guidelines most commonly found in the literature as effective for the self-management and management of major depressive disorder symptoms, and their applicability aimed to induce a state of harmony and balance throughout the body.

Phototherapy has been shown to reduce depressive symptoms and improve irregularities in sleep patterns and quality, especially in older adults with major depressive disorder, as long as it is used with a certain frequency and is administered before 10 AM [14-16,26]. It has also been used in the control of nocturnal hyperphagia and has shown reductions in the percentage of food eaten after dinner and in the number of nocturnal meals eaten per week, reducing the rate of overweight and obesity, as well as being used in the control of fatigue, where it has shown a reduction in the feeling of tiredness [29].

Music therapy applied to adults [24] has been shown to be effective in physical and mental relaxation, reducing anxious and depressive symptoms and promoting well-being in a conscious and healthy way [30]. Listening to soothing noises and classical music associated with rhythmic breathing produced a significantly higher rate of adherence to major depressive disorder treatment, especially in the patients with the highest severity [31-33].

A study has shown that anhedonia and clinically significant depressive symptoms can be resistant to standard treatment but adjuvant treatment with high-frequency inaudible sound therapy increases the reward of related brain circuits and has a synergistic effect on anhedonia [31]. Integrating music therapy with conventional major depressive disorder treatment (therapies and medication) gives people the opportunity to get in touch with their emotions and provides distraction and a means of communication capable of overcoming barriers and limits to verbal expression [30].

Yoga [29,34,35] has been a beneficial exercise for managing sleep quality and other symptoms of major depressive disorder [25,36]. It is an important tool for promoting self-care and, consequently, care for everything around the patient [37]. A study carried out to explore the experiences of patients with major depressive disorder showed that practicing yoga as a self-management strategy helped them gain better insights into their own condition, improving the quality of their health care [37].

Tai chi has been shown to be more effective than traditional rehabilitation (psychotropic drugs and therapies) in relation to insomnia, with an improvement in the quality, duration, and efficiency of sleep and a reduction in thoughts of guilt associated with major depressive disorder [17,29,38]. Acupuncture has been shown to be effective in treating people with major depressive disorder [18,39], mainly in reducing sleep disorders but also in symptoms related to changes in appetite, irritability, anxiety, and sadness, and has not been shown to be effective for suicidal ideation [26,29].

With regard to herbal medicines, St John's wort, *chai hu*, and *gancao* were the most widely used. In 3% (2/62) of the studies, after 2 weeks of administering these herbs (alone or in combination) as an alternative to conventional antidepressants, they produced a statistically significant improvement in symptoms of altered sleep [26,29]. Although the effects of these herbs are not fully understood, it is likely that they produce antidepressant effects through multiple pathways or targets that interact with each other.

To a lesser extent among the studies but no less importantly, aromatherapy [19], cryotherapy, thermotherapy, reflexology, qigong [29], art therapy [40], and chromotherapy [20] improved empowerment in the search for self-care and taking responsibility for one's own health, as well as reducing levels of anxiety and stress, improving sleep disorders, improving the immune system, and lowering blood pressure levels [29].

People with major depressive disorder have shown improvements in sleep disorders, anxiety, and stress, as well as enhancements in immune system function and reductions in blood pressure levels when using respiratory rehabilitation [16,26,27,29,30,36], stretching [16,26,27,29,41,66], warm baths [16], massages [29,41,66], acupuncture, herbal medicine, phototherapy, reflexology, qigong, and yoga [17,19,20,24,26,29,34,38-40] as therapeutic guideline.

Cryotherapy and thermotherapy are not commonly used to treat the symptoms of major depressive disorder, but they help relax the body and mind as a physiotherapeutic resource [16,29]. There was a significant improvement in stress and body pain related to fatigue, anxiety, and swelling in the feet and legs [29].

Another important therapeutic guideline was the adoption of healthy lifestyle habits, such as healthy eating [17,26,27,29,41-46] and physical exercise [21,26,27,30,33,37,38,41-57]. These reduce stress; improve mood, body image perception, and self-esteem; stimulate cognitive functioning; promote greater satisfaction with life [45,46]; and can help people feel stronger and more capable, helping reduce the feelings of hopelessness and helplessness associated with major depressive disorder [53,54].

It should be noted that, regardless of the physical activity chosen, people with major depressive disorder need to make it part of their routine and do it [47] according to their tolerance and state of health [54]. An important concern in relation to physical activity for people with major depressive disorder is the fact that some of the common symptoms of depression (fatigue, lack of energy, psychomotor retardation, despair, and feelings of worthlessness) interfere with the motivation to exercise [57].

In more severe cases, practicing physical activity can be difficult for people with major depressive disorder [55]. This can compromise adherence and long-term permanence in the exercise program [52]. It is recommended to prescribe structured

XSL•FO
RenderX

exercises based on the activities already practiced by the patient to reduce obstacles [33].

Another group of therapeutic guidelines that were also commonly identified in this review were psychotherapies. Mindfulness-based therapy [58,59] is a promising therapeutic approach for treating major depressive disorder and is part of the list of integrative and complementary practices [26,37,60]. It combines elements of therapeutic guidelines [22,61] with the aim of helping people develop a full awareness of the present moment, accepting and acknowledging their thoughts, emotions, and bodily sensations without judgment [62] and learning to observe their negative thoughts and dysfunctional thought patterns without allowing themselves to be involved with or controlled by them [63].

Mindfulness improves self-management of prodromal symptoms [64], represents a stability factor when practiced frequently and in a supervised manner [28], positively influences memory and distorted feelings of guilt, increases cognitive resilience, balances mood and sleep, reduces high levels of stress, and improves self-esteem and anxiety [65] associated with major depressive disorder relapse.

Similarly, cognitive behavioral psychotherapy [26,66] uses positive reinforcement techniques and systematic desensitization, helping people cope with stress, face the challenges of everyday life, change negative thought patterns and behaviors to more realistic and positive ones [23,67], and identify the first signs of relapse and prevent it as it focuses on social skill training [68,69]. Recently, online cognitive behavioral psychotherapy has been shown to be effective for depressed and angry mood as a cost-effective treatment modality for major depressive disorder [70].

Other psychotherapies aimed at influencing the person with major depressive disorder and helping them modify emotional, cognitive, and behavioral problems were self-efficacy psychotherapy [46]; competitive memory training [71]; guided self-help psychotherapy [23,72]; behavioral activation [69,73]; interpersonal psychotherapy [38,57,67]; psychotherapy focused on problem-solving [29,38,74]; and therapy focused on acceptance, commitment, and emotion [62,75].

Leisure time or pleasurable activities as a social practice, contrary to what is often thought, are not only carried out during the summer or on vacation but also in between daily obligations [37]. Thus, they can take the form of individual or group dynamics, whether it is reading a book, listening to music, or going for a walk with friends [37,50]. The relationship between leisure and health has fostered new techniques for the treatment of depressive disorders with the aim of enabling the individual's psychic and social readaptation [37,50].

Painting for leisure, for example, can promote the manifestation of feelings through emotions expressed verbally or not, thus helping understand the mind and its sorrows [38]. In this sense, of the possibilities for leisure activities recommended by the professionals who collaborated with the data found, art therapy [40], group and individual outings [41,50], trips [38], reading books and watching movies [37,38], listening to music [31], and attending religious institutions [50] were the most cited in the studies.

In the context of pharmacological treatment, antidepressants associated with psychotherapies [26,29,37] should be administered with caution and under medical supervision [20,38,41] based on the therapeutic alliance, clinical history, monitoring and reassessment of psychiatric conditions, and adequacy of the diagnosis, and guidance should be provided for families [28,57].

In 5% (3/62) of the studies, the association of psychotropic drugs with therapeutic guidelines was highlighted (due to the severity of the major depressive disorder clinical picture) even in the face of difficulties with medication adherence for different reasons [16,29,38], which should be anticipated and addressed proactively in every contact with the patient. Approximately 30% to 40% of people using antidepressants still do not respond as expected to treatment [27,41].

Relaxation techniques appeared in this review as a more appropriate way of coping with the psychological, environmental, and social stimuli that people with major depressive disorder may face. Among these strategies, breathing techniques [16,26,27,29,30,36], progressive muscle relaxation [33,41,66], massages [29,41,66], stretching [16,26,27,29,66], a warm bath [16], and meditation [30] were the most cited.

In the context of major depressive disorder, these techniques promote muscle relaxation, relieve stress and tension, rebalance emotions, produce hormones such as endorphins, provide a sense of well-being, and significantly improve sleep quality [16]. Incorporating these practices throughout the day or even before going to bed helps people let go of tiredness, become aware of the present moment, and pay attention to their own bodies [16,66].

Finally, therapeutic guidelines for psychoeducation or professional counseling can be used to help with self-management as major depressive disorder generates changes in the family system and structure [16,18,26,36,38], resulting in the need for clarification to relieve anxieties and doubts to improve the psychological well-being of the patient [20,37,42,43].

Thus, the wide variety of therapeutic guidelines found can increase knowledge about the symptoms and aspects of major depressive disorder, allowing the person to self-manage symptoms such as fatigue, sleep disturbances, anhedonia, and mood swings [16,27,29,66] in a more responsible and autonomous way.

These therapeutic guidelines are characterized by providing information on the diagnosis, etiology, prognosis, and course of the illness; the identification of early signs of crisis; the importance of adherence to medication or psychosocial treatment; the promotion of healthy habits and regularity in lifestyle (sleep, diet, physical activity, and substance use); and how to deal with the stigmatization, doubts, fears, and myths regarding major depressive disorder [23,41,42].

Therefore, the implications for practice are based on the fact that therapeutic guidelines help in the self-management of major

XSL•FO
RenderX

depressive disorder through behavioral, social, and emotional changes that allow for better construction of clinical reasoning, adaptation, autonomy, coping, and improvement of general health.

Limitations

The limitations of this scoping review are related to the nature of the review itself as its aim was to provide an overview of therapeutic guidelines, which may not be sufficient for the self-management of major depressive disorder as it is a complex clinical condition with a heterogeneity of symptoms. Furthermore, despite efforts to develop a comprehensive search strategy, it was difficult to find controlled and uncontrolled descriptors for the term "therapeutic guidelines," which is not an indexed descriptor.

Conclusions

By analyzing the methodological approach adopted in this study, and in accordance with the proposed objectives, it was possible to highlight a set of therapeutic guidelines to support a person's self-management in the context of major depressive disorder symptoms. This does not preclude further study of their effectiveness in the self-management of major depressive disorder symptoms but demonstrates their contribution to promoting self-management of major depressive disorder and their power to prevent possible complications.

Self-management is a promising strategy that emphasizes the person's responsibility in the care process. It goes beyond participation in health care interactions and includes dealing with symptoms and disability; managing medication and monitoring indicators; maintaining adequate levels of nutrition and exercise; and adjusting to psychological, social, and lifestyle demands.

These therapeutic guidelines can be applied by all members of a multi-professional mental health team, including nurses, provided they are trained as resources to help the person acquire new knowledge, behaviors, and skills for self-management. These guidelines are also an important resource for health professionals in their role as facilitators of a person's development of knowledge and skills to ensure their capacity for self-management.

Acknowledgments

This study was financed in part by the Coordination for the Improvement of Higher Education Personnel, Brazil (finance code 001) and by National Council for Scientific and Technological Development Ministry of Science, Technology and Innovation call 10/2023, Track A—Emerging Groups (process 403740/2023-1). The funders had no role in the study design; data collection, analysis, and interpretation; writing of the manuscript; or decision to publish. Generative artificial intelligence was not used in the writing of this manuscript.

Data Availability

All data generated or analyzed during this study are included in this published article (and its supplementary information files).

Authors' Contributions

PdCT contributed to the conceptualization, data curation, investigation, methodology, resource management, validation, and software implementation. PdCT was also responsible for visualization and contributed to both drafting the original manuscript and reviewing and editing it; PMM was responsible for data curation, formal analysis, and investigation; DMP contributed to investigation, methodology, and resource management; MAMJ was responsible for validation and visualization; MAdL contributed to data curation and formal analysis. CSF was involved in data curation, formal analysis, supervision, and drafting the original manuscript; CSVdBS contributed to data curation, formal analysis, and drafting the original manuscript. MdPSdSN contributed to the conceptualization of the study, data curation, funding acquisition, investigation, methodology, project administration, resource management, supervision, validation, and visualization. MdPSdSN also played a key role in drafting the original manuscript and in reviewing and editing it. All authors have read and approved the final version of the manuscript.

Abstract

Background: Adult spinal deformity (ASD) is a prevalent condition often treated with circumferential spinal fusion (CF), which can be performed as staged or same-day procedures. However, evidence guiding the choice between these approaches is lacking.

Objective: This study aims to compare patient outcomes following staged and same-day CF for ASD.

Methods: Following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, a comprehensive literature search was conducted in PubMed, MEDLINE, Embase, Cochrane CENTRAL, Web of Science, and Scopus. Eligibility criteria included studies comparing outcomes following staged and same-day CF in adults with ASD. Searches were exported to Covidence, and records were deduplicated automatically. Title and abstract screening, full-text review, and data extraction were performed by two independent reviewers, with all conflicts being resolved by a third reviewer. A meta-analysis was conducted for outcomes reported in 3 or more studies.

Results: Seven studies with 741 patients undergoing CF for ASD were included in the review (staged: n=331, 44.7% and same-day: n=410, 55.3%). Four studies that had comparable outcomes were merged for the quantitative meta-analysis and split based on observed measures. The meta-analysis revealed significantly shorter hospital length of stay (mean difference 3.98, 95% CI 2.23-5.72 days; P<.001) for same-day CF. Three studies compared the operative time between staged and same-day CF, with all reporting a lower mean operative time for same-day CF (mean between 291-479, SD 129 minutes) compared to staged CF (mean between 426-541, SD 124 minutes); however, inconsistent reporting of mean and SD made quantitative analyses unattainable. Of the 4 studies that compared estimated blood loss (EBL) in the relevant groups, 3 presented a lower EBL (mean between 412-1127, SD 954 mL) in same-day surgery compared to staged surgery (mean between 642, SD 550 to 1351, SD 869 mL). Both studies that reported intra- and postoperative adverse events showed more intraoperative adverse events in staged CF (10.9% and 13.6%, respectively) compared to same-day CF (9.1% and 3.6%, respectively). Four studies measuring any perioperative adverse events showed a higher incidence of adverse events in staged CF than all studies combined. However, quantitative analysis of EBL, intraoperative adverse events, and perioperative adverse events found no statistically significant difference. Postoperative adverse events, reoperation, infection rates, and readmission rates showed inconsistent findings between studies. Data quality assessment revealed a moderate degree of bias for all included studies.

XSL•FO
RenderX

Conclusions: Same-day CF may offer shorter operating time and hospital stay compared to staged CF for ASD. However, there was marked heterogeneity in perioperative outcomes reporting, and continuous variables were inconsistently presented. This underscored the need for standardized reporting of clinical variables and patient-reported outcomes and higher evidence of randomized controlled trials to elucidate the clinical superiority of either approach.

Introduction

Adult spinal deformity (ASD) is defined as abnormal curvature of the spine and is becoming increasingly prevalent, affecting up to 68% of the older adult population [1,2]. ASD is a complex spectrum of spinal pathology, including deformities such as lordosis, kyphosis, or scoliosis of the lumbar and thoracic spinal column. Although untreated adolescent ASD does occur, it typically presents in patients older than 60 years due to factors such as age-related spinal degeneration or reduced bone density [1,3].

Individuals with ASD can undergo expectant (observation alone), nonoperative, or operative therapies. At present, there is no high-quality evidence to support the decisions surgeons and patients face in treatment selection [4]. In past years, pain management and physical therapy were the preferred treatment options for ASD due to the high risk of adverse events, prolonged recovery time, and financial burden associated with surgical intervention [1,5]. If nonsurgical approaches fail to improve patients' quality of life, surgical intervention is often considered. Multicenter retrospective cohort studies previously showed an improvement in patient-reported outcomes following the surgical management of ASD [3,6]. Indications for surgery include (1) progressive curvature of the spine with sagittal or coronal imbalance, (2) significant loss of pulmonary function caused by the misalignment and deformity, and (3) loss of function due to pain associated with spinal curvature [7-10]. These are weighted against the patient comorbidities and risks of operation [11].

Long-segment surgical management by circumferential spinal fusion (CF) has increased in popularity due to its added stability granted by both anterior and posterior fixation of the spinal column [12]. CF attempts to remedy the limitations of lateral approaches alone, such as the need for intraoperative patient repositioning, which increases operative time and puts the patient at risk for adverse events due to longer time under anesthesia [13-15]. ASD can be treated by CF in 2 primary ways: staged and same day. Staged fusions occur on 2 distinct operative days, while same-day fusions are completed within a single session. Staging is largely determined by surgeon preference and case complexity, which can cause variability in the clinical management of ASD. The preference to treat with or without staging does not necessitate a gold-standard treatment for a given case complexity but rather can depend on surgical training differences and hospital administration pressures. To our knowledge, there has not been a review of published literature on staging in CF. This systematic review and meta-analysis aims to assess and quantify the patient outcomes after staged and same-day CF for ASD to guide operative decision-making and patient selection.

Methods

Guidelines, Protocol, and Registration

The design and reporting of this study were supported by the following guidelines: PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses; Multimedia Appendix 1) and PRISMA-P (Preferred Reporting Items for Systematic Review and Meta-Analysis Protocols) [16,17]. In accordance with PRISMA-P guidelines, the protocol of the systematic review was registered on the PROSPERO (CRD42022339764) and disseminated through *JMIR Research Protocols* (PRR1-10.2196/4233), with the protocol being published before any data were collected [12]. There were no deviations from the protocol.

Eligibility Criteria

The Population, Intervention, Comparison, Outcome (PICO) framework was used to formulate inclusion criteria.

- Population: Adults with ASD
- Intervention: Staged CF surgery
- Comparison: Same-day CF surgery
- Outcomes: Perioperative outcomes (estimated blood loss [EBL], operative time, and length of hospital stay), adverse events, infection rates, and hospital readmissions or reoperations

Studies that do not differ in surgical timing (staged vs same day), nonhuman or adolescent patient populations, reviews, conference abstracts, single-case studies, or technical notes were excluded from the analysis. Further, only studies originally published in English were considered.

Search Strategy

Databases explored included PubMed, MEDLINE, Embase, Cochrane CENTRAL, Web of Science, and Scopus. A literature search was conducted in accordance with the PRISMA guidelines on August 2, 2023. We used a complex search string that was modified and fitted to the unique search functions of each queried database (Multimedia Appendix 2). Additional

XSL•FO
RenderX

searching through gray literature and reference lists was conducted to identify studies not initially captured by the database query.

Data Selection and Extraction

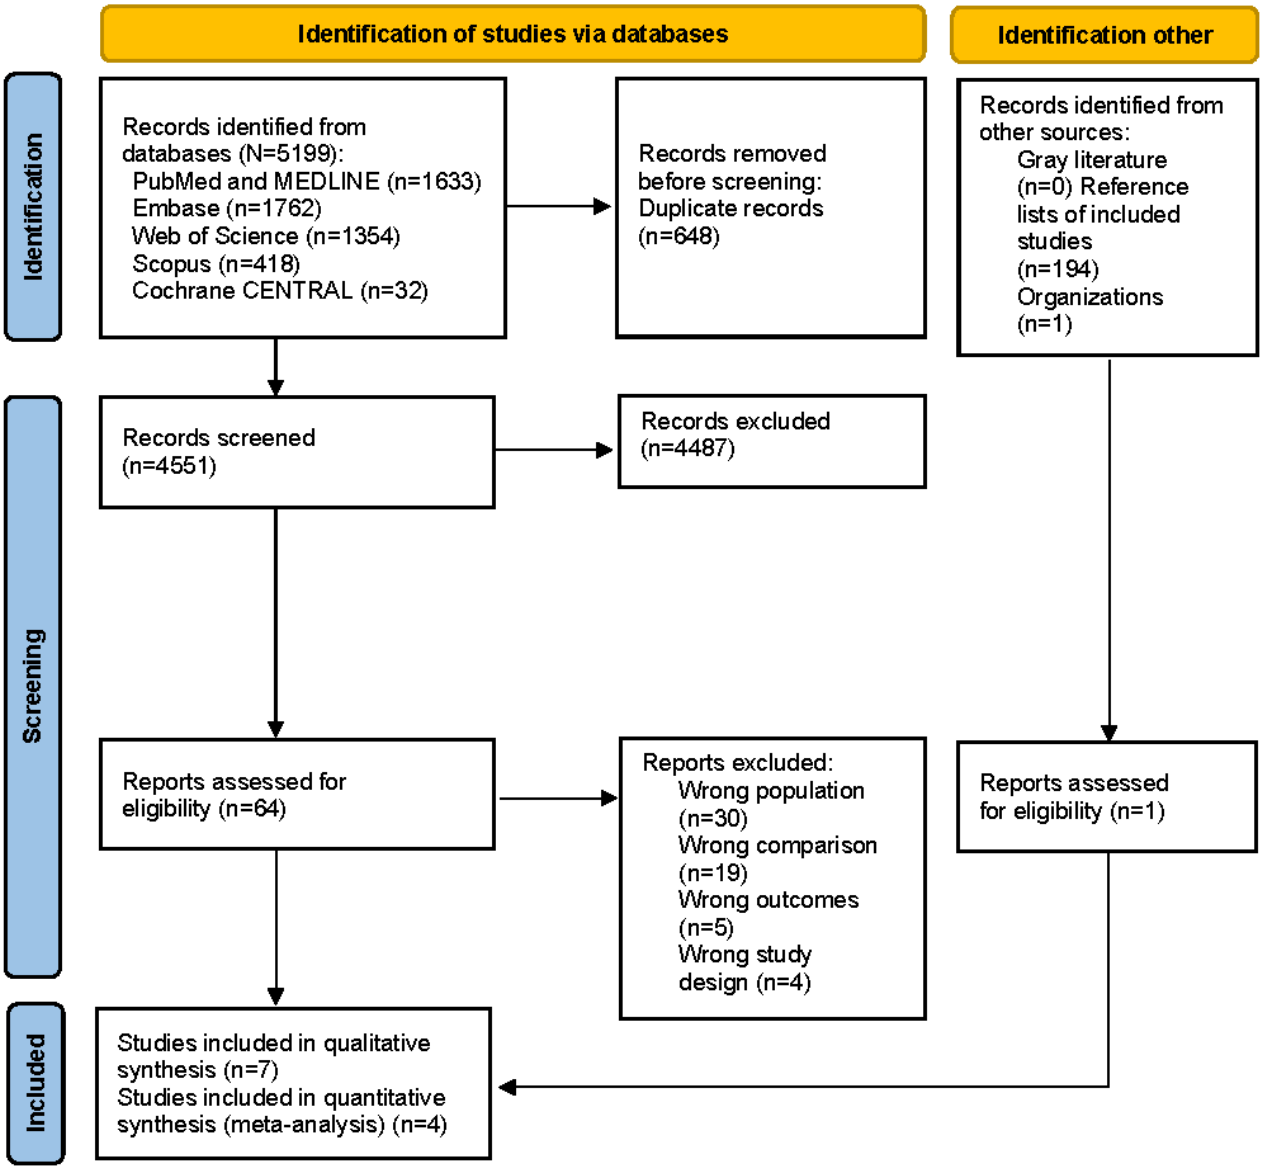
Studies and full text were screened, data were extracted using Covidence (Veritas Health Innovation), and duplicates were automatically removed by the software [18]. Titles and abstracts were first screened independently by 2 reviewers (FCO and ME). Next, the full text of each paper was assessed by 2 reviewers (FCO and ME) to determine the eligibility of the studies. At both stages, a third reviewer (MMD) resolved any conflicts. The following data were extracted by two authors (FCO and ME) with a third (MMD) resolving any conflicts: authors; publication year; location; number of patients; age; study type; population details; surgery details; and results, including intraoperative adverse events, postoperative adverse events, postoperative infection, perioperative adverse events, hospital length of stay (LOS), intensive care unit (ICU) LOS, reoperation, readmission, and patient-reported outcomes.

Data Quality

The ROBINS-I (Cochrane) tool was used to assess the risk of bias in the included nonrandomized studies, covering bias due to confounding variables, patient selection, classification of interventions, deviations from intended interventions, missing data, measurement of outcomes, and selection of reported results [19]. Two reviewers (FCO and JG) independently scored all domains, with a third reviewer (MMD) resolving any conflicts. Robvis was used for figure generation [20].

Data Synthesis

Studies with comparable outcomes were merged for the quantitative meta-analysis and split based on observed measures. After conducting a qualitative evaluation, we determined that there were sufficient data to perform a meta-analysis. RevMan (version 8.4; Cochrane) using random-effects modeling was used for all quantitative analyses. Mean differences for continuous variables (surgical time, EBL, hospital LOS, and ICU LOS) and odds ratios for categorical variables (intraoperative adverse events, postoperative adverse events, postoperative infection, any adverse events, readmission, and reoperation) were the end points of the meta-analysis.



Results

Study Identification

In our search (Figure 1), we identified 5199 unique studies by searching PubMed, MEDLINE, Embase, Cochrane CENTRAL, Web of Science, and Scopus, which were included for abstract screening, of which 64 were forwarded for full-text screening. After full-text review, 7 original studies were included in the data extraction process and 4 of them were in the quantitative analysis [21-27]. Studies were excluded during the full-text review for the following reasons: wrong comparator (n=19, 29.7%), wrong patient population (n=19, 29.7%), pediatric population (n=11, 17.2%), wrong outcomes reported (n=5, 7.8%), and wrong study design (n=4, 6.3%).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Review and Meta-Analysis) flow diagram.

Baseline Parameters

Six of the studies included were conducted in the United States [21-25,27], while 1 study was conducted in Japan [26]. The included studies describe a total of 741 patients undergoing either staged (n=331, 44.7%) or same-day (n=410, 55.3%) CF for ASD: 297 (40.1%) patients underwent anterior lumbar interbody fusion, 408 (55.1%) patients underwent lateral interbody fusion (extreme lateral interbody fusion, direct lateral interbody fusion, and lateral lumbar interbody fusion), 54 (7%) patients underwent either lateral lumbar interbody fusion or transforaminal lumbar interbody fusion, and all 741 patients underwent posterior spinal fixation. The average number of fused vertebrae across studies ranged from 4.4 to 10 (SD 3.9). The largest variation between groups within a study ranged from 7.3 (SD 3.1) in the same-day group versus 10 (SD 3.9) in the staged group. The combined mean vertebrae fused for staged and same-day CF was 7.54 (SD 2.41) and 6.62 (SD 2.40), respectively. The follow-up period over all included studies ranged from 1 to more than 36 months, and the average age of patients ranged from 58.8 (SD 9.0) to 72.3 years. The patients included in the study of Masuda et al [26] and Albayar et al [21] were inverse probability weighted to facilitate the comparison of spinal deformity and control for any differences between the groups (Table 1).

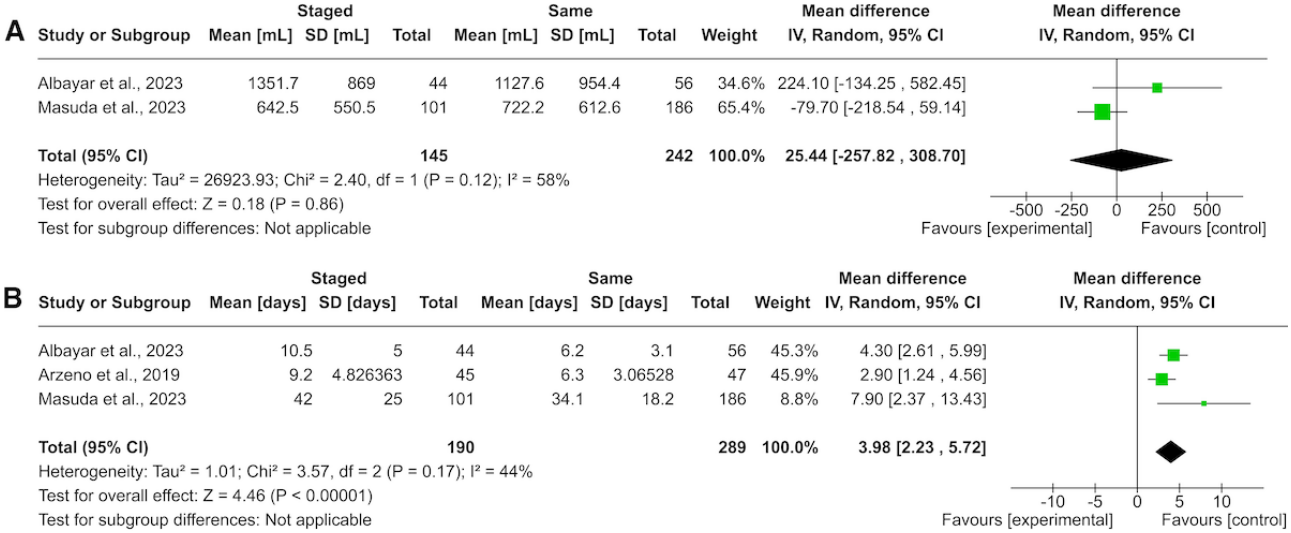
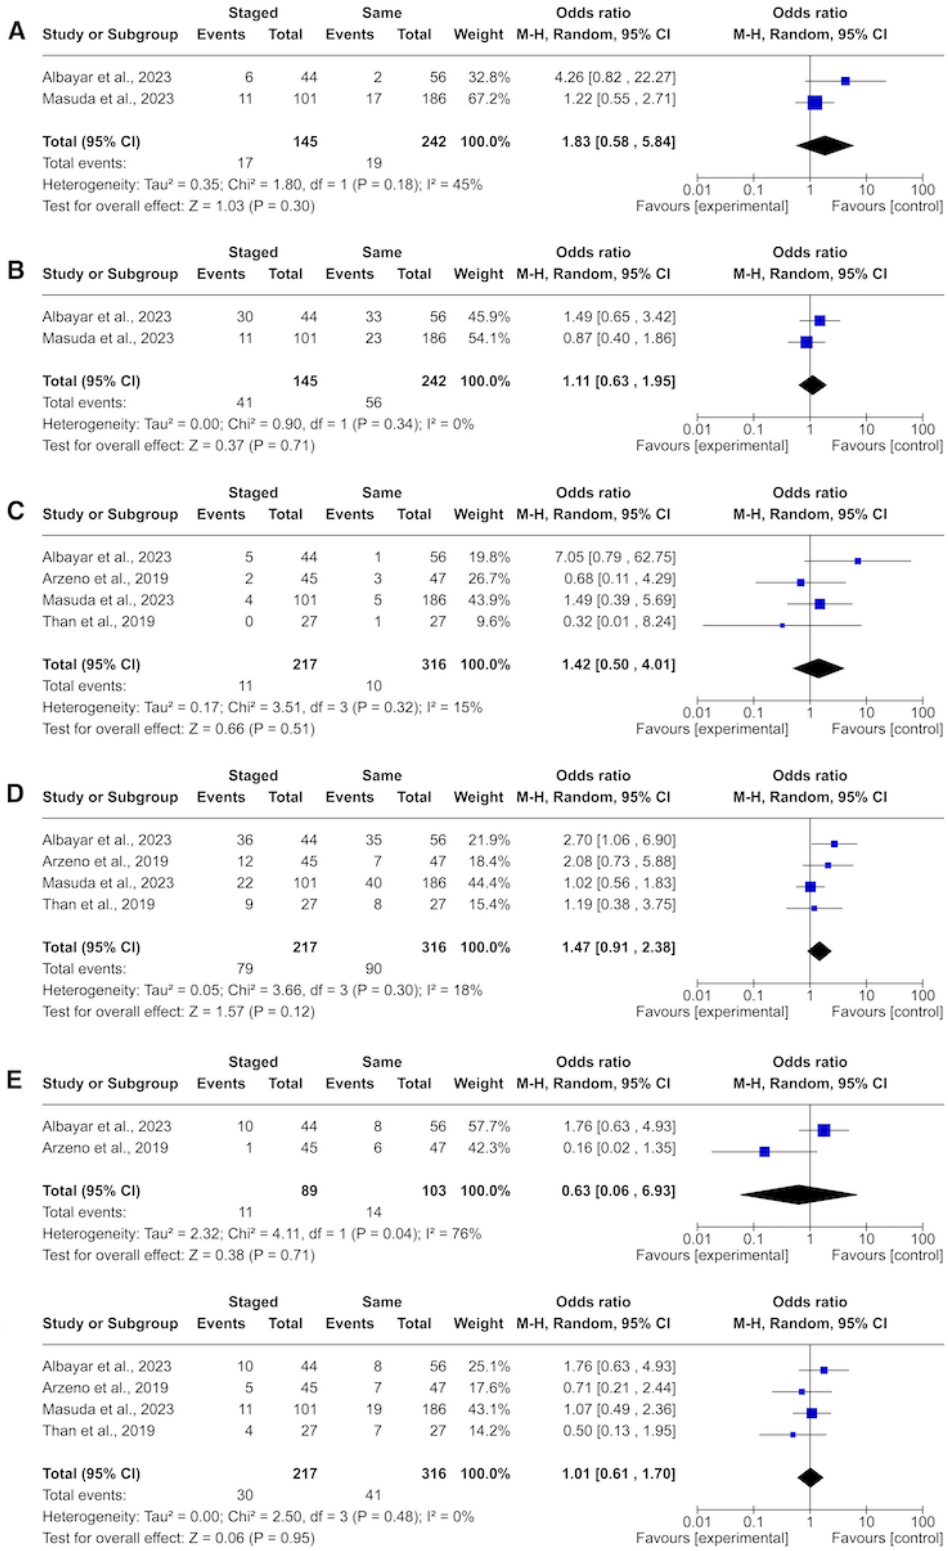
[v]TLIF: transforaminal lumbar interbody fusion.



Quantitative Analysis

Of the included studies, 4 studies compared EBL in the relevant groups, with 3 studies presenting a lower EBL (mean between 412-1127, SD 954 mL) in same-day surgery compared to staged surgery (mean between 642, SD 550, and 1351, SD 869 mL) [21-24]. The meta-analysis shows a nonsignificant advantage for same-day surgery **(**Figure 2A [21,24,26]). Only 2 studies that measured EBL were included in the quantitative analysis because of inconsistencies in reporting, where some did not report variables as measures of variance, which made pooling in these instances not feasible. Three studies compared the operative time between staged and same-day CF, with all of them reporting a lower mean operative time for same-day CF (mean between 291-479 minutes) compared to staged CF (mean between 426-541 minutes) [22-24]. Just 1 group reported mean and SD for odds ratio time, thus restricting the potential for a quantitative analysis.

Three studies comparatively evaluated the hospital LOS [21,22,25]. All three studies consistently found that the mean LOS was less for same-day CF (mean between 6-34.1 days) in comparison to staged CF (mean between 9-42 days). The meta-analysis clearly presented a shorter LOS in patients undergoing same-day CF compared to staged CF (Figure 2B).



Two of the 7 studies compared intraoperative and postoperative adverse events between staged and same-day CF procedures [21,26]. Both Masuda et al [26] and Albayar et al [21] reported more intraoperative adverse events in staged CF (10.9% and 13.6%, respectively) compared to same-day CF (9.1% and 3.6%, respectively); however, the meta-analysis failed to show a statistically significant difference between the groups (Figure 3A [21-27]). Masuda et al [26] reported fewer postoperative adverse events in staged CF (10.9 vs 12.4%), while Albayar et al [21] presented a lower incidence in same-day CF (53.6 vs 68.2%), without a significant difference in the meta-analysis (Figure 3B). Four studies measured any perioperative adverse events [21,22,26,27]. The overarching analysis showed a higher incidence of adverse events in Staged CF over all studies; however, the meta-analysis did not show significance (Figure 3D).

Figure 2. Forest plots comparing (A) estimated blood loss and (B) hospital length of stay between patients who underwent staged or same-day circumferential spinal fusion for adult spinal deformity. IV: inverse variance.

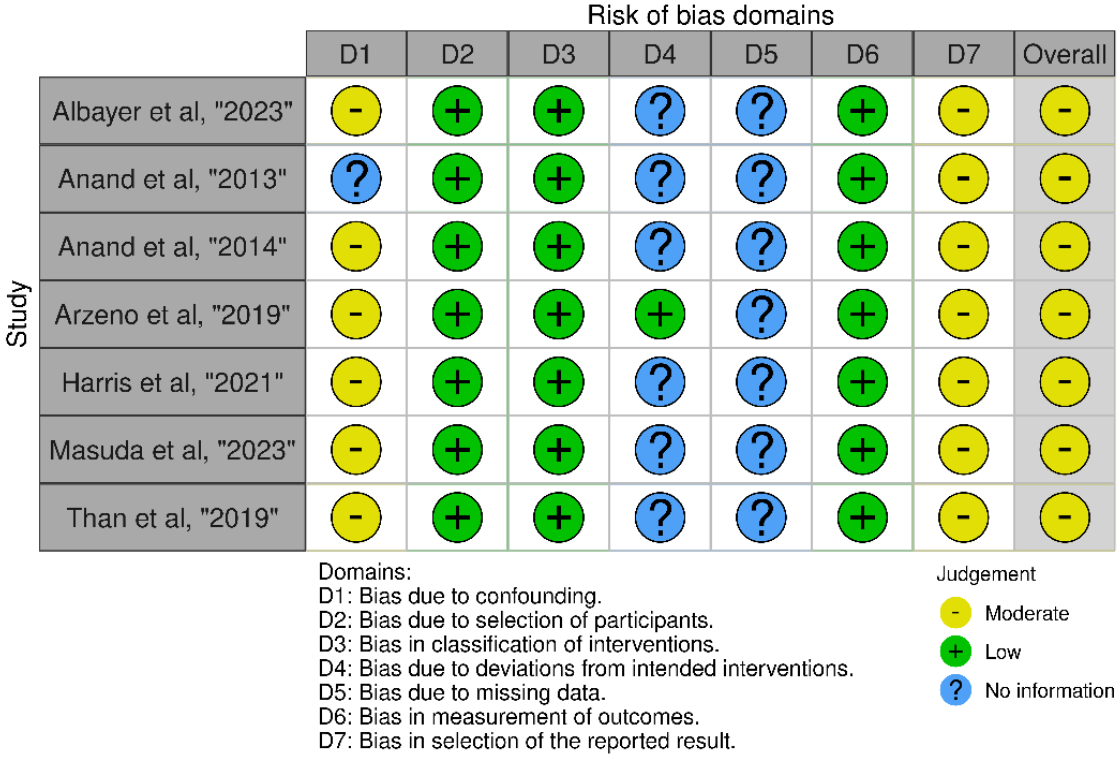
XSL•FO
RenderX

Figure 3. Forest plots comparing (A) intraoperative adverse event, (B) postoperative adverse event, (C) postoperative infection, (D) perioperative adverse event, (E) 30-day readmission, and (F) reoperation rates between patients who underwent staged or same-day circumferential spinal fusion for adult spinal deformity. M-H: Mantel-Haenszel.

Four of the included studies compared reoperation and postoperative infection rates between patient groups [21,22,26,27]. Albayar et al [21] and Masuda et al [26] showed a slightly lower postoperative infection in same-day CF versus staged CF (4.4 vs 6.4%, 2.6 vs 4%, and 1.7 vs 11.4% respectively), while Than et al [27] showed a lower postoperative infection in staged CF (0% vs 3.7%;Figure 3C). While Arzeno et al [24] and Than et al [27] reported a lower reoperation in patients undergoing staged CF (11.1 vs 14.9% and 14.8 vs 25.9%, respectively). Masuda et al [26] and Albayar et al [21] reported less reoperation in patients undergoing same-day CF versus staged CF (10.2 vs 10.9% and 14.2 vs 22.7% respectively). However, none of these differences in

XSL•FO
RenderX

reoperation reached statistical significance in either the original respective studies or our meta-analysis (Figure 3F).



Readmission rates reported by Arzeno et al [24] and Albayar et al [21] demonstrated diverging results. Arzeno et al [24] found a lower readmission for staged CF versus same-day CF (2.2 vs 12.8%), while Albayar et al [21] reported a higher readmission in staged CF versus same-day CF (22.7 vs 14.3%). The meta-analysis did not indicate a conclusive result (Figure 3E).

Harris et al [25] are the only authors reporting on either the Oswestry Disability Index (ODI) or the Scoliosis Research Society Score, showing a better outcome measured by the ODI in same-day CF and no difference in Scoliosis Research Society Score.

Risk of Bias Analysis

There was a moderate degree of bias for all included studies (Figure 4 [21-27]).

Figure 4. ROBINS-I traffic light plot of included studies.

Discussion

Overview

In this systematic review and meta-analysis, we compared differences in perioperative outcome variables for individuals undergoing staged or same-day CF in 7 included studies. The meta-analysis revealed a statistically significant increase in hospital LOS in the staged group when compared to the same-day group. There were no statistically significant differences in EBL, intraoperative adverse event, postoperative adverse event, postoperative infection, perioperative adverse event, 30-day readmission, and reoperation rates between patients who underwent staged or same-day CF for ASD. There were marked differences between patient populations and the subsequent clinical outcomes that were reported in each observational study, which most did not adjust for. Our quantitative results are paradoxical as there were inconsistencies between studies in the staged and same-day subgroups for certain reported outcomes, while other findings had stronger conclusive evidence. Due to the apparent differences in consensus, the research included in the following discussion is organized according to the consistency of results.

Mixed Findings

Heterogeneity in meta-analyses grants the opportunity to examine variable factors that may be leading to the results. There were several reported outcomes that yielded inconclusive evidence in this study. Adverse event rates were reported by authors in several ways, with some splitting between intraoperative or postoperative adverse events, while others reported any adverse event throughout the perioperative course. Two studies reported more intraoperative adverse events in staged CF, but the meta-analysis failed to show a statistically significant difference. This can indicate that there is an increased operative risk when staging, but it can also be due to the generally sicker patients with more spinal deformity that is leading to increased intraoperative adverse events. Further, 1 study presented a lower postoperative adverse events rate during staged CF, while a different group found a higher rate in staged, indicating no difference in postoperative complications between the 2 approaches. When all perioperative adverse events were instead considered, every study reported a higher incidence in staged CF, and this result trended toward significance. Vastly different conclusions depending on the stage of surgery in which the adverse events are considered illuminate the need for greater consistency in reporting outcomes. However, the increased perioperative adverse events seen in staged CF, although not

XSL•FO
RenderX

statistically significant, could be clinically important in decision-making.

The Centers for Medicare & Medicaid Services targeted 30-day readmission rates as a source of unnecessary costs [28]. A study conducted by McCarthy et al [29] found the total hospital costs to surgically treat ASD averaged US $120,394, with primary surgery averaging US $103,143, and total readmission costs of US $67,262 for their cohort. The high costs associated with spine surgery make patient readmission and reoperation lucrative targets. There is profound heterogeneity in reoperation and readmission rates that depend on several factors, such as patient demographics, procedure types, and institutional factors. A recent systematic review found the 30-day readmission rate in spine surgery to be 4.2% and 7.4% [30]. In this review, 2 studies reported readmission with diverging results. Arzeno et al [24] found a lower readmission for staged CF, while Albayar et al [21] reported a higher readmission for same-day CF. Likewise, 4 studies reported reoperation with a split in consensus [21,24,26,27]. Given the small number of studies that measured reoperation and readmission, the results from our meta-analysis were inconclusive. The lack of statistically significant differences in the quantitative analysis combined with the heterogeneity in the qualitative review indicates that no differences in readmission and reoperation rates exist between the 2 groups.

It was also uncommon for the included studies to report specific reasons that reoperation or readmission occurred. As readmission depends on many variables including patient comorbidities, initial risk, or operative adverse events, it is crucial for authors to include these measures in future comparative studies for stronger subgroup analyses. Postoperative infection is also a driver leading to reoperation or readmission, as well as additional health care costs [31]. A recent meta-analysis found the pooled incidence of surgical site infection in 22,475 patients to be 3.1% [32]. Our included studies also reported a low incidence of postoperative infection; however, there were inconsistencies as 3 out of the 4 groups found a lower postoperative infection in same-day CF [21,24,26,27]. There are several risk factors for postoperative infection that may lead to heterogeneity. Farshad et al [33] found that intraoperative EBL was a risk factor for postoperative infection. Some studies found BMIs to be predictors of postoperative infection, although this result remains controversial [34-36]. The discrepancies seen in this review may stem from variations in surgical techniques, perioperative antibiotic prophylaxis, institutional differences, and patient-specific risk factors. The results of this study's meta-analysis do not support any difference between the 2 techniques in postoperation infection risk.

Associations of Operative Variables in CF Staging

For highly invasive spine surgeries, such as long-segmented CF for ASD, patients may require extended resource use [37]. Surgical operative time and LOS are critical metrics in evaluating the efficiency and resource use of staging in CF. Shorter surgical times are generally associated with reduced intraoperative adverse events, lower anesthesia-related risks, and decreased blood loss, thus contributing to improved patient safety and outcomes [15,38]. Peng et al [39] conducted a meta-analysis on correlations between operative time and postoperative infection, and they concluded that there was a 4-fold increase in postoperative infection risk for operations greater than 3 hours [39]. The studies included in our review all found a lower mean operative time for same-day CF.

A shorter LOS is also desirable as it minimizes health care resource use and lowers costs [40]. Further, early mobilization and discharge are associated with improved patient satisfaction and reduced psychological stress [41]. However, reducing LOS has also been associated with an increasing readmission rate at the population level [42]. Our meta-analysis found a significantly lower LOS for same-day CF compared to staged CF. This difference in LOS may be attributed to the cumulative effect of multiple hospital admissions, prolonged recovery periods between surgeries, and the need for additional preoperative preparation in staged CF. While the lower operative time and LOS results in patients undergoing same-day CF seem intuitive, it is important to interpret them cautiously, considering potential factors such as patient selection, discharge criteria, and institutional practices that may differ between studies. Moreover, while shorter operative time and LOS may reduce health care costs and improve resource allocation, they should not compromise patient safety or postoperative care quality.

The results of shorter LOS and operative time combined with the lack of conclusive differences between groups for adverse events, readmission, reoperation, and infection rates indicate that patient prognosis is similar when between staging preferences. The shorter time spent in the hospital and operating room is clinically important and contributes to improved patient safety and outcomes while reducing hospital resource use. However, the potential advantages of staging may outweigh these benefits and thus improve patient prognosis for more complex cases with a higher degree of relative deformity. Therefore, the results from this review and meta-analysis show preference toward same-day CF, while staging may largely depend on a patient's condition. Further studies investigating the impact of patient-specific factors, for example, varying degrees of deformity severity, on treatment selection and subsequent outcomes are required.

Limitations

There are several limitations to this study and the papers included in this review. First, the limited literature comparing staged and same-day CF resulted in only 7 studies being included, which reduced the statistical power of the meta-analysis as only 4 studies qualified for quantitative analysis. All the included studies are retrospective cohort studies with a level of evidence of III or II, and only 2 studies used inverse probability weighting to control for between-patient differences. Consequently, there was a moderate potential for bias, which limited our ability to reach generalizable conclusions. To elucidate the differences in surgical treatment options for CF, it will be necessary to investigate staging in level I or II randomized controlled trials (RCTs). Without RCTs, it is difficult to adjust for surgeon preference bias and the complexity of the case. Each study also demonstrated heterogeneity with respect to the patient outcomes reported,

XSL•FO
RenderX

further limiting the ability for robust statistical analysis. Continuous variables were generally poorly reported since many did not report measures of variance such as mean and SD, but rather mean or median and range (min-max or IQR). This made pooling in those instances not feasible, limiting the generalizability of results. Further, only 1 group presented patient-reported outcomes, such as ODI, which is a standardized clinical variable that can be useful for measuring subjective pain and disability. Novel studies should aim to investigate patient-reported outcomes and standardize the variables being reported, so future meta-analyses will have wider samples to yield more conclusive evidence for staging differences in CF. In doing so, the mixed results presented in this study can be further assessed to support wider implementation of either staged or same-day CF while integrating clinically significant metrics to evaluate patient outcomes.

Conclusions

Here, we present the first systematic review and quantitative meta-analysis on staging in CF to treat patients with ASD. Operative time and hospital LOS were significantly lower in same-day CF surgery, with EBL and perioperative adverse events also trending toward significance. However, there was heterogeneity in additional operative measures, such as intra- or postoperative adverse event rates, reoperation, and readmission, and no differences were found in our meta-analysis. Based on our results, it is suggested that same-day CF is advantageous as a potential time-save with patients spending less time in the operating room and hospital, potentially saving costs. However, it is still unclear whether either same-day or staged CF provides a clinical advantage for patient outcomes. Additional level I and II RCTs should be conducted to elucidate the associations between these variables and provide stronger evidence in favor of either approach.

Data Availability

All data generated or analyzed during this study are included in this published paper.

Authors' Contributions

WCW is the guarantor of the study. MMD and WCW led the conceptualization, data acquisition, analysis, and drafting and revision of the manuscript. RWT, JG, GS, DC, HSA, CAW, TG, JDA, JLG, and BJG contributed to data acquisition, analysis, and drafting. Independent review was performed by FCO, ME, and MMD. All authors contributed to the analysis, interpretation, and drafting. JHS, JWY, AKO, and WCW contributed critical guidance at all stages of the study. The manuscript was reviewed and edited, and its final version was approved by all authors.

Conflicts of Interest

In the past 36 months, AKO has received consulting fees from Medacta and Johnson and Johnson and has served as an E2M ad hoc reviewer for the Journal of Neurosurgery Publishing Group (JNS PG), with no relation to this work. Additionally, within the same period, JWY has received a grant from Johnson and Johnson; consulting fees from Medyssey, TrackX, Richard Wolf, and Johnson and Johnson; holds patents planned, issued, or pending with Kinesiometrics and MedCyclops; and has served in a leadership role on the Scientific Program Committee of the American Association of Neurological Surgeons (AANS)/Congress of Neurological Surgeons (CNS) Joint Section on Disorders of the Spine and Peripheral Nerves, with no relation to this work. All other authors report no conflict of interest.

Abstract

Background: Women have been entering pregnancy less healthy than previous generations, placing them at increased risk for pregnancy complications. One approach to ensuring effective monitoring and treatment of at-risk women is designing technology-based interventions that prevent maternal morbidities and treat perinatal conditions.

Objective: This scoping review evaluates what informatics interventions have been designed and tested to prevent and treat maternal morbidity.

Methods: MEDLINE, Embase, and Cochrane Library were searched to identify relevant studies. The inclusion criteria were studies that tested a medical or clinical informatics intervention; enrolled adult women; and addressed preeclampsia, gestational diabetes mellitus (GDM), preterm birth, Centers for Disease Control and Prevention–defined severe maternal morbidity, or perinatal mental health conditions. Demographic, population, and intervention data were extracted to characterize the technologies, conditions, and populations addressed.

Results: A total of 80 studies were identified that met the inclusion criteria. Many of the studies tested for multiple conditions. Of these, 73% (60/82) of the technologies were tested for either GDM or perinatal mental health conditions, and 15% (12/82) were tested for preeclampsia. For technologies, 32% (28/87) of the technologies tested were smartphone or tablet applications, 26% (23/87) were telehealth interventions, and 14% (12/87) were remote monitoring technologies. Of the many outcomes measured by the studies, almost half (69/140, 49%) were patient physical or mental health outcomes.

Conclusions: Per this scoping review, most informatics interventions address three conditions: GDM, preeclampsia, and mental health. There may be opportunities to treat other potentially lethal conditions like postpartum hemorrhage using proven technologies such as mobile apps. Ample gaps in the literature exist concerning the use of informatics technologies aimed at maternal morbidity. There may be opportunities to use informatics for lesser-targeted conditions and populations.

KEYWORDS

scoping review; maternal morbidity; medical informatics; clinical informatics; mother; pregnant; perinatal; GDM; preeclampsia; maternity; gestational diabetes mellitus

Introduction

Women have been entering pregnancy less healthy than previous generations [1]. Maternal morbidities such as preeclampsia and gestational diabetes, and severe maternal morbidities such as postpartum hemorrhage all have implications for the long-term health of mothers well beyond the postpartum period. Preeclampsia is associated with cardiovascular disease for decades following pregnancy, including chronic hypertension, stroke, and age-adjusted overall mortality [2]. Gestational diabetes mellitus (GDM), a condition that in many cases resolves itself after delivery, can still affect mothers beyond the puerperium [3]. Severe maternal morbidity (SMM) encompasses myriad conditions, including acute myocardial infarction, eclampsia, and hemorrhage. Those who have experienced SMM are more likely to die at any point after delivery and into the decades beyond the postpartum period [4]. Preterm birth (PTB; delivering before 37 weeks gestation) is associated with long-term cardiovascular complications in the mother, including ischemic heart disease, stroke, and atherosclerosis [5].

Informatics interventions offer tools that can help to prevent perinatal health conditions that have long-term health consequences for mothers, monitor these conditions in the perinatal period so that mother and baby remain healthy, and follow mothers post partum to ensure that they continue to receive the health monitoring they need. Technology-based tools that can be used for these purposes include mobile apps, wearable technology, physician decision support, and telehealth, among others. As artificial intelligence (AI) technology becomes more common in health care, a range of interventions can be used to predict, diagnose, and treat maternal morbidities that lead to maternal complications, with the hope of reducing maternal morbidity and mortality [6]. While some patients are hesitant for their physicians to use AI to diagnose or treat medical problems, physicians have demonstrated growing acceptance and belief that AI will improve interactions with their patients [7]. As the landscape of health informatics shifts substantially with the advent of new technologies, it is important to assess what technologies have already been tested to prevent, diagnose, and treat common maternal morbidities so that gaps can be identified and addressed in future research [8].

In this scoping review, we seek to identify what informatics interventions have been designed and tested that address maternal morbidity. In addition, we aim to assess the extent, range, and nature of informatics interventions that have been tested to prevent, diagnose, and treat maternal morbidities known to have long-term health consequences for mothers. The review summarizes discrete populations addressed in the literature, types of informatics interventions tested in the literature, conditions addressed by these interventions, and outcomes measured.

Methods

Search Strategy

Our scoping review methodology was guided by Arksey and O'Malley's [9] framework, stages 1-5, and Joanna Briggs's *Manual for Scoping Reviews*. We asked what informatics interventions have been designed and tested for SMM. Using the PCC (Population, Concept, and Context) framework outlined in the *Manual for Scoping Reviews*, the population was adult women with SMM as defined by the Centers for Disease Control and Prevention (CDC), the concept was informatics interventions, and the context was prospective studies anywhere in the world. We developed a review protocol to guide the process. The literature searches were led by an expert information specialist (JCS) in consultation with the research team. Four electronic databases were searched from inception until June 6, 2022: MEDLINE and Embase (searched simultaneously on Ovid), Cochrane Library (Wiley), and Engineering Village (Elsevier). One database was searched from inception until June 7, 2022: IEEE Xplore (IEEE). The MEDLINE (Ovid) search was peer-reviewed by another expert librarian using the PRESS (Peer Review of Electronic Search Strategies) checklist and modified as required [10]. The search strategy was limited to the English language and encompassed all years of publication. Embase and MEDLINE citations were deduplicated in Ovid before exporting to Covidence online review software. The full search strategies for each database are publicly available in searchRxiv [11]. Lastly, review results are reported using PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) [12]. This checklist can be found in Multimedia Appendix 1. Our protocol was registered retrospectively in Open Science Framework Registries [13].

Study Selection

The inclusion and exclusion criteria are described in Textbox 1. Studies were included that prospectively tested a medical informatics intervention on either a group of women or physicians who treat women. Study methodologies could include both quantitative and qualitative approaches. Only studies analyzing primary data to describe a health-related outcome were included. Studies were included that tested medical or clinical informatics interventions on human subjects to prevent, monitor, or treat maternal conditions that have long-term health consequences for mothers within and beyond the perinatal period. Conditions included preeclampsia or hypertensive disorders of pregnancy, GDM, PTB, new mental health diagnoses, and SMM as defined by the US CDC [14].

XSL•FO
RenderX

Textbox 1. Criteria for inclusion and exclusion.

Inclusion criteria

- Test a medical informatics intervention prospectively
- Medical or clinical informatics interventions
- Adult women or physicians who treat women
- Preeclampsia, gestational diabetes mellitus, preterm birth, perinatal mental health diagnoses, severe maternal morbidity as defined by the Centers for Disease Control and Prevention (21 indicators)
- Physical health, patient-centered outcomes, mental health, health behavior, health knowledge or attitudes, health care use, quality of care outcomes

Exclusion criteria

- Systematic reviews, scoping reviews, literature reviews, opinion pieces, commentaries, proposals, reports, conference papers
- Pilot/feasibility studies
- Bioinformatics studies, including scans, ultrasounds, biomarkers, and predictive algorithms
- Adolescents
- Preexisting conditions: type 1 or 2 diabetes, chronic hypertension, preexisting mental health conditions
- Feasibility, acceptability, user experience

Systematic reviews, scoping reviews, and literature reviews were excluded together with opinion pieces, commentaries, proposals, reports, or gray literature. Studies were also excluded if they focused primarily on bioinformatics, effectively eliminating imaging (eg, ultrasounds), biomarkers, and predictive algorithm development.

Article references were entered into review software for screening and data extraction. The first and senior authors conducted an initial title, abstract, and keyword screening. If any author recommended inclusion, then the article underwent full-text screening. All authors except for the information specialist (JCS) then conducted a full-text screening, with two team members reviewing all articles. Studies with two votes to include were moved forward for extraction; those with two votes to exclude were excluded from the study. During the full-text screening, Cohen κ was used in the initial training to gauge agreement until reviewers reached a κ of 0.80. After training, disagreements were resolved by the first author.

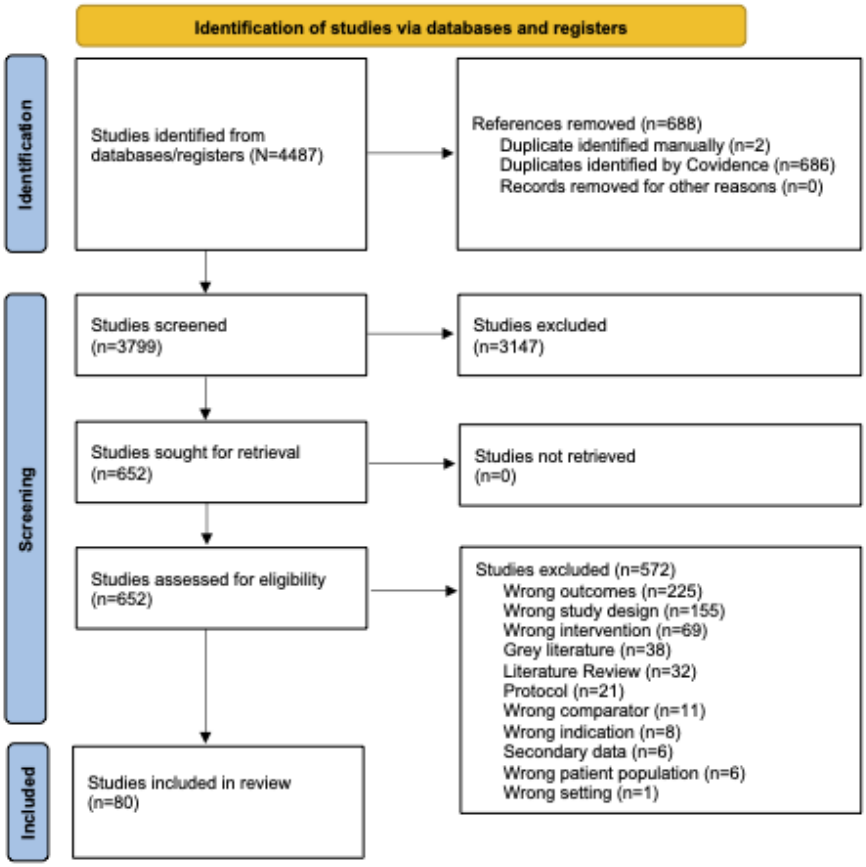
Data Extraction

A subset of four authors extracted data using Covidence review software. Reviewers were given an initial set of 10 articles and met with the first author for consensus before reviewing the remaining articles. All studies were reviewed for extraction by the first author and one additional author. Most data extraction categories were developed a priori, and selection options were developed by the first and senior authors after reviewing all articles for trends. The following data categories were added after the protocol had been developed: aim of the study, years of data collection, population inclusion and exclusion criteria, and total number of participants. These categories were added to the data extraction form iteratively to provide more context to the reviewed studies.

Demographic data collected for each article by reviewers included title of article, year published, lead author surname, and country in which the study was conducted. The following characteristics of included studies were extracted: informatics technology tested, health problem, aim of study, study design, years of data collection, population description, study participation inclusion criteria, study participation exclusion criteria, total number of participants, and health outcome. Reviewers were given the option of selecting multiple answers for each study characteristic. An open-ended "other" option was available for the following study characteristics: informatics technology, health problem, study design, and outcome. Following extraction, the first and senior authors also extracted data on whether a significantly positive result was found in the studies, as well as racial diversity in participant samples for those studies conducted in the United States.

Data were synthesized by tallying the options from each category (study design, region, technology, health outcome, study population, study outcome, and results) and calculating the corresponding frequencies for each option.

Results



Overview

The PRISMA flow diagram for this scoping review can be found in Figure 1. A total of 3799 records were identified for title and abstract screening; 652 records underwent full-text screening for eligibility. Of these, 572 were excluded. Common reasons for exclusion were study design (eg, retrospective, systematic or other review, narrative), type of study outcome (user experience), or the wrong intervention (eg, machine learning algorithms or predictive models not tested with patients or providers). A total of 80 studies underwent full data extraction. A list of the studies and their characteristics can be found in Table 1.

Frequencies for synthesized data can be found in Table 2.

[a]EHR: electronic health record.

[b]DSS: decision support system.

[c]GDM: gestational diabetes mellitus.

[d]HDP: hypertensive disorders of pregnancy.

Included studies were mostly RCTs (n=60). Other study designs included nonrandomized experimental (n=9), cohort (n=6), case control (n=2), retrospective (n=2), and qualitative (n=1). Included studies represented a range of countries and regions. Most of the studies were conducted in North America (n=24), East Asia and the Pacific (n=22), and Western Europe (n=20). Fewer studies were authored from the Middle East and North Africa (n=9), sub-Saharan Africa (n=3), and South Asia (n=2). No studies focused on Latin America or the Caribbean.

Informatics Technologies

The specific informatics technologies tested by the study were described. Descriptive categories included telehealth or telemedicine (remote consultation via telephone or video chat that may replace medical consultation), remote monitoring (patient-performed measurements of vital signs and blood glucose), electronic health record decision support system (tools within the electronic health record that assist providers with clinical decisions), smartphone or tablet applications, SMS text messages (between providers and patients or between patients), web-based programs (patient portals and other programs administered through a web browser, not through a smartphone or tablet application), and other (with the technology charted manually). Studies tested a range of informatics technologies. The most frequently tested technologies included smartphone/tablet applications (n=28) and telehealth/telemedicine (n=23). Technologies tested less frequently included remote monitoring (n=15), web-based programs (n=10), and SMS text messaging (n=8). Technologies assessed in very few studies included electronic health record decision support (n=3), wearable technologies (n=2), and other (cognitive aid on an anesthesia machine; n=1).

Health Problems

Articles were categorized by the health problems treated by the informatics technology; some tested more than one. These included preeclampsia or hypertensive disorders of pregnancy, hypertension, GDM, PTB, hemorrhage, and new (perinatal) mental health diagnoses. Although our protocol searched for "severe maternal morbidity as defined by the CDC" and included a list of 21 conditions [13], after reviewing the articles, it was clear that the only condition from the CDC list that was frequently tested by informatics technology was postpartum hemorrhage. Thus, any additional conditions were added manually in the "other" option. Studies primarily used informatics technologies to address new mental health conditions (n=30) and GDM (n=30). Other health problems addressed by the studies include preeclampsia or hypertensive disorders of pregnancy (n=12), hypertension (n=5), and hemorrhage (n=3). One study each addressed preterm birth and myocardial infarction.

Population Type

Population type was categorized as either: women or medical providers who treat women. Included studies overwhelmingly tested informatics technologies on women, with only 3 studies testing informatics technologies on providers. US studies were also coded for sample demographics.

Outcomes

Finally, outcomes were categorized to gain an understanding of the measures upon which the studies focused; many tested more than one measure. These included medical outcomes (eg, weight loss, blood pressure, blood glucose), number of remote measures (eg, patient-collected and -reported blood pressure or blood glucose measurements), mental health outcomes (eg, Edinburgh Postnatal Depression Scale score, subjective well-being measures), health behaviors (eg, dietary habits, exercise frequency), health knowledge or attitudes (eg, patient's understanding of health condition, patient-reported attitude toward care), health care use (eg, number of emergency room visits, number of prenatal care visits), quality of care (eg, Hospital Consumer Assessment of Healthcare Providers and Systems [HCAHPS] scores, safety of care, effectiveness of care, efficiency of care), or other. Studies measured myriad outcomes, and many studies measured more than one outcome. Many assessed medical outcomes (n=39), mental health outcomes (n=30), and patient health behaviors (n=21). Fewer measured quality of care (n=19), number of remote readings (n=13), and health care use (n=12). Very few measured health knowledge and attitudes (n=5) or other outcomes (n=1).

Effect

Studies were coded as to whether a significant positive effect was exhibited for at least one health outcome measure (yes/no). Most (n=63) studies found that the informatics technology yielded at least one positive effect for a health-related (ie, not user experience) outcome. Some (n=17) studies showed no significant positive effect of the informatics technology tested.

Discussion

Principal Findings

This scoping review was performed to characterize what informatics interventions have been tested to address the maternal morbidities that result in long-term negative health outcomes for mothers. Our results show that most of the tested informatics technologies were tested in North America, East Asia, and Western Europe. They overwhelmingly focused on patient populations diagnosed with GDM, mental health conditions, and preeclampsia. Most were patient focused and most aimed to prevent, diagnose, or treat physical or mental health outcomes.

Women have been entering pregnancy less healthy than previous generations. As the world population grows increasingly obese, high BMI presents critical risks for birthing people, with obesity linked to such perinatal complications as gestational diabetes [95], preeclampsia [96], and postpartum hemorrhage [97]. Women also currently enter pregnancy in poorer cardiovascular health than previous generations, with prepregnancy hypertension especially pronounced in rural populations of childbearing age [98]. This scoping review surveys the landscape of informatics interventions tested to treat these increasingly common conditions.

Most of the technologies were tested in North America, East Asia or the Pacific, and Western Europe. Despite some evidence of resistance to new technologies [99], studies generally show perceptions of mobile health to be positive in sub-Saharan Africa, especially toward maternal health applications [100]. There may be opportunities to test technologies developed in North America, Asia, and Europe in underserved parts of the world. In addition to improving maternal health in these underserved areas, testing in diverse types of populations may yield compelling findings that could be translated into US, Asian, and European contexts through a process of reciprocal innovation [101].

Our results show that most of the tested informatics technologies focused on patient populations diagnosed with GDM; mental health conditions; and, to a lesser extent, preeclampsia. Far fewer focused on preventing or treating postpartum hemorrhage. Although prevalences of GDM and mental health conditions are high, preeclampsia and hemorrhage are leading causes of maternal mortality and pregnancy-associated deaths in both the United States and abroad [101]. Postpartum hemorrhage, in particular, is the leading cause of maternal death worldwide, causing 94% of maternal deaths [102,103].

There are at least two possible reasons for this imbalance in testing of interventions. First, diabetes mellitus and mental health conditions are also common in the general population, unlike preeclampsia and hemorrhage. Thus, preexisting interventions may be more easily transferrable to pregnant populations. Second, GDM and postpartum depression can be diagnosed through routine screening, with GDM diagnosed via prenatal glucose testing and postpartum depression diagnosed using the Edinburgh Postnatal Depression Scale. Indeed, 9.3% of interventions measured the extent/accuracy with which patients review their own biodata, including blood glucose levels. Screening for GDM could be seen as a parsimonious method to improve women's health. On the other hand, postpartum hemorrhage is less predictable, typically being diagnosed through an urgent/emergent presentation. Thus, the ease of routine screening practices may lend certain diagnoses to being more amenable to the implementation of informatics interventions.

Most of the interventions in this review aimed to prevent, diagnose, or treat physical or mental health outcomes, and almost all were patient focused. Very few interventions (n=3, 4%) were tested on providers who treat women. Of those studies, two of the interventions focused on midwives and one used a decision support system to assist physicians in screening for maternal depression. Most interventions in this review were tested on women and involved active participation from patients (eg, taking blood glucose readings, logging symptoms in an app, participating in an online support group). In other words, most of the interventions entrusted patients with aspects of their own health.

This focus on outcomes is logical given the maternal mortality crisis both within and outside of the United States. Mental health conditions are the leading cause of pregnancy-related deaths in the United States according to state Maternal Mortality Review Committees [104] and of non-Hispanic White and Hispanic women when stratified by ethnicity. Cardiac conditions are the leading cause of pregnancy-related death for Black/African American women in the United States, but the focus on interventions aimed at patients themselves minimizes the role provider knowledge and practice within a health system plays in the crisis. Research shows that lack of standardized emergency obstetric care, maternity care coordination [105], and systemic racism [106] can play a role in the safe and effective delivery of care. The results of this scoping review show a large gap in the literature related to using informatics to improve the quality of care for maternal morbidities. Interventions such as telehealth have been shown to improve obstetric quality, including perinatal smoking cessation and breastfeeding [107]. It is possible that expanding such technologies and examining the way they are used by physicians can help improve the quality of care and ultimately save the lives of women.

The need for informatics interventions does not end with birth. Prior research suggests that many physicians, including obstetricians, are unaware of how maternal morbidity can influence maternal health in the decades following pregnancy [108]. Because of this lack of awareness, patients often do not know to monitor their own health in the long term, and they may not receive referrals for proper follow-up services. The paucity of provider-focused technologies identified in this review may also present opportunities for the development of informatics-based interventions targeting physicians and affiliated providers—especially in the treatment and prevention of postpartum preeclampsia and hemorrhage—that could use technologies like decision support to improve maternal health.

Limitations

Our study has several limitations. Because this is a scoping review, we did not systematically assess the quality of individual studies. The studies reviewed may vary in quality or contain potential biases or methodological limitations. Therefore, this study is not intended to assess the quality of the evidence supporting informatics-based interventions on the given perinatal health conditions. Additionally, the nature of a scoping review is not to analytically aggregate studies so as to make claims about effect sizes. When additional, more comparable studies have accumulated, further research is needed to examine which informatics interventions are most effective and the size of the impact on maternal and perinatal health.

In addition, we only considered published studies that tested an informatics intervention and presented health-related outcomes. We excluded many studies because they tested feasibility or acceptability. It is possible that such excluded feasibility studies will eventually test health-related outcomes. Overall, this scoping review summarizes trends in the populations, geographic areas, technologies, and conditions targeted by informatics interventions tested and disseminated in the available literature.

Conclusions

This scoping review paints a picture of the landscape of informatics interventions aimed at preventing and treating maternal morbidity. Most interventions identified in this study were tested in North America, East Asia and the Pacific, or Western Europe. Most tested either smartphone/tablet applications or telehealth/telemedicine, and most technologies tested for new mental health conditions and GDM. Almost all the studies tested technologies on populations of women and reported medical, mental health, and patient behavior outcomes. Results suggest that there may be opportunities to use informatics technologies to target providers who treat women as well as conditions such as postpartum hemorrhage that are more likely to lead to mortality. As the landscape of informatics applications in health care continues to expand, maternal health is poised to be an important target of these interventions.

Abstract

Background: Urinary incontinence affects approximately 7% to 10% of children during the day and 9% to 12% of children during the night. Treatment mainly involves lifestyle advice and behavioral methods, but motivation and adherence are low. Traditional tools such as pen-and-paper solutions may feel outdated and no longer meet the needs of today's "digital native" children. Meanwhile, digital interventions have already shown effectiveness in other pediatric health care areas.

Objective: This scoping review aimed to identify and map innovative, technology-driven, digital tools for managing pediatric urinary incontinence.

Methods: PubMed, Web of Science, and the Cochrane Library were searched in March 2022 without date restrictions, complemented by cross-referencing. Studies were eligible if they focused on pediatric patients (aged ≤18 years) with bladder and bowel dysfunctions and explored noninvasive, technology-based interventions such as digital health, remote monitoring, and gamification. Studies on adults, invasive treatments, and conventional methods without tangible tools were excluded. Gray literature was considered, but non–English-language, inaccessible, or result-lacking articles were excluded. A formal critical appraisal was not conducted as the focus was on mapping existing tools rather than evaluating effectiveness. Data analysis combined descriptive statistics and qualitative content analysis, categorizing tools through iterative coding and team discussions.

Results: In total, 66 articles were included, with nearly one-third (21/66, 32%) focusing on nocturnal enuresis. Our analysis led to the identification of six main categories of tools: (1) digital self-management (7/66, 11%); (2) serious games (7/66, 11%); (3) reminder technology (6/66, 9%); (4) educational media (12/66, 18%), further divided into video (5/12, 42%) and other media (7/12, 58%); (5) telehealth and remote patient monitoring (13/66, 20%), with subcategories of communication (5/13, 38%) and technological advances (8/13, 62%); and (6) enuresis alarm innovations (21/66, 32%), further divided into novel configurations (8/21, 38%) and prevoid alarms (13/21, 62%).

Conclusions: The field of pediatric urinary incontinence demonstrates a considerable level of innovation, as evidenced by the inclusion of 66 studies. Many tools identified in this review were described as promising and feasible alternatives to traditional methods. These tools were reported to enhance engagement, improve compliance, and increase patient satisfaction and preference while also having the potential to save time for health care providers. However, this review also identified gaps in research, highlighting the need for more rigorous research to better assess the tools' effectiveness and address the complex, multifaceted challenges of pediatric urinary incontinence management. Limitations of this review include restricting the search to 3 databases,

XSL•FO
RenderX

excluding non–English-language articles, the broad scope, and single-reviewer screening, although frequent team discussions ensured rigor. We propose that future tools should integrate connected, adaptive, and personalized approaches that align with stakeholder needs, guided by a multidisciplinary, human-centered framework combining both qualitative and quantitative insights.

Introduction

Background

Urinary incontinence (UI) is prevalent among children, affecting approximately 7% to 10% (aged 5-13 years) during the day [1] and 9% to 12% (aged 5-15 years) during the night [2-4]. UI often leads to low self-esteem, shame, and stress, negatively impacting the child's psychosocial well-being and overall quality of life [5-9]. The primary treatment approach for pediatric UI, once anatomical and neurogenic causes are excluded, mainly involves lifestyle advice and behavioral methods [10-12]. These methods vary depending on whether the UI occurs during the day or at night.

For daytime UI (DUI), the recommended first-line approach is standard urotherapy. It encompasses patient education, keeping track of symptoms through bladder diaries, regulating fluid intake and toilet routines, adhering to scheduled voiding, and providing support and encouragement [13-16]. An important part of this treatment is teaching children appropriate responses to their bladder signals. Standard urotherapy achieves success rates ranging from 40% to 56% [17-19]. For nighttime UI, also known as nocturnal enuresis (NE), one of the recommended first-line treatments is NE alarm training [20]. This method uses a moisture sensor that triggers an alarm to wake the child upon bed-wetting. Through this approach, children are conditioned to recognize and respond to bladder signals, ultimately helping reduce bed-wetting episodes. The success rate of alarm training is between 50% and 70% [21]. However, motivation and adherence, both crucial for these behavioral methods to be successful [22,23], are low in practice [22,24,25].

There are many factors that influence motivation and adherence [15,24-27], including duration of therapy, required effort, symptom bother, and awareness but also the supporting tools' usability and acceptance. The evaluation and management of pediatric UI traditionally rely on pen-and-paper bladder diaries [28-30], along with verbal and written instructions for behavioral techniques [16] and traditional NE alarms [31]. However, these analogue methods may seem outdated to today's "digital native" children, who are accustomed to using technology and digital tools [32]. Consequently, traditional approaches to pediatric UI management may no longer meet today's children's needs and expectations, potentially affecting motivation and adherence. Meanwhile, digital interventions have already proven effective as alternatives to traditional methods in other pediatric health care areas such as pain tracking [33], attention-deficit/hyperactivity disorder therapy [34], childhood obesity prevention [35], and asthma management [36].

Objectives

Therefore, our objective was to identify and map innovative, technology-driven, digital tools for pediatric UI management as alternatives to conventional approaches such as pen-and-paper solutions. In addition, we aimed to provide an overview of these tools' characteristics, including their features, design drivers, and any reported evidence supporting their use.

Methods

This scoping review followed the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines as outlined by Tricco et al [37] (see Multimedia Appendix 1 for the PRISMA-ScR checklist).

Eligibility Criteria

Eligibility criteria were determined based on the population, concept, and context framework. The *population* for this review included pediatric patients experiencing conditions such as bladder and bowel dysfunction (BBD), NE, overactive bladder (OAB), underactive bladder, and dysfunctional voiding (DV), as well as neurogenic conditions such as spina bifida. Studies involving adult populations (aged ≥18 years) or unrelated conditions (eg, cancer or rare diseases) were excluded.

The *concept* focused on innovative, technology-driven, digital tools for managing pediatric UI and related dysfunctions. Eligible tools included smartphone apps, multimedia resources, and remote monitoring technologies, whereas conventional methods or treatment plans without tangible tools were excluded.

The *context* was limited to studies that addressed noninvasive therapeutic approaches, particularly behavioral methods such as urotherapy, bladder training, and alarm training. Invasive approaches, including surgeries and their associated tools, were excluded.

All types of literature were considered, including gray literature (eg, conference proceedings, preprints, and technical reports), to provide a broad range of available literature and reduce publication bias. However, articles not presenting results or findings, not written in English, or lacking full-text availability were excluded.

Search Strategy

The search (see Multimedia Appendix 2 for the full search strategy) was conducted in March 2022 across 3 databases—PubMed, Web of Science, and the Cochrane Library—with no limitations on publication dates. The

XSL•FO
RenderX

population, concept, and context framework guided the selection of search terms.

Key search terms for *population* included "children," "adolescents," "pediatric," "bladder bowel dysfunction," and "enuresis." For *concept*, terms such as "digital," "mHealth," "gamification," "multimedia," and "remote monitoring" were used. *Context*-related search terms included "urotherapy," "bladder training," "alarm therapy," "self-monitoring," and "behavior management."

Study Selection

The study selection process was conducted by the first author (LB), with consultation and supervision provided by the team of authors. After removing duplicates, potential studies underwent screening based on their titles and abstracts in line with the eligibility criteria, with any uncertainties discussed with the author team.

Subsequently, LB read and assessed the full-text articles, periodically consulting with the team to ensure consistency and rigor. To reduce selection bias from database choice, we conducted cross-referencing, scanning the reference lists of the included articles to identify additional relevant studies.

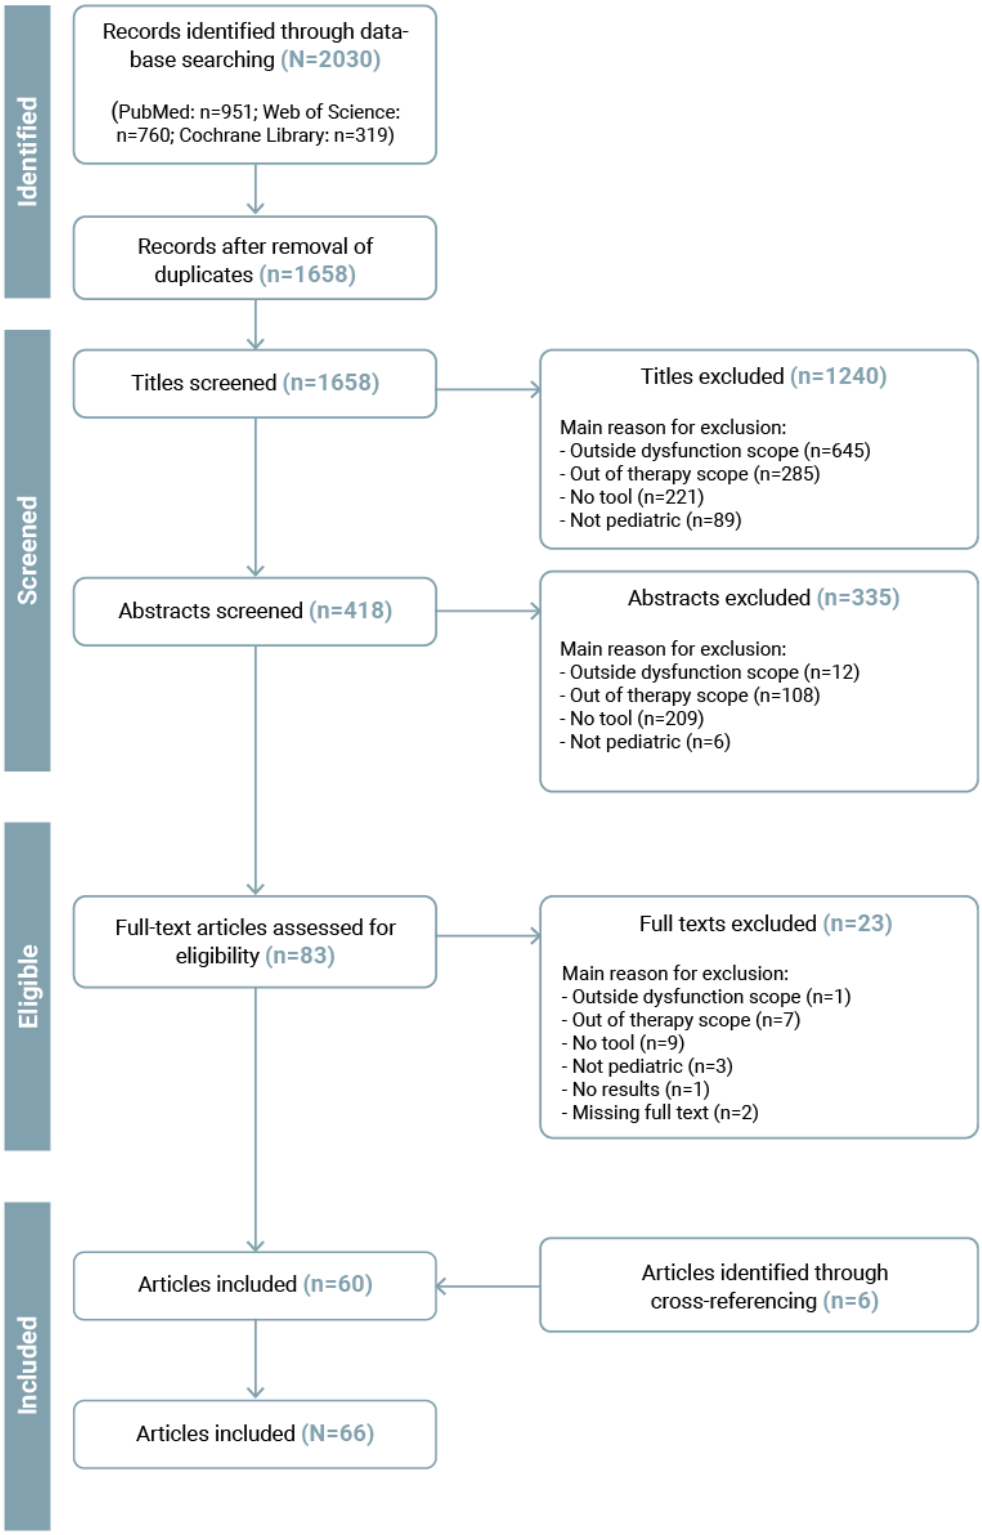
The selected studies underwent final review and confirmation by the entire author team. A formal critical appraisal or methodological quality assessment was not conducted as the aim of this scoping review was to identify and map the available evidence on innovative, technology-driven, digital tools rather than draw formal conclusions on their effectiveness.

Data Extraction

Data were extracted and charted using Microsoft Excel (Microsoft Corp) according to four main heading groups: (1) article information, (2) participant characteristics (population), (3) tool description (concept), and (4) research methods and results (context). Article information encompassed details such as article title, authors, journal, publication year, country, and database source. Participant characteristics included sample size, age range, sex distribution, and dysfunction indication. Tool description covered intended therapy type, tool design details, and its design drivers. Finally, research methods and results comprised study design, intervention groups, study outcomes, and conclusions.

Data Analysis

A combination of descriptive statistics and basic qualitative content analysis was used for data analysis. Descriptive statistics were used to analyze study characteristics, providing frequency counts and proportions for extraction items such as study design and dysfunction indication. Basic qualitative content analysis was used to identify and classify innovative, technology-driven, digital tools into distinct categories. The process began with multiple readings of the extraction items related to the tool description to familiarize ourselves with the data. Following an inductive approach, initial notes were made to generate codes, and coding was manually conducted in Microsoft Excel, where relevant terms were highlighted and grouped into emerging patterns. Through iterative refinement and team discussions, codes were merged, removed, or redefined to eliminate overlap and ensure sufficient distinction. The final set of codes was organized into 6 broad categories, 3 of which were further subdivided to capture more specific aspects. LB conducted the preliminary analysis, and to ensure consistency and reliability, the coding process was reviewed and refined collaboratively by the coauthors at multiple stages. Any disagreements on categorization were addressed through discussions to achieve consensus.



Results

Retrieval of Studies

The search retrieved a total of 2030 articles (PubMed: n=951, 46.85%; Web of Science: n=760, 37.44%; Cochrane Library: n=319, 15.71%). After removing duplicates (372/2030, 18.33%), a total of 81.67% (1658/2030) of the studies were included in the title and abstract screening. Following title and abstract screening, of the 1658 articles, 1575 (94.99%) were excluded, leaving 83 (5.01%) for full-text evaluation. Finally, 60 articles were included in the data extraction process, with an additional 6 identified through cross-referencing, resulting in a total of 66 included articles. Figure 1 illustrates the flowchart of the screening and selection process.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the literature screening and selection process.

General Analysis to Describe the Study Characteristics

Of the included studies (n=66), most were randomized controlled trials (RCTs; 14/66, 21%) and validation studies (13/66, 20%), followed by quasi-experiments (10/66, 15%), prospective studies with no control group (7/66, 11%), and qualitative or mixed methods studies (8/66, 12%), as shown in Table 1. Nearly one-third (21/66, 32%) of the identified tools targeted children with NE, followed by DV (9/66, 14%), BBD (7/66, 11%), and DUI (7/66, 11%). More than one-third (25/66, 38%) of the studies evaluated outcomes related to patient experience, such as satisfaction, motivation, and usability. A mean sample size of 82 (SD 83; range 14-353) participants was found for the RCTs, quasi-experiments, and prospective studies (no control), indicating a large variation in sample size.

We identified and established a total of six primary categories of innovative, technology-driven, digital tools (Figure 2): (1) digital self-management (7/66, 11%), (2) serious games (7/66,

XSL•FO
RenderX

11%), (3) reminder technology (6/66, 9%), (4) educational media (12/66, 18%), (5) telehealth and remote patient monitoring (RPM; 13/66, 20%), and (6) enuresis alarm innovations (21/66, 32%). Further subcategories were identified within educational media, including video (5/12, 42%) and other media (7/12, 58%); within telehealth and RPM, including communication (5/13, 38%) and technological advances (8/13, 62%); and within enuresis alarm innovations, including novel configurations (8/21, 38%) and prevoid alarms (13/21, 62%).

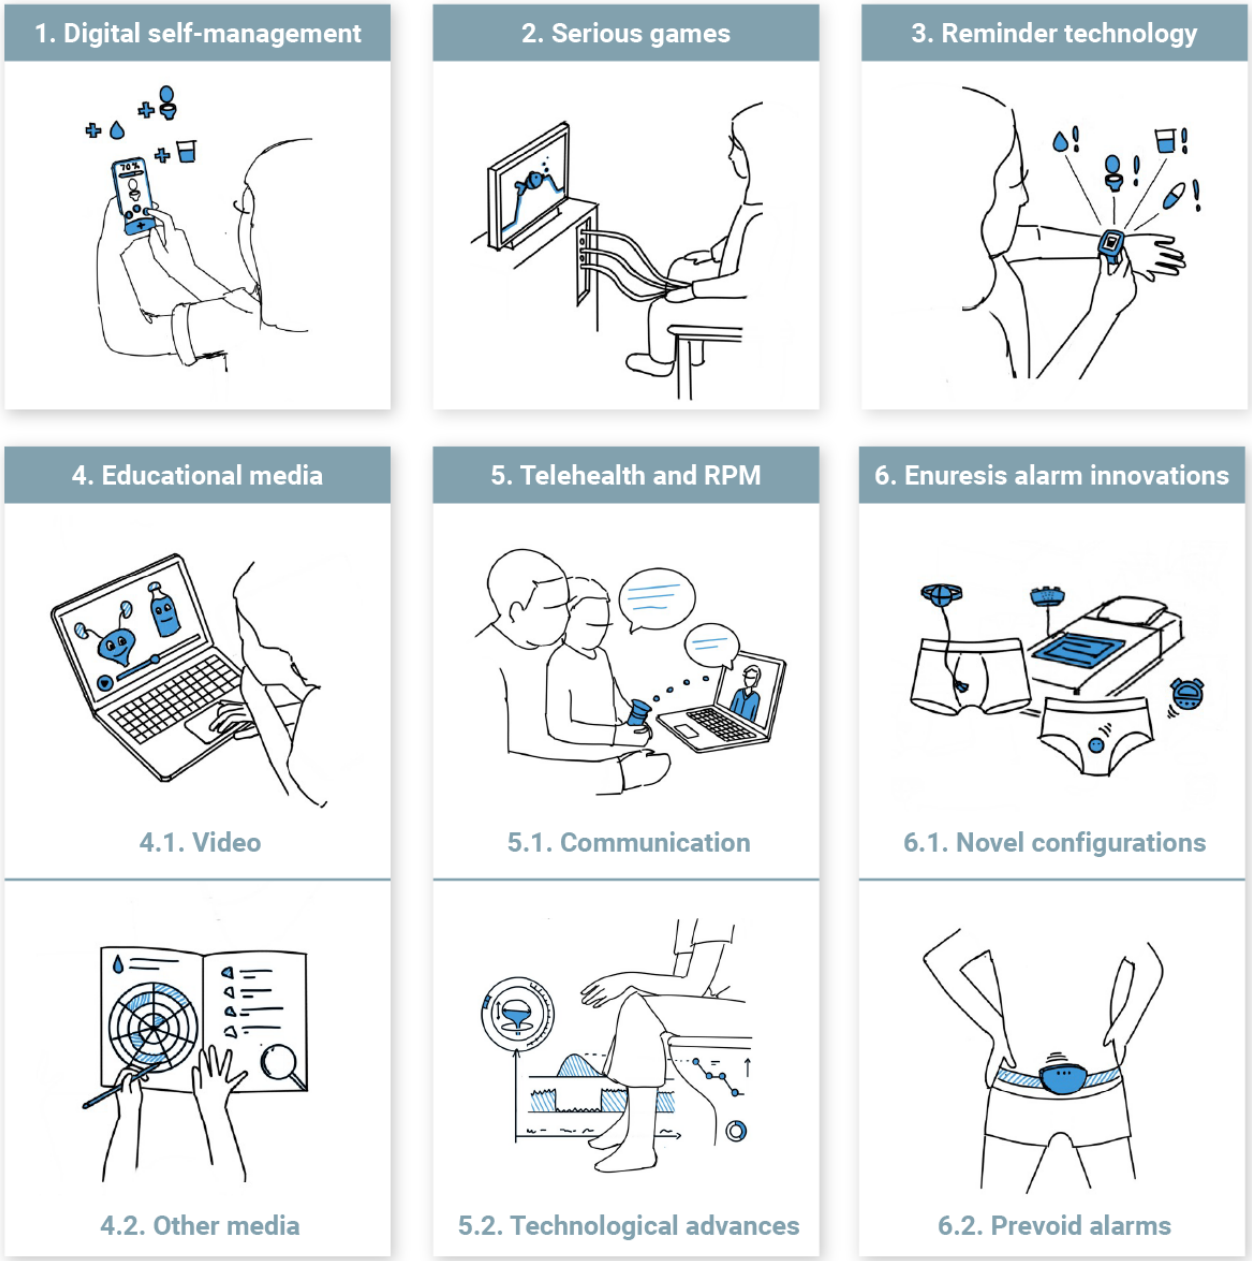


Table 1. Summary of study characteristics (n=66).

Study characteristic	Studies, n (%)
Study design	
RCT[a]	14 (21)
Feasibility or validation study	13 (20)
Quasi-experiment	10 (15)

Figure 2. Overview of the 6 categories and subcategories of innovative, technology-driven, digital tools. RPM: remote patient monitoring.

Overall, we found that the distribution of dysfunction types was generally well balanced across the different tool categories. Digital self-management exhibited a diverse distribution, addressing a range of dysfunctions including BBD (1/7, 14%), DUI or nighttime UI (1/7, 14%), and neurogenic disorders (2/7, 29%). Serious games were predominantly used for DV (5/7, 71%). Reminder technology was used for timed voiding in cases of DUI and OAB (3/6, 50%), as well as for self-management of neurogenic and developmental or neurodevelopmental disorders (3/6, 50%). Educational media was used across a range of dysfunctions, with slightly more use for NE (4/12, 33%) and urinary tract infections (UTIs; 3/12, 25%). Telehealth was primarily used for BBD (4/13, 31%) and DUI or nighttime UI (4/13, 31%), with additional use also observed for DV (3/13, 23%). Finally, enuresis alarm innovations were predominantly associated with NE (16/21, 76%), as expected, although not exclusively. They were also applied for other conditions, such as DUI (2/21, 10%) and developmental or neurodevelopmental disorders (2/21, 10%).

Categories of Innovative, Technology-Driven, Digital Tools

Digital Self-Management

Category Overview and Key Drivers

Digital devices such as smartphones, tablets, and computers have become increasingly prevalent in our society, especially among children and adolescents [38]. Therefore, they offer a practical and accessible medium with a range of health care possibilities, such as digital self-management to enhance patient engagement and improving access, availability, and continuity of care [38,39].

XSL•FO
RenderX

Tools Within This Category

This review identified 11% (7/66) of the studies on digital self-management, with extended details available in Table S1 in Multimedia Appendix 3 [40-105]. These included electronic bladder diary apps [40,41], which served as digital alternatives to traditional paper versions to improve patient compliance. In addition, 3 self-management applications with training programs were included, targeting conditions such as DUI (smartphone app) [42], bowel dysfunctions (internet application) [43], and spina bifida (smartphone app) [44,45]. These self-management applications incorporated features such as weekly modules with exercises; daily goals; self-monitoring of parameters such as fluid intake, toilet visits, medication, and mood status; reminders; progress tracking; personalized feedback; and rewards such as in-application trophies and stars. Furthermore, a parent software portal [46] was identified, enabling parents to monitor their children's symptoms, such as UTIs, to aid clinical decision-making.

Study Results and Conclusions

The studies on digital self-management tools reported feasibility, acceptability, ease of use, and patient and parent satisfaction [40-46]. Furthermore, they described improvements in patient compliance, as observed in both the bowel dysfunction self-management program and the parent software portal, with high completion rates and low dropout [43,46]. However, the parent software portal was described as facing challenges in effectively delivering information to health care professionals, lacking integration into their busy clinical practice [46].

Despite many promising aspects, the studies often reported limitations in providing robust evidence of effectiveness. For example, the electronic bladder diary format was described as offering data quality advantages for certain patients but was not found to be superior to a paper-based bladder diary [40]. The sole RCT investigating a self-management program for bowel dysfunctions reported greater improvements in patients' quality of life and reduction in overall symptom severity. However, this was in comparison to a nonequivalent control group of children on a waitlist who were not receiving any treatment [43].

Serious Games

Category Overview and Key Drivers

Serious games are interactive applications designed as games but intended for educational or therapeutic purposes. By blending elements of fun and seriousness, serious games offer a playful way for children to learn about complex topics such as bladder and bowel health. This approach can be particularly effective for engaging children, who have limited attention spans and may struggle with processing information. Moreover, the entertainment aspect of serious games is crucial for motivating and engaging children as they strive for success within the game [41,106,107].

Tools Within This Category

Table S2 in Multimedia Appendix 3 [40-105] shows that serious games were mainly used for pelvic floor biofeedback training through biogames (6/7, 86%) [47-52]. In these biogames, the game action was controlled by the appropriate muscular contractions and relaxations detected by pelvic floor electromyography (EMG) patches worn by the child. Various animated scenarios were available, such as golfing, flying spaceships, riding an elephant, playing basketball, and swimming with dolphins or fish. In addition, one serious game was found for standard urotherapy, which was played on a smartphone [53]. In this game, the child was rewarded for maintaining a daily bladder diary and voiding adequately during the 3-month training program, with additional rewards for staying dry.

Study Results and Conclusions

Overall, the studies described positive effects of biogames for pelvic floor biofeedback training on health outcomes, particularly for children with DV [47-50,52] and, in one study, for those with underactive bladder [51]. However, understanding the precise impact of adding a game to the therapy is challenging as the studies reported limitations such as retrospective designs [49], lack of control groups [47], and nonequivalent therapy comparisons [48,50,51].

Findings varied across the studies. One study reported similar results in half the time with biogames (mean of 3.6, SD 1.8 sessions) compared to without (mean of 7.6, SD 5.2 sessions) [49], whereas another study reported a relatively high number of treatment sessions with biogames (mean of 9.6, SD 1.3 sessions) [50]. In the sole RCT comparing equivalent therapies [52], no differences were observed in terms of clinical success, cooperation, and motivation between pelvic floor biofeedback training with and without biogames. Nevertheless, subjective observations suggested that using biogames effectively captured children's attention and prevented boredom during the sessions, particularly among younger children [52].

Similarly, in the comparison of standard urotherapy with and without a serious game, no significant differences were reported in training results, quality of life, or motivation [53]. However, children expressed a clear preference for the game. They provided valuable suggestions for its improvement, such as introducing more dynamic gameplay with changing storylines and evolving game types, along with features such as regular updates on training progress and detailed information about their bladder problem.

Reminder Technology

Category Overview and Key Drivers

Reminder technology uses programmable timers to activate alarms aimed at assisting children in adhering to therapy or self-management schedules without requiring constant prompting from parents. This approach supports children's independence as parental reminders may sometimes contribute to resistance, with children preferring autonomy in adhering to their schedules [108].

Tools Within This Category

A total of 9% (6/66) of the studies were categorized under reminder technology (Table S3 in Multimedia Appendix 3 [40-105]). Half (3/6, 50%) of these studies evaluated timer watches, which were used in standard urotherapy to assist with

XSL•FO
RenderX

timed voiding [54-56]. The timer watch can be programmed to automatically alarm at specified intervals, such as every 2 hours, helping children maintain a consistent voiding schedule.

The other half (3/6, 50%) of the studies focused on self-management reminders for children with neurogenic or developmental or neurodevelopmental disorders [57-59]. A laptop calendar program reminded children with prospective memory disabilities to complete and log daily schedules, such as self-catheterization and medication, through visual and auditory modalities [59]. A smartwatch with a built-in fitness tracker displayed visual icons to prompt children with spina bifida to engage in various daily activities from self-care to playtime and rewarding timely completion with stars [58]. Finally, "Potty Monkey," an interactive toy, prompted children with special needs to void at set times, providing reminders, modeling techniques, and positive reinforcement for time-based toilet training [57].

Study Results and Conclusions

Reminder technology for timed voiding using a timer watch was reported to be superior in treating severe DUI in children with OAB compared to standard urotherapy without it, with improved adherence to the voiding schedule playing a key factor [55,56]. In addition, another study described reminder technology as an equally effective but simpler alternative to enuresis alarms (using moisture sensors) in treating DUI, also reporting good adherence rates [54].

For self-management in children with neurogenic or developmental or neurodevelopmental disorders, reminder technology was reported to be feasible, although the findings were based on small sample sizes [57-59]. The tools were described as alleviating anxiety in caregivers and patients by providing a log of tasks [59] and fostering child independence through clear routines [58]. However, patient acceptance varied, with the smartwatch being highly accepted [58] and the interactive toy receiving lower acceptance [57], with aesthetics and flexibility playing a key role.

Educational Media

Video

Category Overview and Key Drivers

Videos, as educational media, offer a visually engaging and interactive format for explaining complex concepts and techniques to patients and parents. They provide a convenient and 24/7-available alternative or supplement to in-person visits. Moreover, videos offer anonymity, which can be beneficial for individuals who feel embarrassed or hesitant to seek medical advice in person. As a result, the internet and video-sharing platforms have become popular sources of health-related information [32].

Tools Within This Category

In our review, 8% (5/66) of the studies were classified under the subcategory of video within educational media (Table S4 in Multimedia Appendix 3 [40-105]). These videos covered a range of topics. Some supported behavioral therapy, such as an animated bladder training video [60,61] and an abundance of YouTube videos on NE therapy [62,63]. Another video focused on preparing children for surgical interventions, featuring actual hospital staff and using role-play modeling techniques to demonstrate the anesthesia process [64].

Study Results and Conclusions

Multiple studies within this subcategory (3/5, 60%) described videos as effective educational media for patients offering alternatives to in-person strategies [60,61,64]. In a noninferiority RCT, the animated bladder training video was found to be equivalent to standard urotherapy in reducing bladder and bowel symptoms [60] and improving quality of life scores [61]. Similarly, the presurgery video was reported to effectively reduce preoperative anxiety and resulted in less postoperative maladaptive behavior [64].

While videos were described as effective tools for educating patients and families, caution is recommended when relying on video-sharing platforms such as YouTube that lack robust systems to ensure the accuracy, completeness, and quality of the information [62,63]. The studies indicated a need for a balance between adherence to evidence-based guidelines and the creation of engaging content that captures and maintains viewer attention.

Other Media

Category Overview and Key Drivers

Effective information delivery is crucial for raising awareness, setting expectations, promoting patient adherence, and ensuring data quality. Unfortunately, verbal explanations by physicians may be poorly understood due to time constraints and complexity, whereas written information may not always be suitable or desirable for children, resulting in limited child participation. Thus, using other types of educational media tailored and engaging for children may help ensure effective information delivery to pediatric patients.

Tools Within This Category

A total of 11% (7/66) of the studies were classified under other types of educational media (Table S5 in Multimedia Appendix 3 [40-105]). This category included 2 homework books for UI: one that used coloring activities to log the severity of incontinence [65] and another that featured practical exercises for standard urotherapy [66]. In addition, a multimedia program for NE was identified, which combined text, drawings, cartoons, and sound to educate children on bed-wetting [67,68]. Finally, educational materials on UTIs included educational urine kits for clean-catch urine collection [69-71] and a low-cost origami-based microscope that used a mobile phone camera to raise awareness of genital hygiene and UTIs in schools [71].

Study Results and Conclusions

The UI homework books were reported to be feasible, usable, and well received, with good compliance [65,66]. In addition, the homework book for standard urotherapy was associated with increased fluid intake and hold time [66].

The multimedia program for NE was noted to show promise in holding children's attention and improving their knowledge, especially for younger children with low literacy levels [67]. However, results from the RCT indicated that, while the multimedia program was not more effective than traditional

XSL•FO
RenderX

verbal and written information, it could help save health care professionals time in patient education [68].

Similarly, urine kits with educational pamphlets for clean-catch urine collection did not result in a significant reduction in contamination rates but may help streamline patient education [69,70]. In addition, the origami-based microscope was described as a promising educational tool for promoting health awareness by detecting UTI-positive urine samples reasonably well [71].

Telehealth and RPM

Communication

Category Overview and Key Drivers

Telehealth and RPM enable remote communication and data exchange between patients and clinicians. Although face-to-face communication has been shown to improve treatment adherence [27,109,110], constraints such as time, cost, and travel can lead to extended intervals between consultations, potentially affecting patient motivation [111]. Telehealth may address some of these issues by offering consistent follow-up visits and motivational support without the need for physical visits.

Tools Within This Category

A total of 8% (5/66) of the studies were classified within the subcategory of communication using telehealth and RPM (Table S6 in Multimedia Appendix 3 [40-105]). One study explored videoconferencing for remote patient visits [72], whereas another study evaluated a UTI home monitoring system [73]. This system facilitated communication between parents of children with neurogenic bladder and urology nursing staff to alert them of potential UTI signs. It comprised a portable urinalysis device, Bluetooth weight scale, thermometer, electronic bladder diary, and mobile communication device. In addition, an embodied conversational agent, "Dr. Evie," was identified, offering personalized lifestyle advice and empathetic coaching for UI self-management while generating reports for general practitioners [74-76].

Study Results and Conclusions

The studies reported high patient and parent satisfaction with telehealth, citing reduced stress and increased convenience, especially for rural families, due to decreased travel time [72-76]. In addition, the UI self-management program featuring an embodied conversational agent was reported to improve patient adherence rates from 50% to 76% on average and alleviate symptoms [74-76]. Advice from nonfamily members and a sense of alliance with Dr Evie were noted to enhance program engagement.

Health care providers expressed mixed feelings about telehealth, acknowledging improved access to care but reporting technical barriers in conducting physical examinations and establishing rapport, particularly with pediatric patients [72]. Integrating RPM systems such as the UTI monitoring system may mitigate these technical barriers by providing valuable data for remote support and enhancing patient and parent self-efficacy [73]. However, patients' selective use of certain products, mainly the urinalysis device, was noted to create data gaps that hinder clinical evaluation. In addition, technical issues contributed to increased workload for clinical teams, emphasizing the importance of careful consideration of all stakeholders' diverse needs and preferences to facilitate successful integration into clinical practice.

Technological Advances

Category Overview and Key Drivers

Technological advances enabling telehealth and RPM aim to overcome limitations of in-clinic procedures, including the psychological stress that children often experience in hospital settings [77,112]. These procedures can also be inconvenient and time-consuming, as seen with noninvasive uroflowmetry, which requires voiding with a full bladder [78]. Similarly, therapies such as EMG biofeedback demand significant time and financial resources due to poor compliance and the need for multiple visits [77]. Meanwhile, invasive studies carry health risks and are often discouraged, especially for young patients [113,114].

Tools Within This Category

In total, 12% (8/66) of the studies were classified in the telehealth and RPM subcategory that focused on technological advances (Table S7 in Multimedia Appendix 3 [40-105]). These ranged from a machine learning algorithm to predict enuresis in children [79] to a noninvasive alternative to traditional invasive urodynamics using near-infrared spectrometry [80].

Advances in uroflowmetry beyond traditional gravimetric methods for home use were also reviewed [78]. These included basic volumetric, mechanical, and electrical methods such as capacitance sensors. Unconventional approaches were also discussed, including image processing for drop patterns, ultrasound Doppler effect, vibration sensors on the penis, and acoustic technology using a smartphone app to record urine sound [78,81].

Several studies (5/8, 63%) explored adapting existing technologies for home use. This included gravimetric uroflowmetry for home use [77,81] and its application in therapy settings to provide biofeedback during voiding [77,82]. Another study introduced home pelvic floor biofeedback through a wearable EMG device featuring a watchlike design with a light scale to indicate muscle activity strength [83]. In addition, transcutaneous electrical nerve stimulation was evaluated as a user-friendly substitute for in-clinic percutaneous tibial nerve stimulation to enhance continence, enabling self-administration at home without invasive needle insertion [84].

Study Results and Conclusions

Overall, the studies described promising advances in technology. The machine learning technology was described as having promising accuracy in screening for enuresis, with older age at toilet training initiation identified as a significant predictor [79]. Both uroflowmetry and EMG biofeedback were described as effective in reducing symptoms in patients with DV [82,83], with home uroflowmetry biofeedback showing promise and patient preference [77]. Transcutaneous electrical nerve stimulation was reported to show efficacy in reducing NE episodes, providing a safe and noninvasive at-home treatment option [84].

XSL•FO
RenderX

However, some novel technologies such as near-infrared spectrometry were described as promising and well accepted by patients but were also noted to lack standardized benchmarks and face challenges in ensuring consistent and reliable data that align with established norms and guidelines [80]. Similarly, while various uroflowmetry methods exist, gravimetric uroflowmeters were favored due to their simplicity and reliability [78]. For example, sound-based uroflowmetry, despite showing strong correlations with conventional uroflowmetry, was reported to have wide limits of agreement, with its accuracy influenced by variables such as smartphone type and toilet settings [81].

Enuresis Alarm Innovations

Novel Configurations

Category Overview and Key Drivers

Enuresis alarms function by detecting urine on 2 conducting strips, causing a voltage change and triggering an alarm [85-87]. Alarms with rigid wires may cause discomfort or psychological effects for the child, whereas fragile sensors can lead to missed alarms due to unintentional or deliberate deactivation. Conversely, overly sensitive alarms may trigger false alarms, which can be discouraging for patients [86]. These design shortcomings related to comfort, durability, and reliability in traditional enuresis alarms are the reason for novel configurations.

Tools Within This Category

We encountered 12% (8/66) of the studies featuring various configurations of enuresis alarms (Table S8 in Multimedia Appendix 3 [40-105]), spanning pad-and-bell to body-worn alarms and wired to wireless alarms. The pad-and-bell alarm used a bed mat with conductive strips, whereas the body-worn alarm had a sensor attached to underwear [86-88]. Wireless versions transmitted signals to an alarm positioned further away, requiring the child to leave the bed to deactivate it [86]. Smart textile sensors integrated conductive threads into underwear or disposable urine pads [85], with recent innovations incorporating wireless transmitters and smartphone apps for notifications and reinforcement strategies [89].

Configurations of the alarm signal itself ranged from loud acoustic alarms to subtler options such as lights, vibrating alarms, or personalized recorded messages [86]. For instance, one study evaluated a code word alarm with a digital voice recorder for parents to record personalized code words, rewarding children for recalling them the following morning [90]. Finally, another, more unconventional approach involved electrical impulses via surface electrode pads to activate the external urethral sphincter to interrupt micturition instead of relying on audible alarms [91,92].

Study Results and Conclusions

Comparative studies on pad-and-bell versus body-worn alarms reported mixed results [87,88]. While one study reported better outcomes with the pad-and-bell alarm [88], another found both equally effective but noted high dropout rates due to embarrassment [87]. Variations in false alarm rates and missed alarms were observed, suggesting that individual device features may have influenced performance more than the alarm type itself.

A review [86] highlighted the potential of smart textiles to enhance comfort and detection efficiency, with studies reporting positive performance and safety during daytime training [85,89]. One of these studies specifically found that a smart textile alarm with an app delivered similar outcomes in less time with high patient and parent satisfaction compared to standard behavioral therapy for toilet training children with autism spectrum disorder [89].

Using a prerecorded code word was reported to improve arousal response and training attitude, reducing dropout by 10%, although it only affected treatment outcomes in a subgroup with monosymptomatic NE [90]. Electrical impulses were reported as effective with perineal placement [91], though based on a small sample, whereas suprapubic placement showed no significant effect [92]. Reported benefits included potentially reducing fully wet beds, boosting self-confidence, and family motivation, but drawbacks such as higher cost, complexity, and potential fear of electrical currents were also noted.

Prevoid Alarms

Category Overview and Key Drivers

Traditional enuresis alarms provide a warning after an enuretic incident has occurred. Consequently, both the child and the parent still experience the inconvenience and consequences of wet pants or sheets during treatment, requiring a substantial level of motivation [93,94] Moreover, the child must establish an indirect link between the full bladder sensation and the alarm as it sounds after the bladder has emptied. These limitations have driven the development of prevoid enuresis alarms, designed to anticipate enuretic incidents by predicting when they might occur and provide a warning in advance.

Tools Within This Category

A total of 20% (13/66) of the studies were found on prevoid alarms (Table S9 in Multimedia Appendix 3 [40-105]), of which most (12/13, 92%) used ultrasound technology to trigger an alarm when bladder volume reached a predefined threshold. Basic ultrasound technology detected the posterior bladder wall rising above the symphysis pubis [93,95], whereas advanced systems estimated bladder volume using an array of transducers to locate both the anterior and posterior bladder walls through ultrasound echoes [94,96-104].

Various specialized measures were implemented to enhance the reliability of prevoid alarms. This included using intelligent software and machine learning to customize for factors such as body morphology, age, and sex [95,98-104]. Furthermore, to mitigate sensitivity to ultrasound probe movement, solutions such as tailored belts [93,95,104], elastic garments [94,98-100], adhesive materials [101-103], and even synchronizing measurements with the child's respiratory rhythm [95] were explored.

One prevoid alarm system estimated bladder volume using wearables and deep learning instead of ultrasound. It tracked impedance using a waist belt sensor, heart rate and sleep stage

XSL•FO
RenderX

using a smartwatch, and limb movement using fabric foot bands [105].

Study Results and Conclusions

The studies on prevoid enuresis alarms were primarily validation and feasibility studies reporting on the technological feasibility of these alarms, with detection rates varying from <50% to 90% [93,95-98,102,104,105]. However, sample sizes were small (1 to 41 patients) or relied on artificial bladder models.

Patient acceptance, influenced by the need for a comfortable, discrete, and nonstigmatizing design, was evaluated for MyPad [99,100] and SENS-U [101,103], both of which were well accepted. SENS-U was also reported to be feasible for both daytime bladder training [101] and nighttime monitoring [103].

Despite feasibility, several challenges were noted, including sensor positioning sensitivity; bladder shape changes due to an enlarged rectum or posture; and compatibility issues with different body types, particularly in children with obesity [93,94,98,100-104]. In addition, daytime observations of SENS-U showed that 23% of children experienced urgency or leakage before reaching the predefined volume-based threshold [101].

Finally, only 8% (1/13) of these studies compared the prevoid alarm with the traditional alarm, reporting comparable cure rates but a treatment duration approximately 3 times longer with the prevoid alarm [94]. The study suggested that awakening to wet sheets may constitute a classic conditioning negative reinforcement potentially essential for the cure process.

Discussion

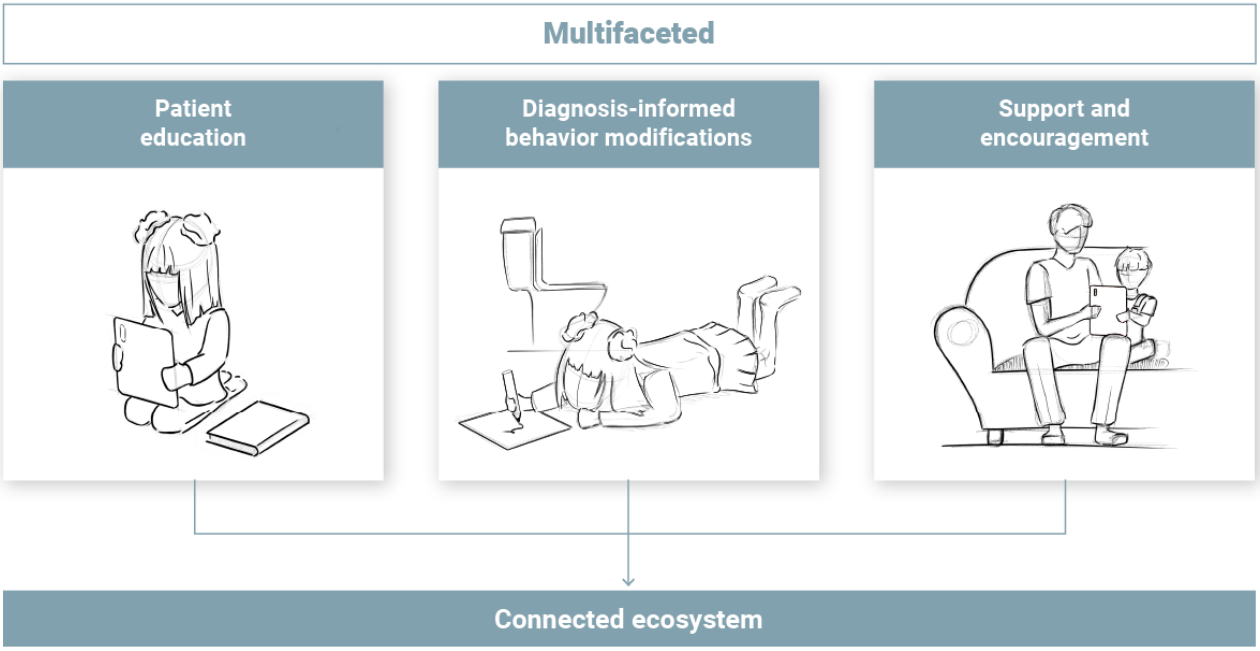
Principal Findings

In this scoping review, we identified and mapped innovative, technology-driven, digital tools for managing pediatric UI. The field of pediatric UI demonstrates a considerable level of innovation, as evidenced by the inclusion of 66 articles, with nearly one-third (21/66, 32%) focusing on NE. Our analysis led to the identification of six primary categories of tools, 3 of which were divided into subcategories. (1) Digital self-management tools, which leveraged the widespread use of smartphones, tablets, and computers, offering a convenient and accessible medium for health-related purposes such as electronic bladder diaries [40,41] and self-management apps or portals [42-46]. (2) Serious games, which engaged children through playful interactions, such as games for pelvic floor biofeedback training [47-52] and standard urotherapy [53]. (3) Reminder technology, which aimed to enhance therapy adherence without constant parental prompting, such as timer watches [54-56] and self-management reminder tools [57-59]. (4) Educational media for delivering health-related information to patients, which was subdivided into videos and other types of educational media. Videos offered visually engaging, 24/7-accessible, and anonymous dissemination of health information on topics ranging from behavioral therapy, such as bladder training and NE therapy [60-63], to preparing for surgical interventions [64]. A variety of other materials were found that provided child-friendly and engaging patient education, such as UI homework books [65,66], an NE multimedia program [67,68], and educational materials for UTIs [69-71]. (5) Telehealth and RPM for remote health information exchange, which was subdivided into communication and technological advances. Remote communication between patients and health care professionals through videoconferencing [72], home monitoring systems [73], and an embodied conversational agent [74-76] can lead to time, cost, and travel savings. Technological advances such as machine learning algorithms [79], new technologies [78,80,81], and new applications enabling home use [77,78,80-84] aimed to overcome the limitations of in-clinic procedures. (6) Enuresis alarm innovations, which were subdivided into novel configurations of traditional enuresis alarms and prevoid alarms. Enuresis alarm configurations encompassed pad-and-bell and body-worn alarms [86-88], wired and wireless systems [86], smart textiles [85,89], and a variety of alarm signals [86,90-92]. Prevoid alarms aimed to predict enuretic incidents and provide warnings in advance [93-105], with most using bladder ultrasound technology [93-104].

Many of the tools identified in this review were described as promising alternatives to traditional methods, with studies reporting their feasibility [40-46,57-59,65,66,93,95-98,102,104,105], potential to improve outcomes [43,47-53,60,61,64,74-76,82-84,90], and ability to save time for health care providers [49,60,61,64,68-70]. In addition, these tools were described as engaging for children, improving patient compliance [43,46,52,54-56,66,67,74-76] and leading to high levels of patient satisfaction and preference [40-46,53,58,72-77,89,100,101,103].

However, the current body of evidence has methodological limitations, including retrospective designs [49,55,82,83]; absence of control groups [47,57,75,76,84,94,101,103]; and small sample sizes, with almost one-quarter of the studies (16/66, 24%) having a sample size of ≤15 participants [45,58,59,73,75,83,85,91,96,98-101,103-105]. While 21% (14/66) of the included studies were RCTs [43,50-52,56,60,61,64,68,77,88-90,92], some of these (3/14, 21%) did not compare equivalent therapies [43,50,51]. Furthermore, the findings varied, with some studies (10/66, 15%) demonstrating differences in outcomes between the novel tools and traditional methods [49,55,56,74-76,88-90,94], whereas others (9/66, 14%) reported similar outcomes [40,50,60,68-70,77,87,92]. These observations highlight the need for more rigorous research to better establish the effectiveness of these tools.

Understanding the Challenges of Managing Pediatric UI



The variability in the reported findings and gaps in robust evidence may also reflect the complexity of managing pediatric UI. This review highlights the multifaceted and multifactorial influences on pediatric UI management.

Multifaceted Influences

Pediatric UI management encompasses various aspects, such as patient education, diagnosis-informed behavior modifications, and providing support and encouragement (Figure 3).

XSL•FO
RenderX

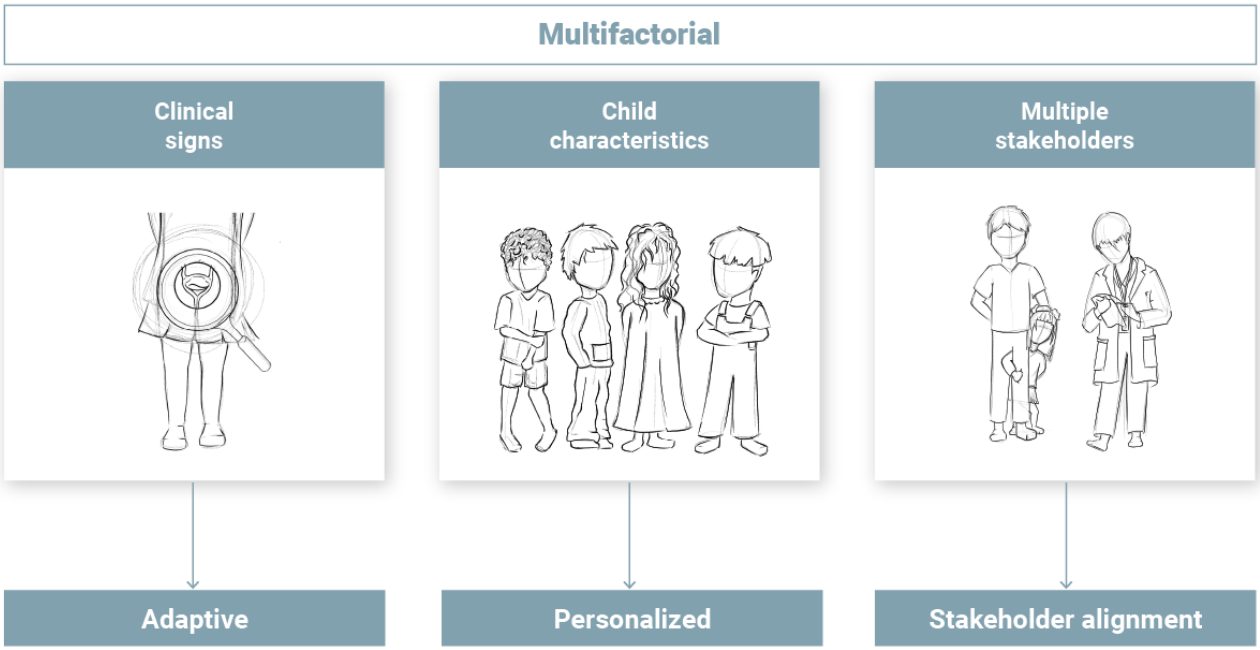
Figure 3. Pediatric urinary incontinence management is multifaceted, including patient education, diagnosis-informed behavior modifications, and support and encouragement. Integrating these aspects into a connected ecosystem might be an ideal way to address this multifaceted nature.

Regarding patient education, the studies included in this review highlighted various educational activities, such as raising awareness [69-71], explaining complex concepts [64], setting expectations [67,68], providing lifestyle advice [60-63,75,76], and promoting adherence [53,65,66,74].

Regarding diagnosis-informed behavior modifications, management typically began with a thorough diagnostic process, as described in several included studies (9/66, 14%) [40,65,72,74-76,78,80,81]. By accurately identifying contributing factors and underlying causes, appropriate therapeutic interventions can be selected. The interventions described in the reviewed studies included providing instructions and reminders to establish healthy bladder and bowel habits [54-59]. Monitoring these habits through the collection of data on fluid intake, voiding patterns, and bowel movements [40,41,53], as well as quality of life indicators [42-45], was reported to help identify patterns and track progress over time [42-46,53,73].

Regarding support and encouragement, the included studies emphasized that support, encouragement, and feedback can help reinforce positive behaviors and maintain therapy consistency whether in the clinic [47-52], at home [42-45,72,74-77,84], or in a group setting [82].

Despite this multifaceted nature, many tools discussed in this review offered stand-alone solutions that addressed specific aspects. Examples include mobile health apps for keeping electronic bladder diaries [40,41], biogames for pelvic floor biofeedback [47-52], timer watches for timed voiding [54-56], educational videos covering specific concepts [60-64], and enuresis alarm innovations for alarm training [85-104]. While these stand-alone solutions addressed particular aspects of pediatric UI management, they did so in isolation, potentially missing opportunities to create synergies and links between different aspects of UI management. This review leads us to wonder whether integrating these various aspects into a connected ecosystem could better address the multifaceted nature of UI management.



Multifactorial Influences

Pediatric UI management is influenced by a range of factors, such as clinical signs, child characteristics, and the involvement of multiple stakeholders (Figure 4).

Regarding clinical signs, the management of pediatric UI depends on the specific type and severity of symptoms that children experience. These can include multiple symptoms related to the bladder and bowel [40,60,61,72,78,80,81] occurring during the day or night [41,74-76,79]. Therefore, each child's therapy journey is unique, with varying underlying causes, progress rates, and potential setbacks. Accurate differentiation during the diagnostic phase, along with continuous monitoring of therapy progress, as described in some studies (11/66, 17%) [42-45,53,74-77,82,83], can support tailoring management plans to the child's specific condition and adapting them as needed. We propose that tools be adaptive to meet the evolving needs of children during therapy and help maintain their motivation. For instance, feedback from children using the urotherapy serious game indicated a desire for more dynamic gameplay that adapts to their training progress [53].

XSL•FO
RenderX

Figure 4. Pediatric urinary incontinence management is multifactorial, influenced by a range of factors such as (1) clinical signs that progress over time, requiring adaptive interventions; (2) child characteristics that demand a personalized approach; and (3) the involvement of multiple stakeholders whose needs must be aligned.

Regarding child characteristics, the management of UI depends not only on the child's clinical signs and physiological needs but also on their psychological and emotional needs. As described in the studies, these needs can influence the child's motivation [52,53,93,94,106], attitude toward training [43,46,55,56,65,66,74,90], and level of maturation and attention span [52,67]. Emotional factors such as self-image, embarrassment, fear, and stress were also described as key influences [59,64,87,91]. These child-specific characteristics can influence outcomes. For instance, varying findings of comparative studies on different enuresis alarm configurations [87,88] suggested that certain configurations may be more effective for some children than for others. In addition, one study reported that reminder technology was an equally effective but simpler alternative to enuresis alarms in treating DUI [54]. We propose that personalizing or selecting tools based on the child's preferences may enhance acceptance and satisfaction and potentially lead to better outcomes.

Regarding multiple stakeholders, each stakeholder involved in pediatric UI management has distinct needs. The studies indicated that parental motivation often depended on constraints such as time, cost, and travel, prioritizing convenience and self-efficacy [22,25,40,41,46,72-76,78,89,91,93,94]. Health care professionals, on the other hand, were described as managing time constraints in busy clinical practices, aiming for efficiency and high-quality data [40,46,49,60,61,64,78,80] while also maintaining empathy and establishing a therapeutic alliance [72,75]. Aligning these diverse needs can be challenging, as described for the UTI remote monitoring system [73]. Although the system comprised a set of products, most parents primarily used the urinalysis device because it met their needs for self-efficacy and reassurance. The other products were underused, leading to frustration among health care providers, who faced added workload for setting up the system without improved data quality. These findings underscore the importance of designing tools that balance the needs of all stakeholders, improving quality of life for patients and families while optimizing time and efficiency for health care professionals.

Transforming Health Care With Connected Ecosystems

Given the multifaceted and multifactorial nature of pediatric UI management, we propose that novel tools should be designed as health care ecosystems that are (1) connected, (2) adaptive, (3) personalized, and (4) aligned with the needs of all stakeholders.

The concept of health care ecosystems for managing pediatric UI is rooted in a broader transformation of the health care industry driven by innovation [115]. Advances such as electronic health records, networked computer systems, and telehealth have revolutionized health care delivery, shifting from a model centered on face-to-face interactions with individual clinicians to a smart, interconnected health care community emphasizing shared decision-making [116]. The COVID-19 pandemic further accelerated this transition, highlighting the critical role of digital technologies in maintaining access to health care [117]. Furthermore, recent breakthroughs in computational power and artificial intelligence promise to expand the capabilities of health care systems even further [116].

A fair part of the currently available medical devices already has the ability to connect and communicate with other devices or systems. This connectivity transforms previously isolated tools into collaborative systems that operate within closed feedback loops, tailoring outputs to the individual [118]. For example, in glucose monitoring, sensors measure blood glucose levels, which then inform insulin delivery systems to maintain optimal glucose control [119]. Similarly, smart pillboxes

XSL•FO
RenderX

improve medication adherence by tracking remaining doses, providing reminders through a connected alarm device [120].

While many of these systems have been tested primarily in contexts such as monitoring older patients at home [121]—where they support independence and reduce health care burdens—pediatric urology presents a significant opportunity for similar innovations. For example, a recently published article on the Minze Homeflow system demonstrates how a connected ecosystem can enhance pediatric UI management [122]. It integrates physical products (uroflowmeter and accessories) with digital tools (Minze app and clinician portal) for remote monitoring of uroflowmetry and bladder diary data. By shifting diagnostics to the home environment, the Homeflow system minimizes stress for pediatric patients while providing more reliable data compared to in-clinic measurements. Such a system demonstrates the feasibility and benefits of connected health care ecosystems in addressing specific challenges in pediatric urology.

Another study demonstrated how the Homeflow ecosystem could be further expanded by connecting additional products to the system, such as a smart drinking bottle and reminder technology, to personalize urotherapy [123]. The smart drinking bottle and home uroflowmeter monitored fluid intake and urinary output, whereas a reminder watch linked these devices, offering personalized voiding prompts based on the child's bladder capacity and fluid intake. This demonstrates the potential of connected ecosystems to adapt and align with the individual care needs of pediatric patients.

Overcoming Challenges in Health Care Innovation

The successful implementation of health care innovation and ecosystems requires addressing important challenges, such as regulatory and privacy concerns, equitable access, screen time considerations, and keeping health care human centered. Thoughtful strategies are needed to overcome these challenges and maximize benefits.

Regulatory and Privacy Concerns

Ensuring patient privacy and data security remains a critical challenge for digital health care innovation [124]. As these tools handle sensitive patient data, robust regulatory frameworks must be established to protect patient data. However, balancing innovation with regulation remains a challenge, especially considering the rapid pace of technological advancements. Current regulations may struggle to keep up, potentially delaying the adoption of transformative tools. A balanced approach is required to ensure safety and trust without hampering innovation that can improve patient care.

Equity in Access

Ensuring equitable access is another challenge for health care innovation, especially in low-resource settings. Individuals in such settings must not be left behind as they are often the ones who stand to benefit the most from these advancements [115]. However, barriers such as limited infrastructure, potentially high entry costs, and digital literacy disparities can hinder adoption [116]. Nevertheless, innovation also has the potential to improve equity by decentralizing care. Shifting diagnostics and therapies from clinics to homes or communities can reduce costs and improve accessibility. In addition, customizable solutions tailored to varying resource levels, aligned with reimbursement models, or supported through public health initiatives can support the equitable implementation of innovation.

Screen Time Considerations

The use of digital tools raises concerns about screen time and its potential impact on children's health. A 2019 systematic review [125] identified associations between excessive screen time and health risks, including adiposity, unhealthy diet, depressive symptoms, and reduced quality of life. However, the review did not consider the influence of content or context on these outcomes. Research indicates that well-designed, age-appropriate content, especially when curated by engaged adults [126], can positively impact learning and behavior [127]. For example, screen time can calm distressed children during medical procedures [128] or support language learning [129]. Moreover, active video games or nature exploration apps can encourage physical activity and imaginative play by connecting on- and off-screen experiences [130].

Nevertheless, certain screen use patterns present clear risks. Screen time before bedtime is strongly associated with sleep disturbances [131]. The mere presence of electronic devices in bedrooms has been linked to shorter sleep duration, partly due to melatonin suppression [132]—an essential consideration for tools addressing NE. A 2024 systematic review [133] reinforced these findings, showing that greater use of mobile devices, particularly at bedtime or in patterns of device dependence, can harm mental health in children and adolescents. At the same time, it emphasized technology's dual impact—while social media often correlates with negative effects, other communication tools can enhance psychological well-being by strengthening social connections and providing access to support. These effects vary across individuals, highlighting the need to identify those most vulnerable to adverse effects.

In summary, the impact of screen time is shaped by multiple factors. To maximize benefits, digital tools should be thoughtfully designed to deliver engaging, age-appropriate content; promote balanced screen habits; integrate on- and off-screen interactions; and avoid bedtime use and overreliance on devices.

Keeping Health Care Human Centered

Digital technology presents significant opportunities to enhance efficiency and accuracy in health care. However, human interaction remains fundamental to preserving empathy, trust, and nuanced clinical decision-making. For example, a study in this review reported that health care providers experienced difficulties building rapport with pediatric patients due to technical barriers [72]. This underscores the importance of designing tools that augment health care professionals' capabilities, ensuring that technology supports rather than depersonalizes patient care. Therefore, a human-centered approach to technology is needed to actively incorporate the perspectives and needs of patients, caregivers, and health care

XSL•FO
RenderX

providers, placing them at the center of smart and connected health care in both research and practice [116].

Such an approach values not only objective evidence but also subjective patient and stakeholder experiences, combining quantitative and qualitative methods. However, in our review, only 12% (8/66) of the studies used qualitative [42,72,99] or mixed methods [40,44,58,67,73] designs. Despite this, more than one-third (25/66, 38%) of studies evaluated outcomes related to patient experience, such as satisfaction, motivation, and usability [42-45,52,53,57,58,66,67,71-73,75,76,82,88-90,94,98-101,103]. This indicates a growing recognition of the importance of patient-centered outcomes but also underscores the need for more qualitative approaches to capture deeper insights.

To incorporate a human-centered approach, we conducted a separate qualitative study alongside this scoping review to explore children's perspectives, experiences, and expectations regarding urotherapy-supporting tools. To facilitate this, we developed a focus group discussion toolkit specifically tailored to pediatric UI [134]. The toolkit incorporated creative tasks involving imagination and play, enabling children to express their thoughts and experiences in a child-friendly and engaging manner. By combining insights from this scoping review with the findings of the focus groups, we aimed to provide a comprehensive perspective that blends existing evidence with the desires and needs of the target population. This integrated approach can guide the development of more effective and user-centered tools for pediatric UI management.

Limitations

This scoping review has certain methodological limitations that should be considered when interpreting its results. First, the search was limited to 3 electronic databases, and only English-language papers were included. Second, only 1 reviewer screened the entire set of search results. However, the team engaged in frequent and extensive discussions throughout the study selection process to ensure rigorous screening. Third, our search had an extensive scope due to our broad criteria for defining innovative, technology-driven, digital tools, as well as having no time limits. The broad field and the potential abundance of relevant tools made it challenging to provide a concise overview of all the information. Consequently, this review encompassed a broad range of studies and a wide variety of innovative, technology-driven, digital tools.

Conclusions

This scoping review offers valuable insights into various categories of innovative, technology-driven, digital tools for managing pediatric UI and their supporting evidence. The inclusion of 66 articles highlights a considerable level of innovation in the field.

We identified 6 main categories of tools: digital self-management, serious games, reminder technology, educational media, telehealth and RPM, and enuresis alarm innovations. Further subcategories were found within these main categories, such as video and other media within educational media, communication and technological advances within telehealth and RPM, and novel configurations and prevoid alarms within enuresis alarm innovations.

Many of these tools were described as promising alternatives to traditional methods, with studies reporting feasibility, effectiveness in improving outcomes, and potential time savings for health care providers. In addition, these tools were described as engaging children effectively, potentially enhancing patient compliance and contributing to high patient satisfaction and preference. However, this review identified gaps in research, highlighting the need for more rigorous research to better assess the effectiveness of these tools and address the complex, multifaceted challenges of pediatric UI management. We propose the development of connected, adaptive, and personalized health care ecosystems that integrate diverse strategies for UI management, including education, diagnosis, therapy, monitoring, and feedback. By enabling synergies and links between these different strategies, such ecosystems could create a closed-loop system that enhances the alignment and efficiency of care.

We suggest that future research and development in this field adopt a human-centered and multidisciplinary approach, combining quantitative and qualitative methods to incorporate user perspectives and involve all stakeholders from the start. This mixed methods approach may help ensure that both objective evidence and subjective experiences are equally valued, supporting impactful innovations in the complex field of pediatric UI management.

Acknowledgments

The generative artificial intelligence tool ChatGPT by OpenAI was used to improve language and readability. The tool provided inspiration on how to rephrase parts of the manuscript, but final edits and decisions were made by the authors. This research is part of a PhD project partially funded by the Flanders Innovation and Entrepreneurship Baekeland grant (project ID HBC.2021.0836) and the company Minze Health.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

The conceptualization of this scoping review, including the formulation of the research question, search strategy, and eligibility criteria, was a collaborative effort involving the entire team of authors. LB took the lead in the study selection process and data

XSL•FO
RenderX

analysis, which included screening titles and abstracts, assessing full-text articles, charting the data, and conducting categorization of the identified tools. Throughout these processes, LB consulted with the team to ensure consistency, rigor, and consensus. GDW and AV provided expertise on pediatric urinary incontinence management, whereas LVC and JV contributed insights on product design and categorization of the tools. All authors offered guidance throughout the research project, including interpretation and critical review. LB drafted the manuscript and finalized the version presented. The final manuscript was critically reviewed and approved by all authors.

Abstract

Background: Artificial intelligence (AI) is increasingly integrated into palliative medicine, offering opportunities to improve quality, efficiency, and patient-centeredness in end-of-life care. However, its use raises complex ethical issues, including privacy, equity, dehumanization, and decision-making dilemmas.

Objective: We aim to critically analyze the main ethical implications of AI in end-of-life palliative care and examine the benefits and risks. We propose strategies for ethical and responsible implementation.

Methods: We conducted an integrative review of studies published from 2020 to 2025 in English, Portuguese, and Spanish, identified through systematic searches in PubMed, Scopus, and Google Scholar. Inclusion criteria were studies addressing AI in palliative medicine focusing on ethical implications or patient experience. Two reviewers independently performed study selection and data extraction, resolving discrepancies by consensus. The quality of the papers was assessed using the Critical Appraisal Skills Programme checklist and the Hawker et al tool.

Results: Six key themes emerged: (1) practical applications of AI, (2) communication and AI tools, (3) patient experience and humanization, (4) ethical implications, (5) quality of life perspectives, and (6) challenges and limitations. While AI shows promise for improving efficiency and personalization, consolidated real-world examples of efficiency and equity remain scarce. Key risks include algorithmic bias, cultural insensitivity, and the potential for reduced patient autonomy.

Conclusions: AI can transform palliative care, but implementation must be patient-centered and ethically grounded. Robust policies are needed to ensure equity, privacy, and humanization. Future research should address data diversity, social determinants, and culturally sensitive approaches.

Introduction

Background

The review focused on studies published between 2020 and 2025 to capture the most recent advances in artificial intelligence (AI) technologies and their application in clinical practice, as the field has evolved rapidly in the last 5 years [1]. This approach ensures the relevance of findings to current and emerging ethical challenges.

AI is a subject within computer science that develops systems capable of performing tasks that simulate human capabilities, such as learning, reasoning, and decision-making. Machine learning (ML) allows algorithms to learn from data without explicit programming within this field. At the same time, deep learning, a subset of ML, uses advanced neural networks to analyze large volumes of information and generate accurate predictions.

AI significantly transforms the traditional health care paradigm toward an evidence-based and patient-centered model. Its application in areas such as the anticipation of complications, the personalization of treatments, and the optimization of resources has proven to be a key catalyst for improving the quality and efficiency of medical care [2].

Palliative medicine has also begun to benefit from the transformative potential of these technologies. This type of care, aimed at patients with advanced or terminal illnesses, seeks to alleviate physical, emotional, and spiritual suffering while seeking to improve quality of life and promote dignity in the final moments [3]. Palliative care encompasses a wide range of conditions, including advanced-stage oncological diseases (metastatic lung, breast, or pancreatic cancer) and nononcological illnesses such as neurodegenerative disorders (amyotrophic lateral sclerosis and late-stage Parkinson), end-stage organ failures (heart, lung, or renal disease), and severe respiratory conditions (chronic obstructive pulmonary disease). These patients, regardless of their specific diagnosis, share everyday needs: symptom relief, emotional support, and dignity preservation as they approach the end of life. The integration of AI in this sensitive context must, therefore, address the heterogeneity of these conditions while upholding ethical principles.

AI in palliative medicine includes tools, such as predictive models, to identify specific needs, wearable devices to monitor symptoms in real time, and virtual assistants that facilitate communication between patients, carers, and professionals. These innovations promise to improve clinical outcomes and enrich the patient experience by offering more personalized approaches [4]. However, its implementation poses significant ethical challenges due to the inherent vulnerability of patients and the complexity of end-of-life decisions. Thus, when we apply AI in palliative care, we must ensure that these tools do not reduce patients to mere actionable data but reinforce their humanity and dignity, honoring their individuality and right to compassionate and ethically informed care. Furthermore, it is crucial to consider how these technologies may affect human dignity and avoid a possible dehumanization of care [5]. In response to these concerns, various institutions have developed ethical guidelines to evaluate and regulate the responsible use of AI-based systems in sensitive contexts.

Despite enthusiasm for AI's transformative potential, significant barriers to its widespread adoption in clinical practice remain. The lack of clear regulatory frameworks and consolidated examples of success highlights the urgent need for integrative research that addresses both the opportunities and the ethical and practical limitations of using AI in palliative care. As Miralles [2] points out in 2023, although multiple promising areas for applying AI in health care have been identified, few consolidated cases have achieved effective adoption in real clinical environments.

In recent years, various ethical self-assessment tools have been developed to verify the suitability of a system based on different ethical principles. In response to these concerns, various institutions have developed ethical guidelines to assess and regulate the responsible use of AI-based systems in sensitive contexts, such as the Ethical Guidelines for Trustworthy AI, the Draft Recommendation on the Ethics of Artificial Intelligence, and [6] the Barcelona Declaration [7]. Also, the AI Ethical Impact Group: From Principles to Practice [8], Technical Methods for Regulatory Inspection of Algorithmic Systems on Social Networking Platforms [9], or the Organisation for Economic Co-Operation and Development (OECD) of AI Systems Classification Framework [10], among others.

In line with international frameworks such as the Institute of Medicine (IOM) and the OECD, this review adopts a multidimensional understanding of "quality of care," which includes safety, effectiveness, patient-centeredness, timeliness, efficiency, and equity as interrelated domains. While "efficiency" is thus an integral component of overall quality, for analytical clarity, we will at times refer to efficiency as system-level performance (resource optimization and process automation) and quality as patient-centered outcomes (dignity and symptom relief). This distinction, while recognizing their overlap, allows us to examine the specific effects of AI on both system operations and patient experience in palliative care.

Theoretical Justification

Ethical reflection on palliative care and AI is rooted in classical and contemporary philosophy.

In his *Nicomachean Ethics* [11], Aristotle posits the notion of the "good life" as the realization of the highest human capacities through virtue, wisdom, and justice. From this perspective, a "good death" implies respecting the dignity and well-being of the patient even at the end of life.

For his part, Immanuel Kant, in the Foundation of the *Metaphysics of Morals* [12], argues that human dignity is an intrinsic and inalienable value, which precludes treating people as mere means to an end, even in medical or technological contexts; this requires that any intervention, including the application of AI, respects the autonomy and inherent value of each patient.

Finally, Emmanuel Lévinas, in *Totality and Infinity* [13], introduces the ethics of otherness, which stresses the importance

XSL•FO
RenderX

of recognizing and preserving the uniqueness of the other. This approach is particularly relevant in palliative care, where care must focus on the individuality and dignity of the patient, avoiding technological reductionism that can depersonalize the end-of-life experience.

These 3 philosophical frameworks provide a sound basis for critically analyzing the opportunities and ethical challenges of integrating AI in palliative care.

We hypothesize that the application of AI in palliative medicine simultaneously offers significant opportunities for personalizing care and presents ethical risks that may compromise patient dignity. This study seeks to explore and examine this hypothesis through an integrative analysis of the recent literature.

Objectives

1. We aim to examine current and potential applications of AI in palliative care: In this systematic review of the literature and recent cases, we will attempt to identify how AI is being used in end-of-life care, including tools for symptom management, clinical decision support, and communication between professionals, patients, and families.
2. To analyze the ethical implications of using AI in palliative care, we will investigate the ethical dilemmas arising from the integration of intelligent technologies in this field, such as privacy and handling of sensitive data, patient autonomy, equity in access to technology, and the possibility of depersonalizing care.
3. We aim to assess the impact of AI on patient experience and dignity at the end of life: To assess how the presence of AI influences the perception of quality of life, respect for dignity, and satisfaction of the emotional and spiritual needs of patients and their families.
4. We aim to propose recommendations for the ethical implementation of AI in palliative care.

Methods

Study Design

This research was carried out as an integrative review, which allows for synthesizing information from various study designs and offers a wide viewpoint on a challenging subject. The review included studies published in Spanish, Portuguese, and English between 2020 and January 2025. Due to their applicability in the biological and technological domains, the scientific databases consulted were PubMed, Scopus, and Google Scholar. Given the rapid development of the field over the past 5 years, we chose to focus on this recent period to ensure the inclusion of the most up-to-date and relevant advancements in AI applied to palliative medicine. This decision is supported by recent systematic reviews documenting a significant increase in the number and scope of published studies in this area [14].

Search and Selection Process

The search strategy was designed to ensure a rigorous and systematic approach. Keywords such as “artificial intelligence,” “palliative care,” “palliative medicine,” “medical ethics,” “machine learning,” and related combinations were used (Multimedia Appendix 1). The search process followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses; Multimedia Appendix 2) guidelines, which provide a standardized framework for transparent and comprehensive reporting, including a 29-item checklist and a 4-phase flow diagram to document the identification, screening, eligibility, and inclusion of studies according to Page et al [15].

Study eligibility was assessed in 2 stages:

- Title and abstract screening: Two reviewers screened all papers and abstracts for relevance.
- Full-text review: The same reviewers independently assessed the full texts of potentially eligible studies.

Two reviewers independently conducted both the study selection and the quality assessment processes. Any discrepancies between reviewers were resolved through consensus discussions or, if necessary, by consulting a third reviewer.

Inclusion criteria were (1) studies published between 2020 and 2025, (2) research addressing the use of AI in palliative medicine, and (3) articles analyzing ethical implications or the patient experience in this context.

Exclusion criteria were (1) studies not explicitly focused on palliative medicine, (2) research lacking ethical analysis or patient experience analysis, and (3) duplicate or non–peer-reviewed publications.

The PRISMA flow diagram summarizes the study selection process, including the number of records identified, screened, excluded, and included at each stage.

Data Extraction

Data extraction was performed independently by 2 reviewers (AGA and ASV). Any discrepancies were discussed and resolved collaboratively. Extracted data included study design, population, AI application, ethical focus, primary findings, and limitations.

Quality Appraisal

The quality of the included studies was assessed using 2 tools to ensure methodological rigor. Two reviewers performed the quality assessment independently, with discrepancies resolved by consensus.

The Critical Appraisal Skills Programme (CASP) checklist [16] was applied as a complementary tool to further assess each study’s methodological quality and transparency (Table 1).

XSL•FO

The Hawker et al (2002) [42] checklist allows for systematic evaluation across diverse research designs. Each study was scored independently across 11 domains: clarity of purpose, study design, methodology, sampling, data analysis, ethical implications, relevance, transferability, results, discussion, and theoretical basis. Scores range from 1 (very poor) to 4 (good) for each domain; an overall quality score was calculated as the mean of all domain scores (Table 2).

Table 2. Methodological quality assessment of all included studies according to the criteria of Hawker et al [42]: 1=very poor, 2=poor, 3=fair, and 4=good.

Study	Clarity of purpose	Design	Methodology	Sampling	Analysis	Ethical implications	Relevance	Transferability	Results	Discussion	Theoretical basis	Overall quality
Balch et al [17]	4	4	4	2	3	3	3	4	4	3	3	3.27

Chua et al [41]	4	3	3	2	3	3	3	4	4	3	3	3.09

Thematic Analysis

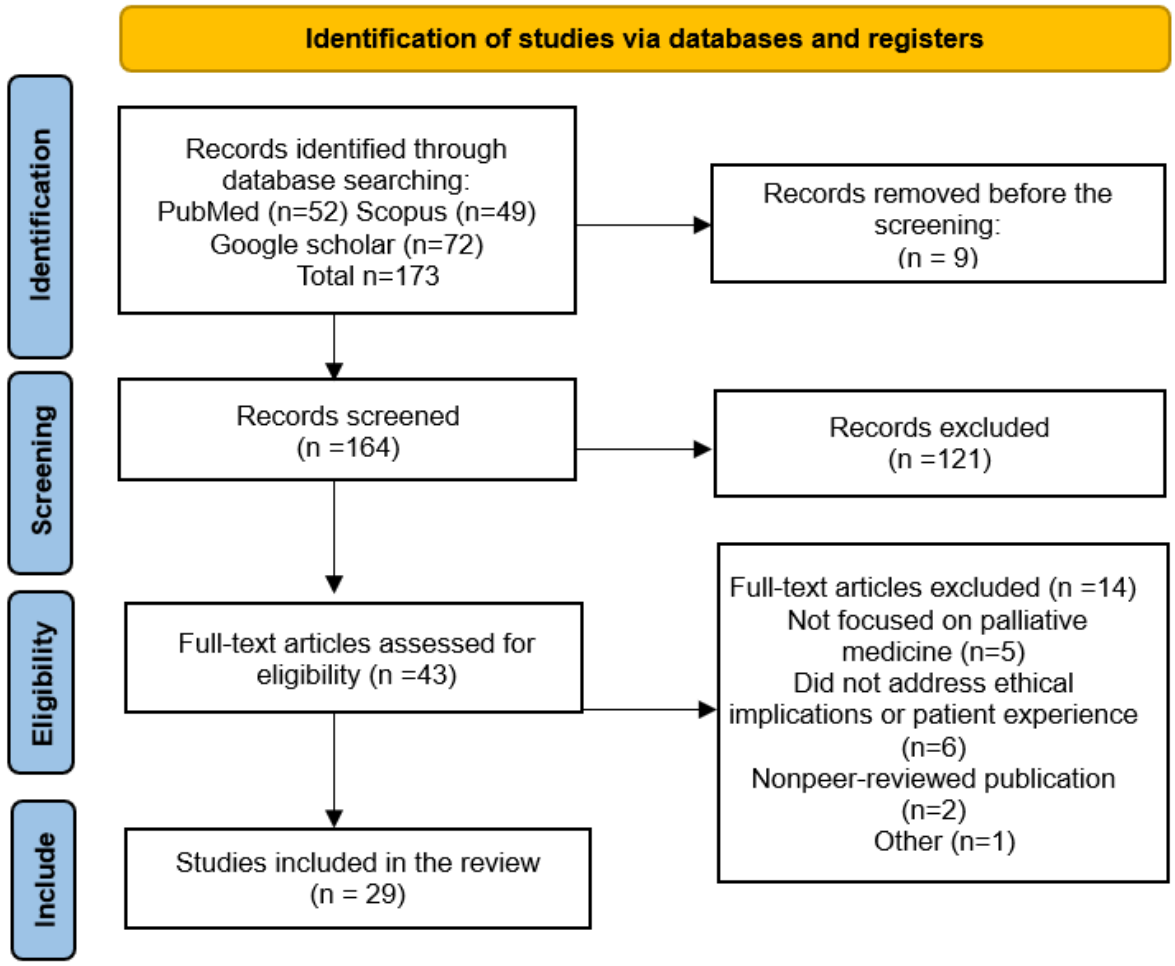
Extracted data were thematically coded and grouped into 6 key categories—prediction and clinical decision-making, symptom management and quality of life, communication and emotional support, process automation and modeling, ethical implications, and research and review of advances in AI [14]—reflecting the main areas presented in the Results section.

XSL•FO
RenderX

Ensuring Methodological Rigor

To maximize the reliability and validity of the review:

- Triangulation: findings were compared across studies to identify consistent patterns.
- Peer review: the methodology was reviewed using bioethics and AI.
- Critical evaluation: each study was assessed for quality, relevance, and validity using the criteria above.



This process allowed identifying strengths, limitations, and potential biases in the included studies [43].

Results

Overview

This section presents a thematic synthesis of the main findings regarding the ethical and practical implications of AI in palliative medicine at the end of life. The 29 included studies, published between 2020 and January 2025, covered various clinical contexts, populations, and AI applications. The results are structured in 6 key areas identified in the literature (Figure 1).

Figure 1. PRISMA 2020 flow diagram illustrating the study selection process. The diagram shows the number of records identified, duplicates removed, records screened, full-text papers assessed, and studies included in the review. Adapted from the PRISMA 2020 Statement [15].

The following tables provide a comprehensive synthesis of the 29 studies included in this review.

In Table 1, we present the ratings obtained for the methodological quality of each study according to the CASP checklist. Two independent reviewers rated each item as "yes," "no," or "unclear," and the percentage of responses was calculated to assign an overall rating of high, medium, or low.

Table 2 shows the quality scores in 9 domains using the Hawker et al [42] instrument. Two reviewers rated each domain from 1 (very poor) to 4 (excellent), and we report both the individual domain scores and the overall mean quality score for each item.

Table 3 summarizes the key characteristics of the included studies. For each study, we list the author, year, country, design, AI/ML application, population or setting, study objective, and principal findings, and group them according to the 5 thematic areas identified in our review.

The analysis of the included studies revealed 6 key thematic areas in the application of AI in palliative care. These thematic areas provide a comprehensive overview of the current landscape and highlight both the opportunities and challenges presented by AI in this field.

[a]AI: artificial intelligence.

[b]PRO: patient-reported outcome.

[c]ML: machine learning.

[d]RCT: randomized controlled trial.

[e]NCCN: National Comprehensive Cancer Network.

[f]LLM: large language model.

Prediction and Clinical Decision-Making

AI has demonstrated significant potential in supporting clinical decision-making and anticipating patient needs in palliative care. For example, Strand et al [18] developed a machine learning model that more accurately identified hospitalized patients with cancer who could benefit from specialized palliative care, outperforming traditional approaches. Similarly, Salama et al [24] and Liu et al [20] reported that AI tools can help personalize pain management and predict imminent terminal events, allowing for more timely interventions. However, Porter et al [23] cautioned that excessive reliance on algorithmic predictions, especially when models lack transparency or interpretability, may undermine human sensitivity and clinical judgment in complex palliative care scenarios.

Symptom Management and Quality of Life

Effective symptom management and quality of life improvement are central in palliative medicine, and AI tools are being tested in oncological and nononcological populations. AI applications have facilitated individualized pain control and symptom monitoring for patients with cancer [24]. In noncancer contexts, Ott et al [26] described using smart sensors for real-time symptom tracking in neurodegenerative diseases. However, studies such as by Deutsch et al [27] highlighted the risk of bias when training datasets underrepresent specific populations (patients without cancer or minority groups), potentially limiting the generalizability and fairness of AI-driven symptom management.

Communication and AI Tools

AI-based communication tools, including chatbots and natural language processing models, have been explored to support interactions between professionals, patients, and families. Gondode et al [29] and Srivastava and Srivastava [30] analyzed large language models GPT-3 to facilitate information delivery and emotional support. However, these tools often reflect Western bioethical principles. They may not adapt well to cultural contexts where family-centered decision-making or gradual truth disclosure is preferred [34]. Several studies reported that AI trained on Anglo-Saxon datasets may misinterpret emotional cues or cultural preferences, underlining the need for culturally sensitive models and community co-design.

Process Automation and Modeling

AI process automation can optimize resource allocation and improve efficiency in palliative care. Reason et al [31] demonstrated how large language models can automate economic modeling, potentially reducing costs and improving service access. Windisch et al [3] emphasized the benefits of AI in improving the timing and quality of palliative interventions. However, Kamdar et al [32] stressed the importance of maintaining a patient-centered approach, even in highly automated environments.

Ethical Implications

The ethical challenges of AI in palliative medicine are complex and multifaceted. Ferrario et al [5] analyzed the need for transparency and accountability in algorithmic prediction of end-of-life preferences. Ranard et al [35] addressed the risks of algorithmic bias, especially when models are trained on

XSL•FO
RenderX

unrepresentative data, which can lead to inequitable care decisions. Finally, See [33] explored the potential of AI as an ethical advisor but noted that this application is still in its early stages and requires further research.

Regarding the ethical design of data-driven decision support tools, Bak et al [44] discuss the importance of considering ethical principles, such as algorithmic fairness and privacy, in the development of decision support tools in oncology, with direct implications for palliative medicine.

Furthermore, regarding the ethical design of data-driven decision support tools, Balch et al [17] discuss the importance of considering ethical principles, such as algorithmic fairness and privacy, in developing decision support tools in oncology, with direct implications for palliative medicine.

Ethical considerations should also be considered in cancer chatbots. In their study, Chow et al [45-52] address the need for transparency and informed consent in the use of AI-based chatbots in cancer care, emphasizing the risks of dehumanization and loss of trust.

Research and Review of Advances in AI

Recent reviews and methodological studies have documented advances and limitations in AI applications for palliative care. Vu et al [14] systematically reviewed ML applications, highlighting the need for more robust, real-world evidence. Reddy et al [39] summarized advances in AI-based symptom management, and Bozkurt et al [1] developed protocols to assess the robustness of these applications. Macheka et al [38] evaluated the included role of AI in postdiagnostic treatment pathways, emphasizing the need for continuous research and ethical oversight.

AI offers innovative prediction, symptom management, communication, and resource optimization solutions in palliative medicine. However, its implementation is accompanied by significant ethical, cultural, and practical challenges, especially regarding equity, humanization, and respect for patient autonomy. The literature highlights the importance of addressing patient heterogeneity, cultural context, and social determinants to ensure that AI applications are practical and ethically acceptable.

Discussion

Principal Findings

This integrative review demonstrates that AI is increasingly present in palliative care, offering innovative solutions for clinical prediction, symptom management, communication, and process automation. The main findings suggest that while AI can improve efficiency and support decision-making, there remains a significant lack of consolidated, real-world examples that simultaneously demonstrate both efficiency and equity in outcomes. Most published studies focus on technical feasibility or operational improvements, but few document how AI enhances equitable access or patient-centered outcomes across diverse populations. This gap underscores the need for more robust, contextually grounded evidence to guide the ethical implementation of AI in end-of-life care [36].

A key finding is the persistent tension between efficiency and quality. Although frameworks such as the IOM and OECD recognize efficiency, equity, and patient-centeredness as embedded dimensions of quality, our review shows that improvements in system-level efficiency (resource optimization, automated symptom tracking) do not always translate into perceived improvements in care quality by patients and families. In palliative care, relational and dignity-centered outcomes, such as humanization, emotional support, and respect for autonomy, remain fundamental and may be at risk if AI is implemented without careful ethical consideration [36].

It should be noted that the paper distinguishes between “quality” of care and “efficiency.” In contrast, efficiency, equity, and patient-centeredness are internationally recognized as embedded measures of quality of care. According to frameworks such as the IOM [49], quality of care encompasses 6 interrelated domains: safety, effectiveness, patient-centeredness, timeliness, efficiency, and equity. Thus, efficiency is not a separate attribute but an integral component of quality, alongside equity and patient-centeredness. We recommend harmonizing the terminology and analysis to reflect this international consensus, avoiding an artificial dichotomy between quality and efficiency.

Comparison to Prior Work

Our findings align with previous reviews, highlighting both AI’s transformative potential in palliative settings and the ethical challenges it introduces. Recent literature confirms that AI’s integration in palliative care is still early, with limited robust evidence for improved equity or patient experience. While some studies report promising advances in prediction and symptom management, others caution about algorithmic bias, lack of transparency, and the risk of dehumanization [50].

The review expands on prior work by addressing ethical principles’ historical and cultural variability. Many AI tools in palliative care are developed and validated in Western contexts, reflecting assumptions about autonomy, truth-telling, and individual decision-making that may not be universally applicable. Studies show that AI models trained on Anglo-Saxon datasets can misinterpret emotional cues or cultural preferences, particularly in Southern European, Latin American, or other non-Western settings where family-centered decision-making and gradual truth disclosure are everyday occurrences [34]. This highlights the need for culturally sensitive AI models and participatory design processes.

Real Case: Mortality Prediction and Advance Care Planning

A recent study analyzed the implementation of an AI system designed to predict the likelihood of a patient dying in the next 12 months to facilitate timely discussions about palliative care. The study developed an explainable ML model using electronic health records data to proactively identify patients with advanced cancer at high risk of mortality. The model demonstrated strong predictive performance (area under receiver operating characteristic curve 0.861) and was intended to support early integration of palliative care in outpatient oncology settings [51]. However, introducing these predictions into the clinical process generated significant disagreements among health care

XSL•FO
RenderX

professionals, patients, and family members. The main concerns included:

- Patient autonomy: algorithmic predictions were sometimes used without adequate informed consent, potentially undermining patients' ability to decide about their care.
- Justice and equity: models trained on unrepresentative data risked introducing bias, disproportionately affecting marginalized groups.
- Beneficence and nonmaleficence: overreliance on AI predictions led to inappropriate interventions, such as premature end-of-life planning, without considering individual complexity.

This case highlights the need for a rigorous ethical approach to integrating AI into palliative care, ensuring that technologies complement clinical judgement and human empathy, not replace them.

Strengths and Limitations

This integrative review has several strengths. First, it offers a comprehensive and up-to-date synthesis of the recent literature on AI in end-of-life palliative care, focusing on the period between 2020 and 2025. This time frame was chosen to reflect the most current technological developments and their ethical implications. Second, the review's methodological rigor is reinforced using 2 quality appraisal tools, CASP and Hawker et al [42], which allowed a systematic evaluation across diverse study designs. Additionally, including philosophical, clinical, and ethical perspectives provides a multidimensional framework for understanding the challenges and opportunities of AI in this sensitive field. Furthermore, the review is enriched by presenting a real-world case, illustrating the practical dilemmas and tensions encountered when implementing predictive AI tools in clinical settings.

Nonetheless, several limitations must be acknowledged. The narrowed time frame may have excluded relevant earlier studies; however, this was a deliberate choice to focus on recent developments most applicable to current practice. The language scope was restricted to English, Portuguese, and Spanish, which may limit the generalizability of findings to other cultural contexts. Additionally, the heterogeneity of study designs and the variability in reporting standards made it difficult to perform a meta-analysis, which was replaced by thematic synthesis. Another limitation is that while some studies addressed social determinants of health (SDOH), such as literacy, socioeconomic status, or geographic inequalities, this aspect was not systematically captured across the entire corpus. Finally, given the fast-evolving nature of AI technologies, the findings and conclusions may become outdated over time, highlighting the need for ongoing surveillance and review.

The review of Ortiz et al [53] addressed the opportunities and challenges in using wearable sensors to monitor patients with cancer, including data integration and user acceptance issues.

Future Directions

Integrating AI into palliative care necessitates a balanced approach that prioritizes ethical rigor, patient-centered outcomes, and cultural adaptability. Based on recent evidence, the following directions are critical for advancing this field responsibly.

Enhancing Predictive Models With Diverse Data

ML models, such as those predicting mortality to facilitate early palliative care referrals in Medicare Advantage populations, demonstrate high accuracy but require broader validation across diverse demographics. Future research must prioritize datasets that include underrepresented groups (patients without cancer and ethnic minorities) to mitigate algorithmic bias and ensure equitable access to palliative services. For instance, models trained on SDOH and multi-institutional data could improve generalizability while addressing systemic disparities in end-of-life care [44].

Ethical Co-Design of Decision Support Tools

The development of AI-driven decision support systems in oncology, as exemplified by the 4D PICTURE project, highlights the importance of participatory design involving patients, clinicians, and ethicists [54]. Key strategies include the following: (1) ethical review processes will need to be integrated to address data bias, privacy, and transparency; (2) ensuring AI tools align with cultural norms (family-centered decision-making in non-Western contexts); and (3) adopting frameworks such as design justice to empower marginalized voices in tool development.

Hybrid Care Models Balancing Telehealth and Human Interaction

While telehealth improves accessibility and psychological comfort for palliative patients, studies emphasize that optimal care requires complementing AI tools with in-person interactions [54]. Future implementations should (1) integrate AI for routine monitoring (symptom tracking via wearables) while reserving complex decisions for clinician-patient dialogues and (2) address technical barriers (poor internet connectivity) that undermine interpersonal connection in telehealth.

Transparency and Explainability in Mortality Prediction

Explainable AI models, such as the transparent mortality prediction tool for patients with cancer developed by Bertsimas et al [55], enhance clinician trust and facilitate shared decision-making. Recommendations include (1) standardizing reporting of model features (weight changes and albumin levels) to improve clinical interpretability and (2) validating tools in real-world settings to assess their impact on goals-of-care discussions and patient autonomy.

AI as a Supplement, Not Replacement, for Human Judgment

Despite their reliability in answering breast cancer surgery queries (average score 3.98/5), AI chatbots such as ChatGPT must be framed as supplements to, not substitutes for, medical expertise [56]. Future work should (1) develop guardrails to prevent overreliance on AI, such as mandatory disclaimers urging users to consult clinicians, and (2) train chatbots to recognize cultural nuances in communication (gradual truth disclosure in specific populations).

XSL•FO
RenderX

Ethical Deployment of Oncology Chatbots

Building on frameworks for human-centered AI in oncology [45], developers must prioritize (1) transparency: disclosing data sources and limitations to users, (2) autonomy: allowing patients to opt out of AI-driven interactions, and (3) equity: ensuring chatbots are accessible across literacy and socioeconomic levels.

Conclusions

AI is poised to transform end-of-life palliative care, offering innovative clinical prediction, symptom management, communication, and resource optimization solutions. However, this review highlights that AI's successful and ethical integration in such a sensitive field is far from straightforward.

First, while AI can improve efficiency and operational aspects of care, there is still a notable lack of consolidated, real-world examples demonstrating both efficiency and equity in outcomes. Most current evidence is derived from pilot studies or technical feasibility reports, with limited documentation of long-term, patient-centered benefits across diverse populations.

Second, the ethical challenges surrounding AI in palliative care are complex and multifaceted. Issues such as algorithmic bias, lack of transparency, risks to patient autonomy, and the potential for dehumanization must be addressed proactively. The review underscores that efficiency, equity, and patient-centeredness are not isolated goals but interrelated dimensions of quality care, as recognized by international frameworks such as the IOM.

Third, cultural context and patient heterogeneity are critical factors. Many AI tools are developed based on Western bioethical assumptions, which may not be universally applicable, especially in settings where family-centered decision-making or culturally nuanced understandings of pain and suffering prevail. Addressing SDOH and ensuring the inclusion of marginalized voices in AI development is essential for equitable implementation.

Fourth, patients' and families' experiences must remain at the heart of palliative care innovation. AI should complement, not replace, clinical judgment, human empathy, and the relational aspects that define quality end-of-life care.

Key Recommendations

Our key recommendations are to (1) develop clear policies and regulatory frameworks to ensure fairness, privacy, transparency, and accountability in using AI in palliative care; (2) promote the humanization of care, design AI tools that support, rather than supplant, compassionate human interaction and shared decision-making; (3) foster continuous, multidisciplinary research to rigorously evaluate the benefits and risks of AI, address algorithmic biases, and adapt tools to diverse clinical and cultural contexts; and (4) encourage participatory approaches involving patients, families, clinicians, ethicists, and community representatives in designing, implementing, and evaluating AI systems.

Final Perspective

Ultimately, the ethical adoption of AI in palliative medicine requires a careful balance between technological innovation and the preservation of human dignity. Only through patient-centered, culturally sensitive, and ethically grounded strategies can we maximize the benefits of AI while mitigating its risks, thus improving the experience and outcomes for patients and families at the end of life.

Acknowledgments

The authors would like to thank the individuals whose support facilitated the conduct of this study.

Authors' Contributions

Each author actively participated in this study's conception, development, and writing. AGA, DGS, and ASV contributed to conceptualizing this study and its methodology, while FLC, ACB, and HM-F contributed technical expertise and interpretation of the findings. AGA and ASV participated in drafting this paper and critically revising the content. All authors have read and approved the final version of this paper.

Conflicts of Interest

Abstract

Background: Digitally delivered physical exercise interventions are becoming increasingly popular in addressing the obesity epidemic. However, there remains uncertainty on their efficacy regarding the reduction of body weight (BW) and body fat, which may, at least partly, be due to variations in study designs and inconsistent adherence to international physical activity (PA) guidelines.

Objective: This study aimed to evaluate the effectiveness of digital exercise interventions based on PA guidelines in reducing BW and fat in adults with overweight or obesity, as well as their impact on PA-related factors.

Methods: This review was conducted following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. Comprehensive searches were performed in October 2024 across PubMed, Cochrane Library, Web of Science, and Ovid MEDLINE databases. Eligible studies included adults (aged ≥18 years) with objectively confirmed overweight or obesity who used digital interventions aligned with international PA guidelines. Risk of bias was evaluated using the Cochrane Risk of Bias (version 2) tool for randomized controlled trials and the Risk of Bias in Nonrandomized Studies of Interventions tool for nonrandomized studies. A random-effects meta-analysis with Hartung-Knapp adjustment was performed using R software.

Results: Out of 4948 studies identified, 188 (3.8%) were screened in full and 30 (0.6%) met the eligibility criteria. Intervention durations ranged from 8 weeks to 24 months (average 6.4, SD 5.5 months). Meta-analysis showed that guideline-based digital exercise interventions significantly reduced BW compared to controls (mean difference [MD]=−1.17 kg; P=.003; I^2=0.0%), with subgroup analysis revealing greater effects in active (nondigital) controls (MD=−1.23 kg; I^2=7.5%) compared to passive (waitlist) controls (MD=−0.52 kg; I^2=0.0%). A significant reduction in BMI was observed (MD=−0.50 kg/m^2; P=.003), although with substantial heterogeneity (I^2=70.0%), and subgroup analysis showed greater effects compared to passive controls (MD=−0.70 kg/m^2; I^2=43.1%) rather than to active controls (MD=−0.45 kg/m^2; I^2=74.5%). No significant effect was observed for body fat percentage overall (MD=−0.08%; P=.84; I^2=7.4%). Qualitative analysis (including findings from noncomparative studies) showed that guideline-based digital exercise interventions led to significant reductions in BW (22/25, 88% studies; range −1.3 to −8.4 kg); BMI (19/23, 83% of studies; range −0.4 to −3.4 kg/m^2); waist circumference (15/16, 94% of studies; range −2.1 to −9.2 cm),

XSL•FO
RenderX

body fat percentage (9/9, 100% of studies; range −0.3% to −4.1%); and fat mass (7/7, 100% of studies; range −0.4 to −6.5 kg), while findings for waist-to-hip ratio and PA outcomes were inconsistent.

Conclusions: Guideline-based digital PA and exercise interventions show potential in reducing excess BW in adults with overweight or obesity, with stronger effects when compared to nondigital interventions. However, their superiority over traditional methods is uncertain for BMI and body composition. Substantial variations in study designs present challenges in drawing definitive conclusions on specific characteristics of effective digital exercise tools.

Introduction

Background

Overweight and obesity are among the most pressing public health challenges of the 21st century, posing significant health risks and economic burdens worldwide [1]. According to the World Health Organization (WHO), the prevalence of adult obesity has more than doubled since 1990 [2]. By 2022, 43% of adults aged ≥18 years were classified as overweight, and 16% were living with obesity, making it a major risk factor for several chronic diseases, including cardiovascular disease, type 2 diabetes, musculoskeletal disorders, and cancer [2]. Data shows that being overweight or obese is associated with approximately 2.8 million deaths each year [3]. This highlights the urgent need for effective interventions to manage body weight (BW) and improve body composition in adults with excess body fat.

Physical activity (PA) is recognized as a critical component of obesity prevention and management strategies [4]. The WHO guidelines recommend that adults engage in at least 150 to 300 minutes of moderate-intensity aerobic activity or 75 to 150 minutes of vigorous-intensity activity per week [5]. It has been well documented that adherence to these recommendations is associated with significant improvements in body composition [6], emphasizing the critical role of PA in mitigating obesity-related health issues. Despite its proven benefits, adults often struggle to maintain sufficient levels of PA due to barriers such as time constraints, lack of access to fitness facilities, and motivation, highlighting the need for innovative solutions that make PA and exercise more accessible and sustainable [7].

Today's digital world represents a transformative change in how we live, work, and interact [8], characterized by the integration of digital technologies into almost every aspect of human life. One of the most significant outcomes of this technological revolution is the expansion of mobile apps, which have become integral tools in daily life. An app is defined as software designed for specific tasks, which can be downloaded and installed on mobile phones or other digital devices [9]. In recent years, the advancement of digitalization has led to the emergence of digital health interventions as promising tools for supporting BW management and promoting healthy lifestyles [10]. Among these, PA and fitness apps have gained considerable attention by leveraging technological advancements to offer and deliver exercise plans, while also monitoring PA and fitness progress [11].

Over the past 2 decades, several studies have examined the effectiveness of health and fitness apps in BW management and other health outcomes [12-22]; however, the results have been inconsistent, with some studies reporting significant benefits while others found minimal or no effect on target outcomes. This variability in results may be attributed to differences in study design, population characteristics, app features, and intervention characteristics. More importantly, existing studies on digital PA and exercise interventions often lack a standardized implementation of key exercise characteristics (such as type, frequency, duration, and intensity) based on international PA guidelines. This inconsistency makes it difficult to compare interventions and assess their adequacy, thereby potentially influencing the outcomes. Therefore, a comprehensive review of digital PA interventions that are based on PA guidelines, such as those from the WHO or an equivalent framework, is needed to ensure more consistent and reliable outcomes.

Objectives

The primary objective of this systematic review was to evaluate the effectiveness of digital exercise interventions that were based on international PA recommendations on body composition, as well as PA and fitness outcomes, in adults with overweight and obesity. In addition, while this review aimed to identify gaps in the literature, its overarching goals were to provide insights that inform clinical practice and public health initiatives, and to guide the design of future digital interventions, thereby contributing to the effective management of overweight and obesity on a broader scale.

Methods

Study Protocol

This systematic review and meta-analysis was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [23]. The PRISMA checklist was used to guide the reporting across all stages of the review, encompassing the formulation of the research question, establishment of eligibility criteria, development of the search strategy, study selection, data extraction, and synthesis of results. The review protocol was

XSL•FO
RenderX

registered prospectively in the PROSPERO under the registration number CRD42024620020. The protocol's title was revised during the review process; however, no other deviations from the registered protocol occurred.

Eligibility Criteria

The eligibility criteria encompassed multiple dimensions guided by the population, intervention, comparison, outcome, and study design framework [24], along with additional considerations. The population of interest comprised adults aged ≥18 years with overweight or obesity. Overweight and obesity were defined using established thresholds: a BMI ≥25.0 kg/m^2 [25] or ≥23.0 kg/m^2 for Asia-Pacific adult populations [26], body fat percentage (BF%) ≥25% for male individuals and ≥36% for female individuals [27], or a waist-to-hip ratio (WHR) ≥0.90 for male individuals and ≥0.80 for female individuals [28]. Baseline measures of BW status had to be objectively assessed; studies relying on self-reported anthropometric data were excluded. To ensure the feasibility of participation in PA and exercise interventions, studies were required to include participants without severe health conditions or physical limitations that could hinder PA and exercise engagement. Studies involving trained participants who had been regularly engaged in PA, exercise, or sports within the 3 months before the intervention were also excluded. Furthermore, studies were excluded if they included participants who were pregnant or within 1 year postpartum, as these conditions can significantly influence body composition.

Regarding the intervention criteria, the review targeted interventional studies assessing the effectiveness of digital PA and exercise programs designed in alignment with WHO guidelines on PA, that is, a minimum of 150 minutes of moderate-intensity PA or 75 minutes of vigorous-intensity PA per week [5], or a comparable framework. "PA" refers to any bodily movement produced by skeletal muscles that requires energy expenditure, while "exercise" or "physical exercise" is a subset of PA that is planned, structured, and repetitive, with the specific objective of achieving or maintaining health and fitness [29,30]. Eligible studies implemented PA or exercise interventions with a minimum duration of 8 weeks. In controlled trials, the control group (whether consisting of participants not engaging in physical exercise or those who did not engage in any digital interventions) was considered the comparator. For single-arm interventional studies, comparisons were made against baseline values of the same participants assessed before the intervention.

The primary outcomes of interest included anthropometric and body composition measures: BW, BMI, BF%, fat mass (FM), waist circumference (WC), and WHR. All outcomes had to be objectively measured; studies relying on self-reported data were excluded to minimize bias and ensure reliability. Any study that reported at least one of these outcomes was eligible for inclusion. The secondary outcomes included PA-related or physical fitness variables, regardless of the assessment method. Finally, eligible studies were restricted to publications in English or German, and no limitations were applied regarding the publication period, context, setting, or geographic location.

Information Sources and Search Strategy

A comprehensive search strategy was used to identify relevant studies for inclusion in this systematic review, conducted from October 1 to 10, 2024. The databases searched included PubMed, Cochrane Library, Web of Science, and Ovid MEDLINE. The search strategy used a combination of keywords and Medical Subject Headings (MeSH) terms with the Boolean operators "AND" and "OR," as detailed in Multimedia Appendix 1. In addition to the database searches, the reference lists of the included studies and relevant review articles were manually reviewed to identify any additional publications that may not have been captured in the database search.

Study Selection and Data Extraction

The study selection process was conducted using Covidence, a specialized tool for systematic screening and data extraction. Two independent reviewers (MM and DT) screened the titles and abstracts of all retrieved articles based on the predefined eligibility criteria. Any discrepancies between the 2 reviewers were resolved through discussion. Articles deemed potentially relevant during the abstract screening phase underwent full-text review, and the same reviewers thoroughly assessed the full text of each article, while reasons for exclusion were documented. A third reviewer (CD) was consulted for the final decision if consensus could not be reached. Studies that met all the eligibility criteria during the full-text screening process advanced to the data extraction phase, where the same reviewers extracted the data. The extracted data encompassed several domains, including study characteristics, study design, intervention details, sample size, population, app or digital tool specifics, PA or exercise protocols, comparators, anthropometric and body composition outcomes, and PA and fitness outcomes. When the data were unclear, incomplete, or missing, the reviewers contacted the authors of the studies to request clarifications or additional information. When multiple articles reported the same study with identical population, outcomes, and data, the earliest publication was included to avoid data duplication. Any exclusions were carefully considered and documented to ensure transparency in the selection process.

Risk of Bias Assessment

The risk of bias in the included studies was assessed using standardized tools to ensure a thorough evaluation of methodological quality. Two independent reviewers (MM and DT) assessed the risk of bias, and any discrepancies were resolved through discussion. For randomized controlled trials (RCTs), the Cochrane Risk of Bias (version 2) tool was used [31]. This tool evaluates bias across 5 key domains: randomization process, deviations from intended interventions, missing outcome data, measurement of the outcome, and selection of the reported result. Each domain is assessed for potential sources of bias that could impact the validity of the trial's findings. The Risk of Bias in Nonrandomized Studies of Interventions tool was used for nonrandomized and single-arm studies [32]. This tool evaluates 7 domains: confounding, selection of participants, classification of interventions, deviations from intended interventions, missing data, outcome measurement, and selection of the reported result. Using both tools enabled a comprehensive assessment of the methodological

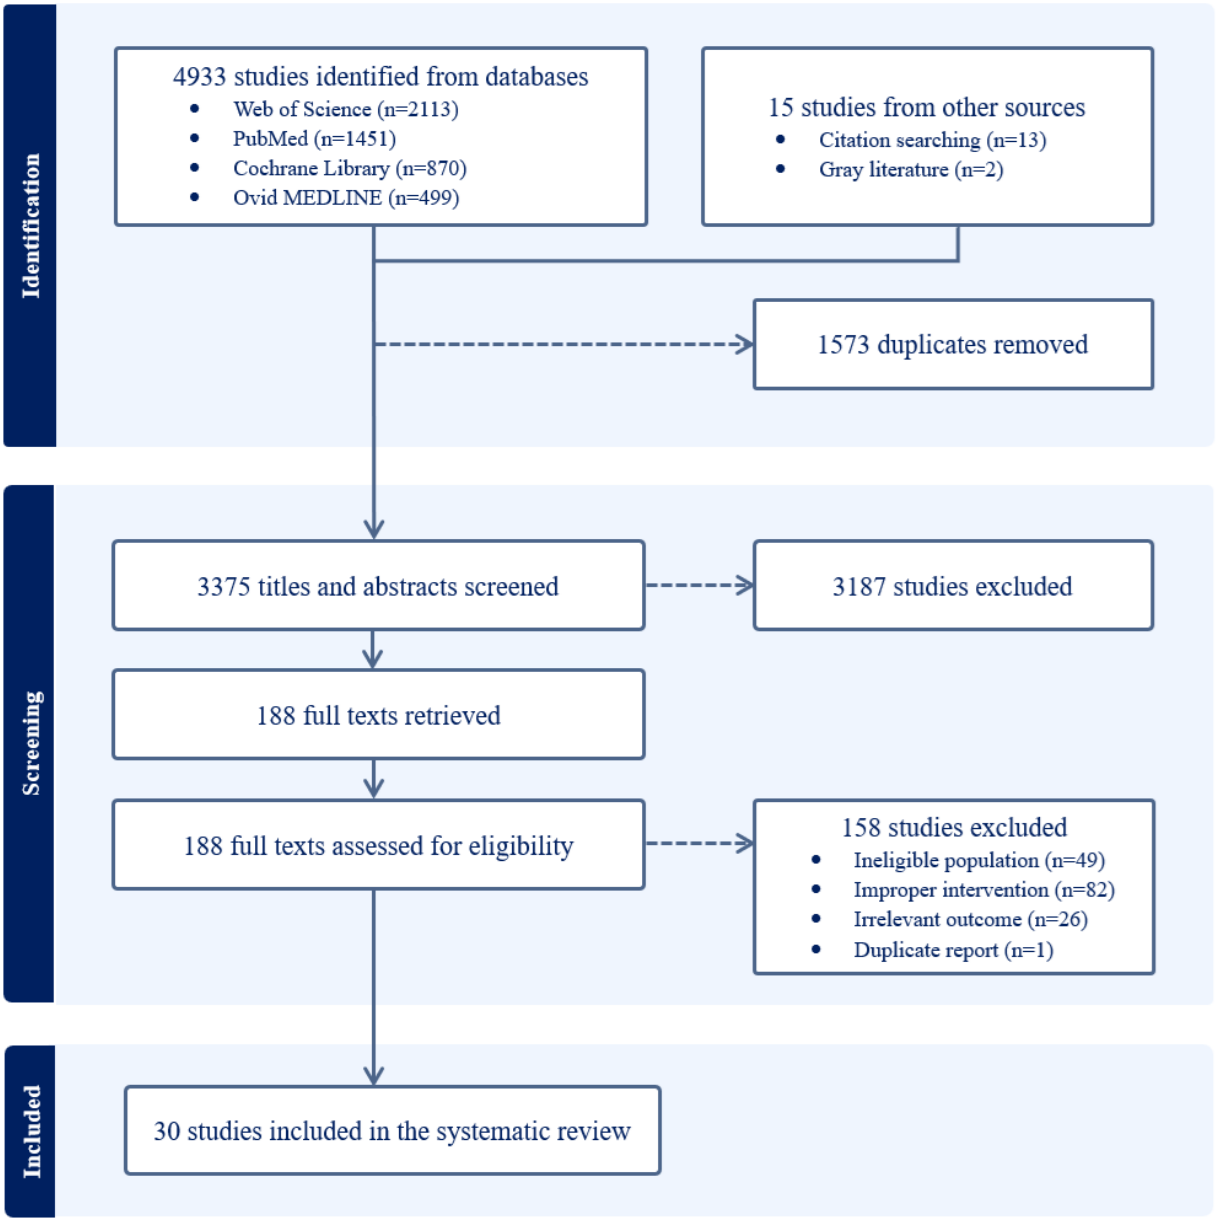
XSL•FO
RenderX

rigor and potential biases in each study, ensuring a reliable interpretation of the evidence.

Data Synthesis

A qualitative synthesis of the data was conducted, focusing on the various outcomes reported across studies. The extracted data were systematically grouped and analyzed by outcome categories and variables (study design, population, study group, app or digital tool, intervention, primary outcomes, and PA outcomes), enabling a detailed exploration of trends and patterns in the evidence. The synthesis aimed to identify consistent trends across studies while also highlighting areas of agreement, inconsistencies, or discrepancies in the findings. This approach provided a deeper understanding of the broader implications of the data and helped identify areas where further research is needed to resolve conflicting results or clarify uncertainties.

Meta-analysis was performed using R (version 4.5.0; R Foundation for Statistical Computing) to evaluate the effects of digital exercise interventions on primary outcome variables. A random-effects model with Hartung-Knapp adjustment was applied to account for potential between-study heterogeneity and to provide robust CIs. The primary effect size metric was the mean difference (MD) between intervention and control groups, expressed in the original units for each outcome. Subgroup analyses were conducted to examine potential differences in intervention effects by control type. Studies were stratified based on the type of control condition: (1) active controls (ie, nondigital interventions or usual care) and (2) passive controls (ie, waitlist—participants assigned to receive the intervention after the study period—or no intervention). When studies included multiple eligible intervention arms, each arm was treated as a separate unit of analysis to avoid statistical dependency, with the intervention arm serving as the unit of analysis. Heterogeneity was assessed using the I^2 statistic, τ^2, and Cochran Q test. All procedures were conducted following the PRISMA guidelines, and results are reported with 95% CIs and corresponding *P* values.



Results

Selection Process

A total of 4948 studies were initially identified through the databases and reference sources. After removing duplicates, 68.21% (3375/4948) of the studies were screened by title and abstract, of which 5.57% (188/3375) of the studies were retrieved for full-text review. Ultimately, 30 studies met the predefined eligibility criteria and were included in the systematic review. Figure 1 presents the PRISMA flowchart outlining the study selection process.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart showing the study identification, screening, and inclusion process.

Included Studies

The final sample of included studies consisted of 26 RCTs and 4 nonrandomized studies. Out of the 30 included studies, 11 (37%) were conducted in the United States, 3 (10%) in Australia, 3 (10%) in Korea, 2 (7%) in the United Kingdom, 2 (7%) in Germany, 2 (7%) in Spain, and 1 (3%) each in Sweden, France, Canada, Belgium, Singapore, China, and Hong Kong. The sample sizes varied from 16 to 750 participants, with an average of 132 participants. Of the 30 included studies, 6 (20%) exclusively included female participants, while none of the included studies focused solely on male participants. Table 1 provides a summary of the characteristics of the studies included in the review.

XSL•FO
RenderX

Table 1. Summary of the characteristics and outcomes of the studies included in the systematic review. The studies are ordered by intervention duration.

Study, year, and country	Design and population	Study groups	Intervention	Primary outcomes and findings	PA[a] outcomes and findings
Intervention duration: 24 months					
Jakicic et al [33], 2016, United States	Two-arm RCT[b]; sample size: 470; median age 30.9 years; 71.1% female participants; median BMI 31.2 kg/m^2	• Enhanced intervention (n=237) • Standard intervention (n=233)	Digital tool: FIT Core; BodyMedia; a 24-month intervention where all participants initially increased PA, followed a low-calorie diet, and attended group counseling. At 6 months, telephone counseling, text message prompts, and website access were introduced. The standard group used a website for self-monitoring, while the enhanced group used a wearable device with a web interface. Moderate to vigorous PA progressed from 100 to 300 min per week over 4-week intervals.	Significant decreases in BW[c] BMI, BF%[d], and FM[e] in both groups; no significant between-group differences for BMI, BF%, and FM, while postintervention BW was significantly lower in the standard group.	Significant improvements in LPA[f] and MVPA[g] in both groups; no significant between-group differences
Svetkey et al [34], 2015, United States	Three-arm RCT; sample size: 365; mean age 29.4 years; 69.6% female participants; mean BMI 35.2 kg/m^2	• mHealthh (n=123) • Personal coaching (n=120) • Control (n=122)	Digital tool: Investigator-designed app; a 24-month intervention delivered via a smartphone app based on social cognitive theory and transtheoretical model, incorporating goal setting, behavioral self-management, and motivational enhancement, with a PA target of achieving ≥180 min per week of moderate PA.	Significant differences in BW between the study groups, with greater reductions in the personal coaching group at 6 and 12 months, but not at 24 months.	—[i]
Intervention duration: 12 months					
Héroux et al [35], 2017, Canada	Single-arm intervention trial; sample size: 28; mean age 49.6 years; 100% female participants; mean BMI 32.2 kg/m^2	• Intervention (n=28)	Digital tool: The online Precision Nutrition Coaching Program; a 12-month online program focused on daily physical exercise, dietary habits, and health behavior lessons, with coaching delivered via computer, tablet, and mobile device. The exercise program included detailed daily workouts (aerobic interval training, weight training, or walking) with progressive intensity over time.	Significant decreases in BW, WC[j], and FM (but not in BMI).	—
Lynch et al [36], 2017, United States	Single-arm intervention trial; sample size: 46; mean age 39 years; 65.2% female participants; mean BMI 31.8 kg/m^2	• Intervention (n=46)	Digital tool: Lean Eating by Precision Nutrition Coaching; a 12-month weight loss intervention with daily components of physical exercise, nutrition, behavioral modification strategies, and health lessons via an online platform, along with online coaching. The PA component included at least 150 min of physical exercise per week, with a minimum of 2 strength training sessions per week.	Significant decreases in BW, BMI, and BF% (but not in WHR[k]).	—
Watson et al [37], 2015, United Kingdom	Two-arm RCT; sample size: 65; mean age 52.2 years; 55.4% female participants; mean BMI 32.6 kg/m^2	• Web-based (n=32) • Usual self-care (n=33)	Digital tool: Imperative Health; a 12-month web-based weight loss intervention incorporating PA and dietary components, along with goal setting and tailored feedback and support provided by physiologists via telephone and email. The PA program included a weekly schedule for planning activities at light to vigorous intensity levels.	Significant decreases in BW in the intervention group, with significant between-group differences at 3 and 6 months, but not at 12 months. Significant between-group differences in BMI and WC at 3 and 6 (but not at 12) months.	Significant between-group differences in daily PA at 3 months, but not at 6 and 12 months.
Intervention duration: 6 months

Study, year, and country	Design and population	Study groups	Intervention	Primary outcomes and findings	PA[a] outcomes and findings
Alcántara-Aragón et al [38], 2018, Spain	Two-arm RCT; sample size: 183; mean age 44.5 years; 83.6% female participants; mean BMI 34.75 kg/m^2	• Telematic intervention (n=91) • Nontelematic intervention (n=92)	Digital tool: PREDIRCAM2 web platform; a 6-month tailored physical exercise and dietary plans based on international PA guidelines and the Mediterranean diet. The telematic group received online support and virtual contact, while the nontelematic group followed traditional methods.	Significant decreases in BW, WC, and WHR in the telematic intervention group; no significant between-group differences.	—
Allen et al [39], 2013, United States	Four-arm RCT; sample size: 68; mean age 44.9 years; 77.9% female participants; mean BMI 34.3 kg/m^2	• Intensive counseling (n=18) • Smartphone only (n=17) • Intensive counseling+smartphone (n=16) • Less intensive counseling+smartphone (n=17)	Digital tool: Lose It!; a 6-month intervention (PA and diet) using an eclectic approach combining social cognitive theory, behavioral self-management, and motivational interviewing techniques to achieve 5% BW loss and a minimum of 150 minutes of moderate-intensity PA per week. Intensive groups attended frequent in-person sessions, while less intensive and smartphone-based groups had fewer sessions.	Significant decreases in BW, BMI, and WC in all groups; no significant between-group differences.	No significant between-group difference in MVPA.
Apiñaniz et al [40], 2019, Spain	Two-arm RCT; sample size: 110; mean age 38.5 years; 71.8% female participants; mean BMI 32.7 kg/m^2	• Health advice+app (n=54) • Health advice (n=56)	Digital tool: AKTIDIET; a 6-month intervention consisting of health advice (PA and dietary) based on international guidelines for both groups. In the intervention group, this advice was reinforced through an app consisting of aerobic and muscle training programs and food intake tracking.	Significant decreases in BW in both groups; no significant between-group differences.	—
Batsis et al [41], 2021, United States	Single-arm intervention trial; sample size: 53; mean age 72.9 years; 69.8% female participants; mean BMI 36.5 kg/m^2	• Intervention (n=53)	Digital tool: Video conferencing; a 6-month weight management program combining synchronous videoconference-based physical exercise and nutrition sessions, remote Fitbit monitoring, and periodic face-to-face interactions. Participants attended 75-minute, twice-weekly group exercise sessions led by a trained physical therapist.	Significant decreases in BW, BMI, and WC; no change in WHR.	Significant improvements in 30-second sit-to-stand and 6-minute walk test; no changes in gait speed or grip strength.
Block et al [42], 2015, United States	Two-arm RCT; sample size: 339; mean age 55.0 years; 31.3% female participants; mean BMI 31.2 kg/m^2	• Alive-PD intervention (n=163) • Usual care control (n=176)	Digital tool: Alive-PD; a 6-month program with weekly goal setting (PA and dietary) delivered via web, email, interactive voice response calls, and a supportive mobile app. The PA target included 150-300 minutes of aerobic activity and resistance training weekly, based on baseline levels and progress.	Significant decreases in BW, BMI, and WC in both groups, with significantly greater reductions in the intervention group.	—
Duncan et al [18], 2020, Australia	Three-arm RCT; sample size: 116; mean age 44.5 years; 70.7% female participants; mean BMI 31.7 kg/m^2	• Enhanced (n=39) • Traditional (n=41) • Waitlist control (n=36)	Digital tool: Balanced app; a 6-month multicomponent (PA and dietary) mHealth intervention delivered via a smartphone app, providing educational materials, goal setting, self-monitoring, and feedback; the enhanced group received additional sleep-related support. PA action planning focused on MVPA, resistance training, and step count increases.	No significant between-group difference in BW, while postintervention WC was significantly lower in the traditional group.	No significant between-group differences in MVPA and LPA.
Hartman et al [43], 2016, United States	Two-arm RCT; sample size: 55; mean age 59.5 years; 100% female participants; mean BMI 31.9 kg/m^2	• Technology-based (n=36) • Usual care (n=18)	Digital tool: Fitbit and a website; a 6-month weight loss intervention focused on developing and practicing self-monitoring and self-regulatory skills, with a goal of losing 10% of BW by engaging in at least 150 minutes per week of MVPA and restricting calorie intake.	Significant decreases in BW in the intervention group, with a significant between-group difference (no BW change in the usual care group).	Significant improvement in daily MVPA in the intervention group, with no significant between-group differences.

Study, year, and country	Design and population	Study groups	Intervention	Primary outcomes and findings	PA[a] outcomes and findings
Haufe et al [44], 2021, Germany	Two-arm RCT; sample size: 314; mean age 48.1 years; 14% female participants; mean BMI 33.3 kg/m^2	• Telemonitoring physical exercise (n=160) • Waitlist control (n=154)	Digital tool: Custom-designed smartphone app; a 6-month telemonitoring-supported lifestyle intervention focused on regular physical exercise, including individual exercise recommendations provided during face-to-face meetings and via a smartphone app, aiming for at least 150 minutes of PA per week.	Significant decrease in WC in the intervention group, with a significant between-group difference (less but significant decrease in WC in the control group).	Significant increase in exercise capacity in both groups, with a significantly greater increase in the intervention group.
Hutchesson et al [20], 2018, Australia	Two-arm RCT; sample size 57; mean age 27.1 years; 100% female participants; mean BMI 29.4 kg/m^2	• Intervention (n=29) • Control (n=28)	Digital tool: Be Positive Be Health e; a 6-month weight loss program delivered via eHealth technologies (website, app, email, text messages, and social media), incorporating goal setting and grounded in social cognitive theory and control theory, aligned with international PA and dietary guidelines.	Significant decreases in BW, BMI, FM, and BF% in the intervention group, with no significant between-group differences except for FM. Significant decreases in WC in both groups.	No significant changes in MVPA, MPA[l], and VPA[m] in any study group.
Lim et al [45], 2022, Singapore	Two-arm RCT; sample size: 148; mean age 53.1 years; 39.9% female participants; mean BMI 29.8 kg/m^2	• Intervention (n=72) • Control (n=76)	Digital tool: nBuddy Diabetes app; a 6-month in-app dietitian coaching incorporating behavioral strategies (goal setting, stimulus control, problem-solving, self-monitoring, cognitive restructuring, and motivational interviewing), with a PA goal of 150 minutes per week of moderate-intensity physical exercise.	Significant decreases in BW and BMI in both groups, with significantly greater reductions in the intervention group.	Significant improvement in general PA in the intervention group; no significant between-group difference.
Rogers et al [46], 2016, United States	Three-arm RCT; sample size: 39; mean age 39.9 years; 79.5% female participants; mean BMI 39.5 kg/m^2	• Standard (n=14) • Technology (n=12) • Enhanced technology (n=13)	Digital tool: BodyMedia Fit and LINK; a 6-month mHealth intervention program incorporating PA and dietary components, alongside self-monitoring and feedback. The PA component involved unsupervised, home-based physical exercise at moderate intensity, with a gradual increase in session duration.	Significant decreases in BW, BMI, WC, BF%, and FM in all groups; no significant between-group differences.	—
Intervention duration: 12-16 weeks

Study, year, and country	Design and population	Study groups	Intervention	Primary outcomes and findings	PA[a] outcomes and findings
Hurst et al [47], 2021, United States	Single-arm intervention trial; sample size: 30; mean age 38.1 years; 43% female participants; median BMI 32.7 kg/m^2	• Intervention (n=30)	Digital tool: Telehealth coaching; 16-week telehealth intervention delivered in primary care clinics, using wearable devices, automated text messaging, and trained health coaching (including real-time feedback) to support physical exercise and nutrition goals, including achieving at least 150 minutes of PA per week.	Significant decreases in BW and BMI.	Significant improvement in MVPA.
Stephens et al [48], 2017, United States	Two-arm RCT; sample size: 62; median age 20.0 years; 71% female participants; median BMI 28.5 kg/m^2	• Smartphone + health coach (n=31) • Control (n=31)	Digital tool: Lose it!; a 3-month intervention using a behavior-based smartphone app (primarily grounded in self-efficacy theory) for weight loss, combined with counseling sessions and text messages from a health coach, with goals of losing 1-2 pounds per week and engaging in at least 150 minutes of moderate-intensity PA weekly.	Significant decreases in BW, BMI, and WC in the intervention group (but not in the control group), with significant between-group differences.	Significant improvement in PA score in the intervention group, with no significant between-group difference.
Wong et al [49], 2021, Hong Kong	Two-arm RCT; sample size: 77; mean age 58.9 years; 55.8% female participants; mean BMI 27.02 kg/m^2	• App (n=38) • Booklet (n=39)	Digital tool: MetS app; a 3-month lifestyle intervention delivered via a mobile app to support participants' individual physical exercise routines through goal setting, logging exercise type and duration, and self-monitoring. The PA goal was at least 30 minutes per day, 5 days per week.	Significant decreases in BW and BMI (but not in WC or WHR) in the app group, with significant between-group differences for BW and BMI (no change in the booklet group).	Significant improvements in exercise score and exercise self-efficacy in the app group, with significant between-group differences.
Zhang et al [50], 2023, China	Three-arm RCT; sample size: 750; mean age 70.1 years; 53.9% female participants; mean BMI 27.7 kg/m^2	• Remote PA and diet (n=250) • Remote PA (n=250) • Control (n=250)	Digital tool: mHealth app; a 3-month remote weight management intervention focused on PA (with or without dietary components) including health assessments and guidance from exercise instructors and nutritional professionals. The PA program included 20 minutes of resistance or aerobic exercise or walking 6000 steps daily.	Significant decreases in BW, BMI, WC, and WHR in the remote PA and diet group, with significant between-group differences at day 90, but not at day 45.	No significant changes in total PA and PA levels in any study group.
Anderson et al [51], 2018, United Kingdom	Two-arm RCT; sample size: 78; mean age 47.1 years; 88% female participants; mean BMI 32.7 kg/m^2	• Intervention (n=39) • Control: lifestyle booklet (n=39)	Digital tool: LivingWELL; a 12-week intervention consisting of 1 face-to-face session, 4 phone consultations, and web-based support to achieve 5% BW reduction. It included a personalized diet and physical exercise plan with behavioral techniques such as motivational interviewing and action planning.	Decreases in BW, BMI, and WC in the intervention group, but not in the control group.	Increases in daily MPA and daily steps (but not daily VPA) in the intervention group.
Bughin et al [52], 2021, France	Two-arm RCT; sample size: 50; mean age 52.2 years; 54% female participants; mean BMI 36.5 kg/m^2	• Telerehabilitation program (n=25) • Usual care (n=25)	Digital tool: Telemouv app; a 12-week multicomponent intervention (PA, diet, and education) available on smartphones and a website. The PA program included endurance exercises (targeting 150 minutes of PA per week), muscle strengthening (with gradual increases in volume), and balance exercises.	Significant decreases in BF% and FM in both groups, with no significant changes in BW, BMI, or WHR. No significant between-group differences for any outcomes.	No significant within- or between-group change or difference in the 6-minute walk test.
Hebden et al [53], 2014, Australia	Two-arm RCT; sample size: 51; mean age 22.8 years; 81% female participants; mean BMI 27.3 kg/m^2	• mHealth intervention (n=26) • Control (n=25)	Digital tool: ePASS; a 12-week mHealth program targeting key lifestyle behaviors associated with weight gain, delivered via smartphone apps, internet forums, text messages, and emails. The PA program included 30 minutes of moderate-intensity PA per day for general health and 60 minutes per day for weight management.	Significant decreases in BW and BMI in both groups; no significant between-group differences.	Significant increase in daily LPA (but not MVPA) in the intervention group.

Study, year, and country	Design and population	Study groups	Intervention	Primary outcomes and findings	PA[a] outcomes and findings
Hong et al [54], 2022, Korea	Two-arm RCT; sample size: 31; mean age 79.9 years; 100% female participants; mean BF% 41.6	• Intervention (n=12) • Control (n=17)	Digital tool: Smartphone telepresence platform; a 12-week smartphone mirroring-based telepresence physical exercise program conducted at home with 3 sessions per week, primarily focused on resistance training (with gradual intensity increases), all based on international guidelines; while the control group performed the same program in person.	Significant decreases in BF% in both groups and in BW in the control group; no significant between-group differences.	Significant left-hand grip strength improvement in the intervention group and right-hand in the controls; no significant between-group differences.
Hurkmans et al [16], 2018, Belgium	Four-arm RCT; sample size: 81; mean age 45.0 years; 71.6% female participants; mean BMI 32.0 kg/m^2	• Face-to-face (n=28) • App (n=30) • Combined (n=22) • Control (n=22)	Digital tool: Mobile Weight Loss App; 12-week weight loss programs using face-to-face, mobile, and combined approaches, offering physical exercise and dietary guidance aligned with standard guidelines, along with personalized exercise plans provided by a coach.	Significant decreases in BMI in the face-to-face, app, and combined groups; no significant difference between the 3 interventions.	Significant improvements in MVPA; no significant between-group differences.
Johnson et al [55], 2019, United States	Three-arm RCT; sample size: 30; mean age 43.2 years; mean BMI 36.1 kg/m^2	• Videoconferencing (n=10) • In-person (n=10) • Control (n=10)	Digital tool: Withings app and Healow app; 12-week telemedicine-based health coaching, including physical exercise routines, goal setting, and PA progression, with feedback provided by a registered dietitian and exercise physiologist. PA program followed international guidelines recommending at least 150 minutes of PA per week (30 minutes of MVPA, 5 days per week).	Significant differences in BW reduction between the study groups, with greater reduction in the videoconferencing group; no significant between-group differences in BMI. Decrease in BW and BMI in all groups.	Improvement in daily steps in all groups, with a significantly greater improvement in the videoconferencing group.
Pressler et al [56], 2010, Germany	Two-arm RCT; sample size: 105; median age 48 years; 11.8% female participants; mean BMI 29.0 kg/m^2	• Structured web-based exercise (n=66) • Nonstructured web-based exercise (n=39)	Digital tool: Interactive internet platform; a 12-week intervention with structured or nonstructured internet-delivered physical exercise programs performed individually, alongside education sessions. The exercise program included 3 moderate endurance sessions and 1 strength training session per week.	Significant decreases in WC in both groups and in BMI and BF% in the control group; no significant between-group differences in any of these outcomes.	No significant changes in daily step counts in any study group.
Intervention duration: 8-10 weeks

Study, year, and country	Design and population	Study groups	Intervention	Primary outcomes and findings	PA[a] outcomes and findings
Ballin et al [57], 2020, Sweden	Two-arm RCT; sample size: 77; mean age 71.0 years; 50% female participants; mean BMI 29.2 kg/m^2	• Web-based exercise (n=38) • Supervised exercise (n=39)	Digital tool: Healthy Ageing Initiative; a 10-week intervention consisting of a web-based progressive interval training program (10 weekly videos, 3 sessions per week), while the supervised exercise group participated in in-person sessions.	Significant decreases in BF% and FM in both groups, and in BMI only in the supervised exercise group; no significant between-group differences, except for FM (with a greater reduction in the supervised exercise group).	—
Hyun [58], 2021, Korea	Two-arm RCT; sample size: 16; mean age 38.4 years; 100% female participants; mean BMI 25.6 kg/m^2	• Moderate intensity training (n=8) • High intensity training (n=8)	Digital tool: Real-time video web program; a 8-week real-time video web program based on international PA and exercise guidelines, including bidirectional communication along with instructor feedback. Training sessions lasted 30 minutes (for moderate intensity group) or 50 minutes (for high intensity group), held 3 times weekly, with exercise intensity increasing biweekly for the high intensity group.	Significant decreases in BW, WC, FM, BMI, and BF% in both groups, with significant between-group differences for BMI, WC, and FM (greater reductions in the high intensity group), but not for BW or BF%.	Significant left-hand grip strength improvement in the high intensity group and right-hand in both groups; significant between-group differences.
Seo et al [59], 2023, Korea	Three-arm RCT; sample size: 75; mean age 48.3 years; 100% female participants; mean BMI 25.5 kg/m^2	• Virtual reality exercise (n=25) • Indoor bicycle exercise (n=25) • Control (n=25)	Digital tool: VRFit app; an 8-week virtual reality physical exercise program using an Internet of Things sensor attached to an indoor bicycle, connected to a smartphone, and paired with a head-mounted display for immersive virtual reality exercise. Exercise sessions were conducted 3-5 times weekly, following international guidelines.	Significant decreases in BMI in the virtual reality group, with significant between-group differences (no BMI change in the 2 other groups).	Significant improvement in exercise fun in the virtual reality group, along with significant between-group differences.

[a]PA: physical activity.
[b]RCT: randomized controlled trial.

[h]mHealth: mobile health.
[i]Not available.
[j]WC: waist circumference.
[k]WHR: waist-to-hip ratio.
[l]MPA: moderate physical activity.
[m]VPA: vigorous physical activity.

Qualitative Data Synthesis

The duration of the interventions ranged from 8 weeks to 24 months, with an average of 6.6 (SD 5.5) months. Although all studies included interventions involving PA or exercise through action planning, coaching, or goal setting, there were substantial variations in the PA-related methods and techniques used, as well as in the inclusion of other lifestyle components alongside PA. A total of 14 studies [18,35-38,41,44,50,52-54,56,57,59] used digital interventions that delivered structured physical exercise programs, while other studies included flexible PA or exercise routines based on international guidelines. Regarding the type of physical exercise, all studies incorporated aerobic or moderate to vigorous PA (MVPA) as a core component, while 13 studies [18,35,36,40-42,44,50,52-54,56,57] additionally included resistance or strength training. All but 3 studies [44,56,59] incorporated multiple lifestyle components, including diet, sleep, and stress management, with diet being the most commonly used component alongside PA. Dietary guidance was provided in the form of dietary plans, goal setting based on dietary guidelines, nutritional advice, dietary coaching, and behavior change strategies related to eating habits.

Various digital tools, including mobile apps, websites, wearable devices, telecommunication platforms (eg, videoconferencing), virtual reality, or a combination of 2 or more in most studies, were used in the interventions. These tools supported features such as program delivery, coaching, feedback provision, goal

XSL•FO
RenderX

setting, tracking, and progress monitoring. They were implemented in various ways, including automated or manual feedback, self-guided or professionally guided programs, real-time or asynchronous coaching, gamification elements, integration with other health platforms, and different levels of interactivity. This resulted in a diverse range of intervention designs, delivery modes, and user engagement levels.

While 4 studies [35,36,41,47] used a single-arm design, the control groups in the other studies exhibited considerable variability, including active controls (such as alternative digital or nondigital interventions or usual care) [33,34,37-40,42,43,45,46,49,51-58], passive control (such as no intervention or waitlist group) [20,44,48], or a combination of both [16,18,50,59], reflecting a diversity in methodological designs and approaches. All single-arm design studies demonstrated a significant reduction in outcome variables. Similarly, interventional studies comparing digital interventions to passive controls showed favorable effects. However, in studies comparing experimental groups to nondigital active controls, the results were inconsistent, with some reporting greater reductions in outcome variables following digital interventions [37,42,43,45,49,51,59], while others found no significant difference [16,18,38-40,46,50], and one [34] even reported less reduction following digital interventions. Common nondigital interventions included educational booklets, self-care advice, and in-person physical exercise programs.

Among the studies included in this review, 25 evaluated BW as an outcome variable. Overall, 22 studies (with an average intervention duration of 6.5, SD 4.9 months, ranging from 8 weeks to 24 months) reported significant BW reduction (range −1.3 to −8.4 kg) following digital intervention programs [18,20,33,35-43,45-51,53,55,58], while 3 studies found no significant change in BW following a 12-week multicomponent telerehabilitation program [52], a 12-week smartphone mirroring-based telepresence exercise program [54], or a 24 months of mobile health (mHealth) intervention [34]. A total of 10 studies (with an average intervention duration of 9.0, SD 8.4 months, ranging from 3 to 24 months) found significant differences in postintervention BW between their study groups [33,34,37,42,43,45,48-50,55], most of which used active control groups, with one study [48] using passive controls and another [50] using a combination of both. However, 10 studies (with an average intervention duration of 4.7, SD 1.7 months, ranging from 8 weeks to 6 months) reported no significant between-group differences in BW [18,20,38-40,46,52-54,58], most of which used active control groups, with one study [20] using passive controls and another [18] using a combination of both. No clear pattern was observed in BW outcomes when comparing experimental groups to nondigital active controls, with some studies reporting greater BW reduction following digital interventions [37,42,43,45,49], while others found no significant difference [18,38-40,46] or reported less BW reduction following digital interventions [34].

In this review, 23 studies examined BMI as an outcome measure. In total, 19 studies (with an average intervention duration of 5.9, SD 5.2 months, ranging from 8 weeks to 24 months) observed a significant reduction in BMI (range −0.4 to −3.4 kg/m^2) following digital intervention programs [16,20,33,36,37,39,41,42,45-51,53,55,58,59], while 4 studies (with an average intervention duration of 5.1, SD 4.6 months, ranging from 10 weeks to 12 months) reported no significant BMI change following digital interventions [35,52,56,57]. A total of 8 studies (with an average intervention duration of 4.6, SD 3.4 months, ranging from 8 weeks to 12 months) reported significant differences in postintervention BMI between study groups [37,42,45,48-50,58,59], most of which used active control groups, while one study [55] used passive controls and 2 others [50,59] used a combination of both. However, 9 studies (with an average intervention duration of 6.3, SD 6.8 months, ranging from 10 weeks to 24 months) found no significant between-group differences in BMI changes [16,20,33,39,46,52,55-57], most of which used active control groups, with one study [20] using passive controls and another [16] using a combination of both. No clear trend was observed in BMI outcomes when comparing experimental groups to nondigital active controls, with some studies reporting greater BMI reduction following digital interventions [37,42,45,49,59], while others found no significant difference [16,39,46].

A total of 16 studies examined WC as an outcome measure. Overall, 15 studies (with an average intervention duration of 5.7, SD 3.0 months, ranging from 8 weeks to 12 months) found a significant reduction in WC (range −2.1 to −9.2 cm) following digital intervention programs [18,20,35,37-39,41,42,44,46,48,50,51,56,58], while one study [49] showed no significant change following a 3-month multicomponent lifestyle intervention delivered via a mobile app. In total, 8 studies (with an average intervention duration of 5.3, SD 3.1 months, ranging from 8 weeks to 12 months) reported significant between-group differences in postintervention WC [18,37,42,44,48-50,58]; however, 5 studies (with an average intervention duration of 5.4, SD 1.3 months, ranging from 12 weeks to 6 months) indicated no significant between-group differences [20,38,39,46,56]. There was also no clear trend in WC outcomes when comparing experimental groups to nondigital active controls, with 3 studies [37,42,49] reporting greater WC reduction following digital interventions, while 3 others [38,39,46] found no significant difference. WHR was assessed in 6 studies, with 2 studies (conducting 6-month and 3-month interventions) reporting a significant reduction in WHR (−0.02 and −0.01, respectively) [38,50], while the other 4 studies (with an average intervention duration of 6.0, SD 4.2 months, ranging from 12 weeks to 12 months) found no change in WHR following digital intervention programs [36,41,49,52].

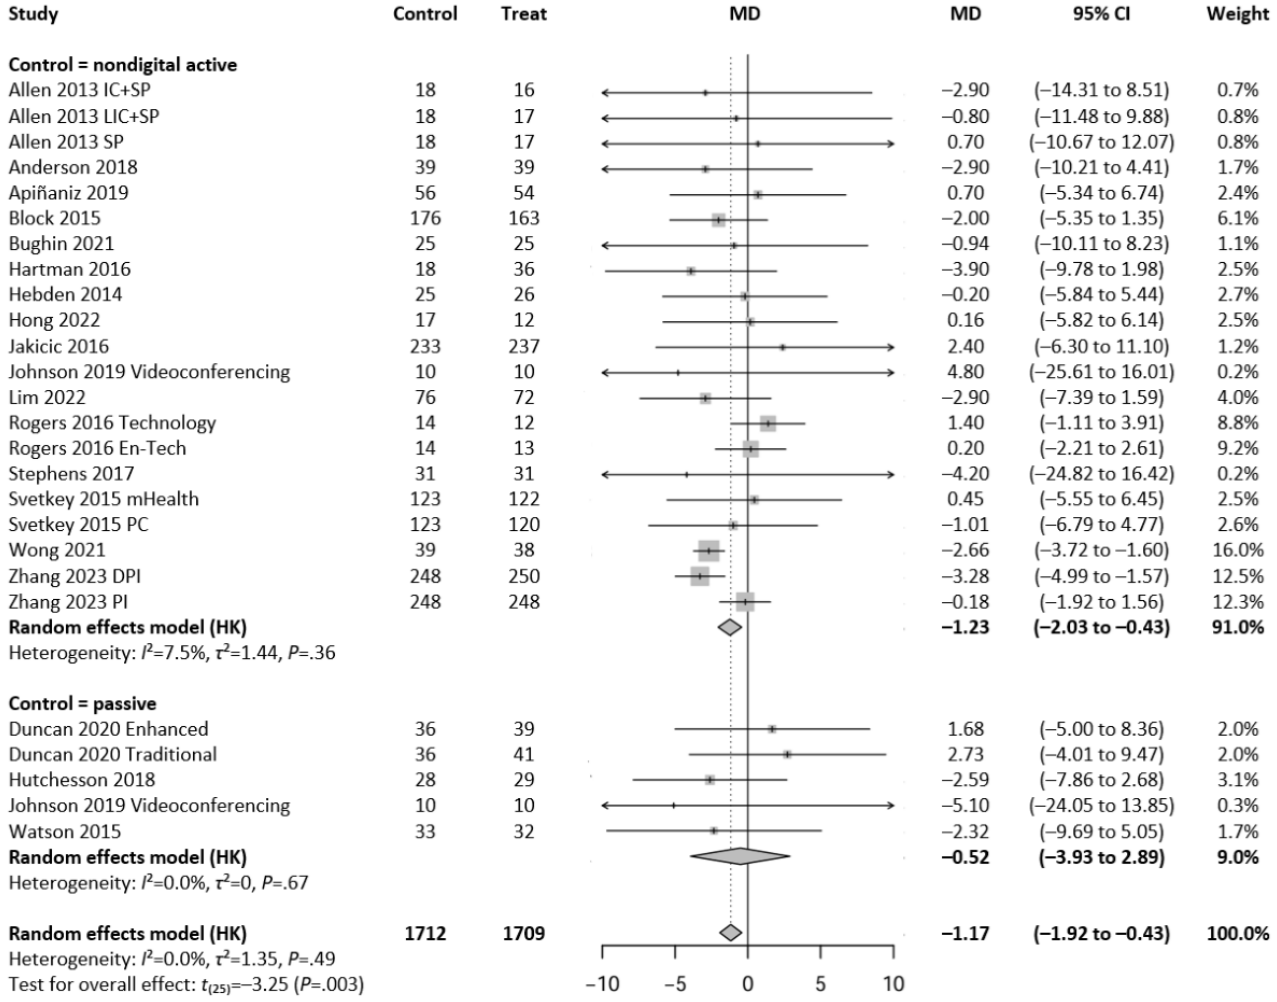
In this review, FM was examined as an outcome measure in 7 studies (with an average intervention duration of 7.9, SD 7.8 months, ranging from 8 weeks to 24 months), all of which found a significant reduction (range −0.4 to −6.5 kg) following digital intervention programs [20,33,35,46,52,57,58]. Among them, 3 studies (with an average intervention duration of 3.5, SD 2.2 months, ranging from 8 weeks to 6 months) reported significant between-group differences after the intervention [20,57,58], while 3 others (with an average intervention duration of 11.0, SD 11.3 months, ranging from 12 weeks to 24 months) found no significant difference in FM between their study groups [33,46,52]. In terms of BF%, 9 studies measured this outcome

XSL•FO
RenderX

(with an average intervention duration of 6.8, SD 7.1 months, ranging from 8 weeks to 24 months), all of which found a significant reduction (range −0.3% to −4.1%) from pre- to posttests in digital intervention groups [20,33,36,46,52,54,56-58]. However, the majority (8 studies) reported no significant between-group differences in BF% changes, and one study [36] followed a single-arm design. No clear trend was observed in FM and BF% outcomes when comparing digital-based experimental groups to nondigital active controls.

Regarding PA, 8 studies provided information on changes in MVPA following digital interventions, with 4 reporting significant improvements with an average intervention duration of 9.2 (SD 9.9; range 3-24) months [16,33,43,47] and the other 4 observing no change in MVPA with an average intervention duration of 5.2 (SD 1.5) months [18,20,39,53]. A similar trend of inconsistent results was observed across other PA-related variables, including general PA [37,45,48-50], light PA [18,33,53], moderate PA [20,51], vigorous PA [20,51], daily steps [51,55,56], grip strength [41,54,58], and the 6-minute walk test [41,52]. In addition, 5 other variables, including exercise capacity [44], exercise fun [59], exercise self-efficacy [49], sit-to-stand test [41], and gait speed [41], were each assessed in just one study. Inconsistent trends in postintervention changes were observed in these variables, with some showing significant improvements [44,49,59], while others displayed no significant changes [50], and some revealed mixed results within individual studies [41,54].

Meta-Analysis



A total of 26 intervention arms from 19 independent studies were included in the meta-analysis assessing the effect of digital exercise interventions on BW. The overall pooled analysis revealed a significant reduction in BW following digital exercise interventions compared to control conditions (MD=−1.17 kg, 95% CI −1.92 to −0.43; P=.003; t_{25}=−3.25). Heterogeneity was not significant (I^2=0.0%; τ^2=1.35; P=.49), indicating consistency across studies. Subgroup analyses based on control type showed a greater effect in studies comparing digital interventions to active (nondigital) controls than to passive controls (MD=−1.23 kg vs −0.52 kg, respectively). Figure 2 [18,20,33,34,37,39,40,42,43,45,46,48-55] shows the results of the meta-analysis assessing the effect of guideline-based digital exercise interventions on BW.

Regarding BMI, a total of 26 intervention arms from 17 independent studies were included in the meta-analysis. A random-effects model revealed a statistically significant reduction in BMI favoring digital interventions (MD=−0.50 kg/m^2, 95% CI −0.82 to −0.19; P=.003; t_{25}=−3.32), with significant heterogeneity across studies (I^2=70.0%; τ^2=0.40; P<.001). Subgroup analyses based on control type showed a greater effect in studies comparing digital interventions to passive controls than to active (nondigital) controls (MD=−0.70 kg/m^2 vs −0.45 kg/m^2, respectively). Figure 3 [16,20,33,37,39,42,45,46,48-53,55,57,59] shows the results of the meta-analysis assessing the effect of guideline-based digital exercise interventions on BMI.

Regarding BF%, a total of 7 intervention arms from 6 independent studies were included in the meta-analysis. The overall analysis revealed no statistically significant difference between interventions and control conditions (MD=−0.08%, 95% CI −0.94 to 0.79; P=.84, t_6=−0.21). Heterogeneity was not significant (I^2=7.4%; τ^2=0.25; P=.37). Figure 4 [20,33,46,52,54,57] shows the results of the meta-analysis assessing the effect of guideline-based digital exercise interventions on BF%.

Risk of Bias

Figure 5 [16,18,20,31-59] summarizes the risk of bias assessment for the included studies, with panel A presenting the overall assessment for RCTs and panel B for nonrandomized studies. Among the 26 RCTs, 4 (15%) were classified as having a "low risk of bias," indicating a strong methodological design with minimal threats to validity. In total, 65% (17/26) of the studies were rated as having "some concerns," suggesting potential sources of bias that could affect the reliability of their findings. In addition, 19% (5/26) of the studies were deemed to have a "high risk of bias," highlighting significant methodological limitations that may compromise the robustness of their results. Among the 4 non-RCTs, 2 (50%) were found to have a "moderate risk of bias," implying methodological shortcomings that could impact their conclusions. The remaining 50% (2/4) of the studies were rated as having "some concerns," indicating the presence of potential biases that warrant caution when interpreting their findings. Excluding studies with a high or serious risk of bias did not substantially alter the overall pattern of results. Similarly, findings from the 4 low-risk-of-bias studies [42,44,45,52] aligned with the general patterns, and the 7 studies with high or serious risk of bias showed the same pattern [16,35-37,40,55,58].

Figure 5. Summary of risk of bias assessment using (A) the Cochrane Risk of Bias (version 2) tool for randomized controlled trials and (B) the Cochrane Risk of Bias in Nonrandomized Studies of Interventions tool for nonrandomized studies.

Discussion

Principal Findings

This systematic review and meta-analysis assessed the effectiveness of guideline-based digital exercise interventions in improving body composition in adults with overweight and obesity, aiming to identify gaps in the literature and recommend strategies for developing and implementing future digital health interventions. In addition, alterations in PA were considered as a secondary outcome. The main findings of the meta-analysis were (1) guideline-based digital exercise interventions significantly reduced BW (MD=−1.17 kg; *P*=.003), with greater effects observed when compared to active (nondigital) controls; (2) BMI was also significantly reduced (MD=−0.50 kg/m^2; *P*=.003), with stronger effects observed in studies using passive (waitlist) control groups; and (3) no significant effect was found for BF% (MD=−0.08%; *P*=.84). The main qualitative findings were (1) digital exercise intervention programs led to significant reductions in BW (22/25, 88% studies; range −1.3 to −8.4 kg); BMI (19/23, 83% studies; range −0.4 to −3.4 kg/m^2); WC (15/16, 94% studies; range −2.1 to −9.2 cm); BF% (9/9, 100% studies; range −0.3% to −4.1%); and FM (7/7, 100% studies; range −0.4 to −6.5 kg); (2) inconsistent results were observed for WHR and PA outcomes; (3) no clear trend was identified between intervention duration or type and improvements in outcome variables; and (4) substantial variations were observed in intervention designs, comparators, confounders, and participant characteristics. The digital exercise apps and tools included in this review addressed behavior change through multiple evidence-based strategies grounded in established health behavior theories. Most interventions incorporated goal setting, self-monitoring, and feedback loops, known as core components of behavior change techniques. For instance, studies using apps such as Lose It!, Alive-PD, MetS App, and Balanced App featured personalized goal setting for PA, daily exercise reminders, and tracking tools to enhance user accountability and adherence [18,42,48,49]. Several interventions explicitly applied behavioral theories, such as social cognitive theory, the transtheoretical model, and motivational interviewing, emphasizing constructs such as self-efficacy, stages of readiness, and problem-solving [20,34,45,51]. These constructs were operationalized through coaching, interactive feedback, and gradual PA progression plans. In this context, evidence indicates that human-computer interaction plays a vital role in the effectiveness of digital health interventions, as well-designed interfaces enhance user engagement and adherence through personalized feedback, interactivity, and intuitive navigation [60]. Moreover, some studies used peer interaction or professional coaching via telehealth, which are known to enhance engagement in PA [33,37,47]. Together, these elements show that digital exercise apps, when grounded in PA guidelines and behavior change theory, may extend beyond the delivery of exercise routines to potentially support sustained behavior change by addressing key psychological and social determinants of health behavior.

Body Composition Outcomes

Consistent with this review, evidence from other review studies suggests that mHealth and digital tools can be effective for BW reduction [61-65]. Results from a systematic review [66] indicate that eHealth interventions are generally more effective than no care or usual care interventions, aligning with this meta-analysis, which found a significant average BW loss of approximately 1.17 kg associated with digital exercise interventions. This effect remained significant when compared to active (nondigital) control interventions (MD=−1.23 kg), suggesting that digital platforms may have advantages over traditional, face-to-face programs. These advantages may stem from features such as improved accessibility, personalization, and real-time feedback, all of which can contribute to greater user engagement. Research suggests that the impact of digital interventions on BW reduction may be influenced by factors such as intervention duration and design. In particular, the effectiveness of mHealth interventions for BW reduction tends to increase with longer intervention durations [63,67]. Furthermore, it has been documented that digital interventions incorporating personalized feedback and human interaction are more effective than fully automated programs [66,68]. In this regard, evidence suggests that successful digital interventions often include components such as self-monitoring, social support, goal setting, and prolonged engagement, all of which are crucial for enhancing user engagement and promoting sustained behavior change [69,70].

In line with the results of this review, evidence from comparable review studies suggests that mHealth and digital interventions can be effective in reducing BMI [61-63,71,72], with their impact largely influenced by factors such as the type of intervention, its integration with other health services, and user engagement levels [66,73,74]. In this review, no clear pattern was found between the type and duration of interventions and BMI reductions. However, a stronger effect was observed in studies using passive (waitlist) control groups compared to active controls. A review [63] found that longer intervention duration enhanced the effectiveness of mHealth and digital interventions in reducing BMI. Cultural and regional factors may also indirectly influence the effectiveness of mHealth interventions in BW outcomes; nevertheless, a study evaluating a digital weight loss intervention across multiple countries [75] found similar BW outcomes although levels of participants' engagement varied. These factors may contribute to the high degree of heterogeneity among studies on this topic, as their inclusion adds complexity to the interventions. However, it is important to note that the methodological quality of studies on digital interventions for BW and BMI reduction varies significantly, which can affect the reliability of their findings and the associated review studies [66,76], although excluding studies with low methodological quality did not substantially alter the overall pattern of results in this study.

WC and WHR are 2 important obesity-related measurements used to assess fat distribution. A meta-analysis [61] reported a statistically significant reduction in WC in adults with overweight and obesity following mHealth interventions. Similarly, another review study [72] found a consistent reduction in WC following web- and mobile-based interventions. These findings align with the results of this review, which examines

XSL•FO
RenderX

the effectiveness of guideline-based digital exercise interventions on WC. Results from another systematic review [77] show that mHealth and eHealth interventions, particularly those with personalized feedback, have been associated with reductions in central obesity measures. While there is a lack of similar review studies in the literature assessing the impact of digital interventions on WHR, this review identified 2 studies reporting a reduction in WHR, while 4 other studies reported no change following digital intervention programs. This insignificant trend, which has not been observed in BW, BMI, or WC, may be attributed to the fact that WHR appears to be an inaccurate measure of obesity in individuals with obesity, as both waist and hip circumferences reflect fat accumulation in these individuals [78], and fat loss occurs throughout the body, not in specific regions.

Consistent with the qualitative findings of this systematic review, several studies [63,72] have reported that mHealth and digital interventions can lead to significant reductions in BF%. However, this meta-analysis found no statistically significant difference in the change in BF% between intervention and control groups, with subgroup analysis also revealing no significant effect when compared to active controls. This may be attributed to the limited number of studies assessing BF%, highlighting the need for further research. Consistently, results from a meta-analysis show an insignificant change in BF% following mHealth interventions in adults with overweight and obesity, while FM reduction was significant [61]. The discrepancy in BF% but not in FM, compared to the findings of this review, may be due to the primary focus of this review on the PA component, specifically guideline-based PA, as physical exercise contributes to increased lean mass, thereby having a greater impact on BF%. Research shows that interventions using telehealth and text messaging have also demonstrated positive effects on body fat reduction by providing continuous support and motivation, which can enhance adherence to the lifestyle changes necessary for fat reduction [79]. The use of multiple electronic modalities, such as combining mHealth with other digital tools, tends to yield more significant results in fat reduction compared to single-modality interventions, offering a more comprehensive and engaging intervention experience [80]. Although mHealth and digital interventions demonstrate potential for fat reduction, evidence indicates that the long-term sustainability of these interventions remains uncertain, and their effectiveness may differ based on factors such as socioeconomic status and ethnicity, which could contribute to disparities in health outcomes [81]. Overall, based on the available literature and the present findings, effective digital PA interventions for improving body composition typically incorporate human interaction and sustained engagement, with personalized feedback, social support, and goal setting further enhancing their efficacy.

PA Outcomes

There is limited evidence showing apps to be more effective for PA outcomes than face-to-face interventions [61,82,83]; however, digital tools may offer benefits in terms of cost-effectiveness and the ability to reach a larger and more geographically dispersed population [10,11]. Insufficient and inconsistent results were found for PA outcomes in this review. However, reports from other review studies indicate an increase in general PA [84], daily step counts [65], and weekly MVPA [65] following mHealth interventions. Another review study [85] examining the effects of mHealth interventions on older adults reported an increase in weekly MVPA. A recent umbrella review of mHealth and eHealth interventions [86] reported a significant increase in daily step counts among adult populations. However, 2 systematic reviews found no significant change in general PA [82] or MVPA [61] following mHealth interventions. These discrepancies, which have also been observed in this review, may be explained by variations in intervention design and duration, target populations, and the methods used to measure PA outcomes. A review study [83] highlighted that combining digital media with face-to-face support showed the greatest potential for increasing PA compared to digital-only interventions. This highlights the need for more rigorous research to confirm the long-term benefits of digital interventions in improving PA; however, the methodological quality of the included studies in this review did not alter the results related to PA outcomes.

Limitations and Strengths

This systematic review contains limitations that need to be acknowledged. While the variability in intervention designs and duration has made direct comparisons challenging, variations in participant characteristics (such as baseline BMI, PA levels, sex distributions, age, socioeconomic status, and comorbidities) may have influenced individual study results, and consequently, the findings of this systematic review. In addition, it is important to elaborate on the potential confounding variables that may have influenced the results across the included studies. These confounders, often unevenly distributed or poorly controlled across trials, can influence both the internal and external validity of the findings. For instance, dietary intake, a key determinant of physical and metabolic outcomes, was not consistently reported or controlled in many studies, making it difficult to isolate the effects of the mHealth interventions alone. Similarly, factors such as motivation, digital literacy, and health literacy can substantially influence both adherence and outcomes but were rarely measured or adjusted for. In some populations, cultural factors may also affect attitudes toward PA and technology use, further complicating comparisons across studies conducted in different geographic or cultural contexts. These unmeasured or uncontrolled confounding variables introduce heterogeneity and potential bias into the pooled results, and their presence highlights the need for better standardization and reporting in future mHealth intervention studies. The quality of evidence supporting mHealth interventions should also be considered, as it may vary widely, although this was not observed in this study. Previous systematic reviews and meta-analyses [87,88] have rated the methodological quality of mHealth studies as low to moderate, with only a few achieving high-quality ratings, primarily due to differences in study design, sample size, and outcome measures.

Despite the limitations, this systematic review presents a comprehensive evaluation of guideline-based digital exercise interventions across multiple anthropometric and body composition outcomes, as well as PA-related variables. The inclusion of a variety of intervention formats allows for a broad

XSL•FO
RenderX

understanding of the effectiveness of mHealth and digital approaches. In addition, the review follows a rigorous methodology, ensuring high-quality data analysis and synthesis, thereby contributing to the growing body of evidence-based literature on digital health interventions for improving body composition and promoting PA.

Overall, this review provides insights for individuals, trainers, coaches, health care providers, health organizations, app developers, and policy makers by identifying the potential benefits of apps and digital tools focusing on PA for BW management, thereby contributing to the broader effort to manage overweight and obesity effectively. In addition, the findings highlight areas for future research to optimize the design and implementation of fitness apps for better health outcomes. Future research should focus on the role of personalized and adaptive digital programs, as well as their integration with other lifestyle interventions. By understanding the essential characteristics that enhance the effectiveness of digital health interventions, stakeholders can make informed decisions about integrating them into weight management programs and public health strategies. Meanwhile, clinicians and health care providers can leverage digital technologies to improve accessibility, enhance patient engagement, optimize treatment adherence, and support long-term success in weight management programs.

Conclusions

This study highlights the potential of guideline-based digital exercise interventions for addressing overweight and obesity. While significant reductions in BW and BMI were observed, results were less clear regarding body composition changes. Although longer-duration interventions showed a trend toward greater BW reduction, no clear pattern emerged between the type or duration of interventions and improvements in body composition. Key characteristics that are often identified as critical for successful digital PA interventions include personalized content, regular user engagement, and integration with other health strategies, such as dietary management and social support. While this review highlights the potential benefits of guideline-based digital exercise interventions for weight management, it also provides valuable insights to inform decisions about integrating them into health programs and public health strategies. Overall, digital health interventions can reach a larger population at a lower cost and have been shown to be effective for weight loss; however, evidence of their superiority over traditional methods is limited and inconsistent, suggesting that digital interventions may serve as a complementary approach rather than a definitive replacement for traditional methods. As technology continues to evolve, future interventions have the potential to examine and offer more tailored, engaging, and effective solutions for weight management.

Abstract

Background: A popular trend in depression forecasting research is the development of machine learning models trained with various types of smartphone sensor data and periodic self-ratings to derive early indications of changes in depression severity. While most works focus on model performance, there is little concern about the universal usability and reliable operation of such systems across smartphone platforms. This review serves as foundational work for the MENTINA clinical trial, which investigates smartphone-based health self-management for depression. The usability and reliability of mobile apps for depression are commonly perceived through the lens of the approaches and interventions offered rather than the reliability of the built-in mobile phone functions to support effortless and exact delivery of intended interventions.

Objective: This work aimed to synthesize existing systematic reviews to identify smartphone sensor modalities used in mental health monitoring and, building on this foundation, assess the cross-platform availability of these data streams using PhoneDB to inform the design and implementation of digital depression indication systems.

Methods: To identify the already used hardware and software sensors and their purposes in mental health monitoring, an umbrella review was conducted. Three electronic databases, including PubMed, Web of Science Core Collection, and Scopus, were searched using smartphone, sensor data, and depression keyword combination to retrieve relevant literature reviews published within the last 5 years (2019-2024). Once the initial search was completed, the extracted hardware sensors were checked for availability on Android and iOS smartphones by analyzing device specifications in PhoneDB over the last 10 years.

Results: The extracted data streams observed across the 9 included studies covered 16 hardware and 3 software data streams. Hardware data streams included accelerometers, barometers, battery levels, Bluetooth, cameras, cellular networks, GPSs, gyroscopes, humidity, light sensors, magnetometers, proximity sensors, sound sensors, step counters, temperature sensors, and Wi-Fi. Software data streams included app usage, call and message logs, and screen status. Hardware component availability on Android and iOS systems showed the changes in component trends from 2014 to 2024 as of September 2024, with the accelerometers, batteries, cameras, and GPSs remaining consistent on Android and iOS, while components such as gyroscopes, step counters, and barometers gradually increased over the years, particularly on Android.

Conclusions: Multiple data streams identified in the literature review showed a consistent increase in availability over time, enabling improved use of these outputs for depression forecasting and the training of machine learning models with diverse smartphone data, including sensor-derived information. For more precise and reliable data to be used in the mental health field, particularly in critical areas such as tracking and predicting changes in depression severity, further research is required to streamline

smartphone data across varying mobile hardware and software configurations to provide reliable output for digital mental health purposes.

(Interact J Med Res 2025;14:e69686) doi:10.2196/69686

KEYWORDS

umbrella review; mobile phone; smartphone; sensor data; digital health; depression; cross-platform; data availability

Introduction

Background

The vast variety of personally generated data can provide useful insights that empower individuals with depression to better manage experienced symptoms. Smartphone apps allow for the easy collection of personalized data over long time periods and enable the use of powerful machine learning models that can potentially identify individual data patterns related to the severity of depression or predict changes in symptoms and the probability of relapse or remission. Periodic self-ratings concerning depression-related symptoms and life events are mostly collected actively via questionnaires, whereas data from hardware and software components are mostly recorded passively to derive biomarkers, behavior patterns (eg, phone and app usage) and external moderating factors (eg, environmental conditions).

Several promising works are already using smartphone data to train supervised machine learning models for mental health monitoring [1-6], but only a few are based on continual data from studies lasting longer than 30 days. The existing studies show insufficient consideration of the reliability and practicability of the chosen algorithms in real-world scenarios. Once models are deployed and operated, the performance of model prediction results may vary depending on the algorithm's capability to handle missing and erroneous data due to reasons such as varying smartphone platforms or data availability. Moreover, the variety of installed hardware and software components and the steadily evolving technology in this field make it even more challenging to build fail-safe applications that work across various environments in the present and future.

Recent literature lists plenty of passively collected smartphone data streams mostly used in a transformed manner for mental health monitoring. While hardware components like accelerometers, ambient light sensors, Bluetooth, cameras, GPSs, gyroscopes, microphones, and Wi-Fi are among the most used smartphone data sources [7-15], hardware components like barometers [8] and temperature [13] sensors are named only a few times in relevant works, but can also play an important role in the context of mental health monitoring. Most sensors are not directly used for depression modeling but rather serve as a proxy for key figures that are correlated with depression symptoms. Typical key figures derived from smartphone hardware components data are estimates on physical activity, sleep duration, sociability, mobility, circadian rhythms, stress, and the environment recognition [7-15]. The use of sensors for deriving key figures varies widely across the literature. For example, sociability has been inferred using microphones, analyzing silence, noise, and voices [14], or by detecting nearby devices via Bluetooth or Wi-Fi [10]. The term "environment" has been applied inconsistently in the literature, encompassing aspects such as an individual's visual and acoustic surroundings as well as environmental parameters like climatic conditions. For instance, microphones have been used to identify acoustic environments to infer stress [15], while temperature, humidity, and accelerometer sensors have been used to assess environmental hazards [13].

Besides hardware components, smartphone operating systems also provide valuable information for mental health monitoring. Software sensors measuring smartphone and app usage offer key figures on sociability, distractedness, stress, and mood estimates in the case of access permissions to app, phone call, and text message logs [7-15].

Given the presence of multiple existing systematic reviews on smartphone sensing for depression, an umbrella review was chosen to synthesize high-level evidence and critically appraise the quality of these sources—an important step for informing evidence-based mental health app development. By identifying consistently reported sensor modalities and methodological patterns, this review provides a foundation for informed decisions related to recruitment and data collection setup in upcoming clinical studies using smartphone-based mental health monitoring. In particular the results of this work can serve as a comprehensive path for the setting up of the MENTINA trial. The subproject MENTINA trial is part of the European Union–funded research project MENTBEST [16] and aims to investigate the value of data-driven interventions in the context of management of depression severity. Participants of the trial will use an app for 1 year that collects data from smartphone sensors passively while requiring the users to periodically give feedback on personal well-being via self-reports. Besides providing biweekly feedback using the Patient Health Questionnaire 9 [17], participants will also be asked to provide daily ratings on their mental health condition by answering the Patient Health Questionnaire 2 [18] throughout the trial. The app will be available on Android and iOS smartphones and is based on the Monsenso app developed by the Danish digital health solution provider [19-21].

Objectives

In alignment with the preparation of the MENTINA trial, the following research questions should be answered in the course of this work:

1. Which data streams provided by smartphones have been used in the literature to build models for depression monitoring?
2. Which smartphone data streams are available across smartphone vendors and operating systems to build reliable platform-independent software systems for depression monitoring?

XSL•FO
RenderX

3. Which proxies have been constructed from raw smartphone data streams to build key figures for depression models?

Methods

Umbrella Review

Protocol and Registration

The umbrella review has been registered in the PROSPERO database (CRD42024581256) and was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [22].

Information Source and Search Strategy

During the preparation phase of the MENTINA trial in September 2024, the umbrella review was performed by querying the scientific databases PubMed, Web of Science Core Collection, and Scopus to get a comprehensive overview of the existing reviews in the field. The search strategy included querying the scientific databases with the search term "smartphone sensor data depression" to find reviews related to clinical depression or dealing with depression symptoms. To capture the most recent syntheses of evidence on smartphone data streams relevant for current mental health monitoring, filters were applied to include only review papers published within the past 5 years (2019-2024). This time frame aligns with findings that individuals typically replace their smartphones within a 5-year period [23], reinforcing the relevance of focusing on reviews that reflect contemporary device usage and capabilities.

Eligibility Criteria

Studies were considered only when the screening of the title and abstract confirmed that the study was a review written in English or German and focused on more than 1 smartphone sensor to build digital phenotypes of individuals' mental health. The authors JL and MP independently assessed the eligibility of the studies based on titles and abstracts, with UH serving as a supervising rater, resolving any conflicts that arose during the assessment process.

Selection of Studies

The full-text versions were obtained and the contents of potentially relevant papers were analyzed to select items matching the following criteria: (1) reviews already summarizing the use of raw smartphone sensors over multiple other works, and (2) reviews showing sensor purposes in terms of depression recognition. The preselection of studies based on the selection criteria was performed by author JL.

Quality Assessment

For quality assessment, reviews were evaluated using the AMSTAR (A Measurement Tool to Assess Systematic Reviews) checklist [24]. Reviews were chosen only if particular items could be answered with "yes". The items of relevance were the following:

- Item 2 ("Was there duplicate study selection and data extraction?")
- Item 3 ("Was a comprehensive literature search performed?")
- Item 6 ("Were characteristics of the included studies provided?")
- Item 11 ("Were potential conflicts of interest included?").

The full texts were independently quality-assessed by authors UH, MP, and JL. Final inclusion decisions were made through majority consensus.

Narrative Synthesis

To synthesize the relevant literature, each included review was screened for smartphone data streams previously used in mental health monitoring. These data streams were extracted and categorized into hardware (derived from installed components) and software (provided by the operating system) categories to distinguish their sources. For each identified data stream, the utilization for deriving mental health insights was assessed and extracted. The extracted data were organized into a table, listing smartphone data streams as rows and relevant studies as columns. Table cells indicated whether a data stream was mentioned in a study regarding mental health monitoring. If a data stream was mentioned but its specific use was unclear, the corresponding cell was marked as "listed." To enhance readability, similar terms were clustered, and a separate table mapped original terms to umbrella terms. The hardware data stream collection further served as the foundation for investigating cross-platform sensor availability.

The data extraction process was conducted by JL, with MP verifying the extracted data and decisions. UH supervised the process, resolving any conflicts.

Cross-Platform Sensor Availability

Smartphone Operating System Market Analysis

To assess the prevalence of commonly used mobile operating systems, market share data from the past 2 years was analyzed using statistics from the portal Statista [25-29]. To highlight the global significance of Android and iOS, worldwide market share data were extracted. Additionally, regional analyses were focused on Europe, with a particular emphasis on Denmark, Germany, and Spain, to provide insights into the operating system market landscape in these countries where the MENTINA trial will be conducted.

Additionally, to approximate real-world smartphone usage in Germany, the best-selling Android and iOS smartphones in the country for September 2024 were extracted from Counterpoint [30], and the sensor availability in these models was analyzed to better represent the likely scenarios in one of the MENTINA countries.

Phone Specifications Database

PhoneDB maintains the world's largest database for mobile device specifications, providing technical details for smartphones, tablets, smart watches, and several other types of handheld devices [31]. While PhoneDB is not a complete collection, it gives a comprehensive overview of smartphone releases over the past 20 years [32]. PhoneDB was used in a couple of other scientific works [32,33] and serves as a valuable

XSL•FO
RenderX

data source for deriving trends for technical specification trends. Besides information on the operating systems the devices are running, the database provides more than 290 parameters per device, including information on the presence of installed hardware sensors. PhoneDB offers licensed database dumps or free limited access to the database via preconfigured database queries using PhoneDB's web-based detailed parametric search tool. The search tool allows querying device specifications based on built-in sensors, which has been used for this work.

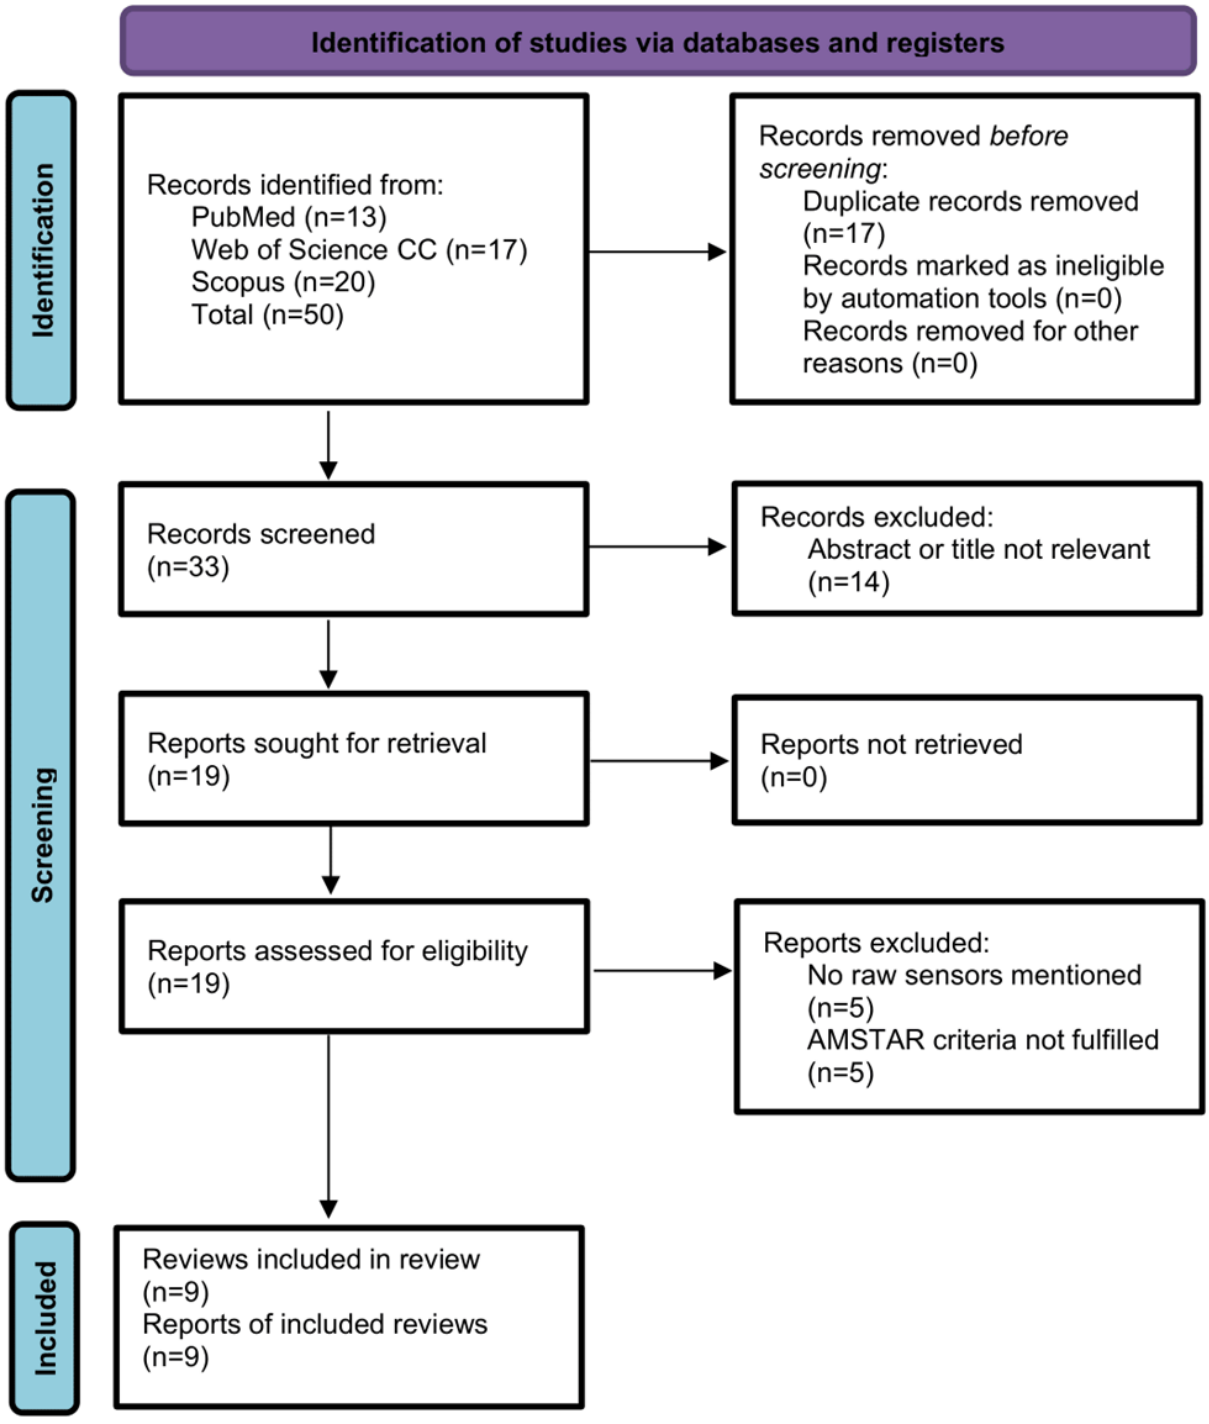
Data Queries

PhoneDB was queried multiple times to retrieve the number of devices matching the search criteria. The search criteria included filters on the device category, release date, operating system, and installed hardware including whether the devices are equipped with built-in hardware components. To identify operating system–dependent trends in hardware component availability, the database was queried for annual Android and iOS smartphone specifications with corresponding components installed from 2014 to 2024. To get a baseline, queries without any hardware component filter were executed to get the annual total number of Android and iOS releases for each year.

Additionally, PhoneDB was queried for each considered device to collect pricing information, including price, currency, market countries, and market region, to facilitate analysis of the correlation between price and hardware availability.

Data Analysis

The PhoneDB query results were saved in 1 file for iOS and 1 file for Android. Each file consisted of a data table with hardware components as rows and years as columns. The table cells represented the number of device releases in the particular year that had the corresponding hardware component installed. For the baseline, a row consisting of the total number of device releases over the considered years was added to each file. Based on the Android and iOS data tables, the hardware component availability as a percentage was calculated by dividing the number of device releases with the corresponding hardware component installed by the total number of device releases in the respective year and multiplying by 100.



Results

Umbrella Review

A PRISMA flow chart (Figure 1) has been created to illustrate the information flow of the umbrella review. Aligned with the search strategy, 50 records were found in total across the 3 queried scientific databases (PubMed, n=13; Web of Science Core Collection, n=17; Scopus, n=20). After removing duplicates (n=17), 14 records were removed due to nonrelevant abstract and title. For the remaining 19 records, full-text reports were requested and screened to meet the eligibility criteria. Ten records were excluded for either not reporting the use of raw sensors (n=5) or for not meeting the AMSTAR criteria (n=5) [24]. Finally, 9 reviews were selected for data extraction and synthesis.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow chart. CC: Core Collection; AMSTAR: A Measurement Tool to Assess Systematic Reviews.

The studies included in the umbrella review are listed in Table 1. For transparency, the list of excluded records along with their exclusion reasons can be found in Multimedia Appendix 1. Table 2 depicts the results of the data extraction and synthesis by listing the found smartphone data streams in rows over the relevant studies as columns. The table cells indicate whether a smartphone data stream has been mentioned in the respective article regarding mental health monitoring.

[a]The data stream was not mentioned.

[b]The data stream was mentioned but its specific use was unclear.

[c]Proximity sensors are usually realized with an emitting infrared LED and a detecting photodiode [34].

[d]Step counts are usually derived by sensor fusion of multiple other hardware sensors. Modern smartphones are equipped with dedicated motion coprocessors to do this task in an energy-efficient manner [35].

To improve the readability of Table 2, clusters were built for similar terms. A list of mapped original terms to umbrella terms is shown in Table 3.

XSL•FO
RenderX

Table 3. Mapping table of umbrella terms and assigned terms found across the literature.

Umbrella term	Original terms in the literature
Data stream	
App usage	app usage, application usage, browser usage, in-phone activity
Light	light, ambient light
Screen	screen status, lock/unlock status, screen time, screen events
Sound	sound, microphone, audio, voice, speech
Purpose	
Circadian rhythm	circadian rhythm, daily-life behavior, behavioral marker
Environment	environment, surrounding, workplace conditions
Mobility	mobility, location, homestay
Physical activity	physical activity, motion, human activity, movement
Sleep	sleep, bedtime, sleep disturbance
Social activity	social activity, loneliness, social avoidance, social rhythm, social function, social habits, social interaction, sociability, social anxiety
Stress	stress, distractedness

As the results in Table 2 show, the most mentioned hardware data streams included accelerometers, light sensors, and GPSs. While accelerometers are mostly used to derive a proxy measure for physical activity, light sensors are broadly used to gather insights about the sleep behavior of individuals. GPSs serve various purposes to build proxy measures for mental health [7-15]. The most prominent application of GPSs in terms of mental health monitoring is to derive information about individuals' mobility, which includes, for instance, the number of location changes or the time spent at home. Similar information could be also retrieved from the current position of a smartphone in cellular networks, which was also mentioned in 1 study [12]. In contrast to cellular network information, GPSs were also broadly used to track physical activity and helped to determine one's circadian rhythm, gathering, for instance, markers for daily life behavior. Only a few studies mentioned GPSs in context of measuring social activity [10,15], but according to the included studies, social activity is often approximated by identifying the number of closely located devices in one's environment using Bluetooth [7-11,14,15].

Similarly, some of the studies mention the use of microphones or cameras to get a measure for social activity by analyzing individuals' acoustic and visual environments [7-10,14,15]. Several studies also mention the use of microphones to estimate individuals' circadian rhythms, including sleep patterns [8-10,13-15]. Those patterns are also approximated by interpreting battery levels, as a couple studies referenced [8,9].

A couple of other hardware data streams were additionally mentioned for estimating circadian rhythms, including data derived from proximity sensors, gyroscopes, or Wi-Fi components [8,13]. Furthermore, Wi-Fi and gyroscopes were mentioned in the context of various other proxy measures for mental health monitoring, including mobility, social activity, and physical activity [7-10,12,14,15].

Beyond the hardware data streams already mentioned, step counts were used many times but exclusively to derive key figures for physical activity [7-9,12-14]. To complete the list of hardware data streams used for representing physical activity, temperature sensors, barometers, and magnetometers were also mentioned in the literature reviews for this purpose [8,13]. Finally, 1 relevant article stated the use of humidity sensors for approximating a person's well-being [13].

Furthermore, all included studies also listed software data streams for the monitoring of mental health (Table 2), including the data from call and message logs as an insightful data source for building proxy measures for mental health. While most studies stated that call and message logs were used to estimate individuals' social activity [7-10,12,14,15], 2 referred to using the logs for constructing metrics on circadian rhythm [8,13]. Additionally, estimates for mood and stress were listed as a derivate of call and message logs [11,14,15]. In principle, the same mental health characteristics were derived from using app and screen usage data across the literature, while a few studies stated that screen status was also used to approximate sleep behaviors [14,15].

Cross-Platform Sensor Availability

According to data from Statista [25], the worldwide smartphone operating system market is dominated by the Android and iOS operating systems, covering 72% and 28% of the market share, respectively, as of the second quarter of 2024. Similarly, the smartphone operating system market in Europe is dominated by Android and iOS [26]. In 2018, Android devices covered 67% of the European market, while the market share for iOS was 32%. In 2023, approximately 65% of European smartphones were still running Android, while the remaining market was almost completely covered by iOS devices. The mobile operating system market shares in Germany, which is part of the MENTINA trial, were similar to those of the broader European market, consisting of 60% Android devices and 39% iOS devices in 2023 [27]. As of March 2024, the mobile operating system market in Spain, another country included in the MENTINA trial, was dominated by Android with a share

XSL•FO
RenderX

of approximately 80%, while iOS covered approximately 20% [28]. In contrast, as of April 2024, 57% of mobile devices in Denmark, the third country in the MENTINA trial, were running iOS, while 42% of devices had Android installed [29]. Table 4 summarizes the operating system market shares for the considered regions.

Table 4. Smartphone operating system market shares according to Statista [25-29].

	Android (%)	iOS (%)
World	72	28
Europe	65	35
Germany	60	39
Spain	80	20
Denmark	57	42

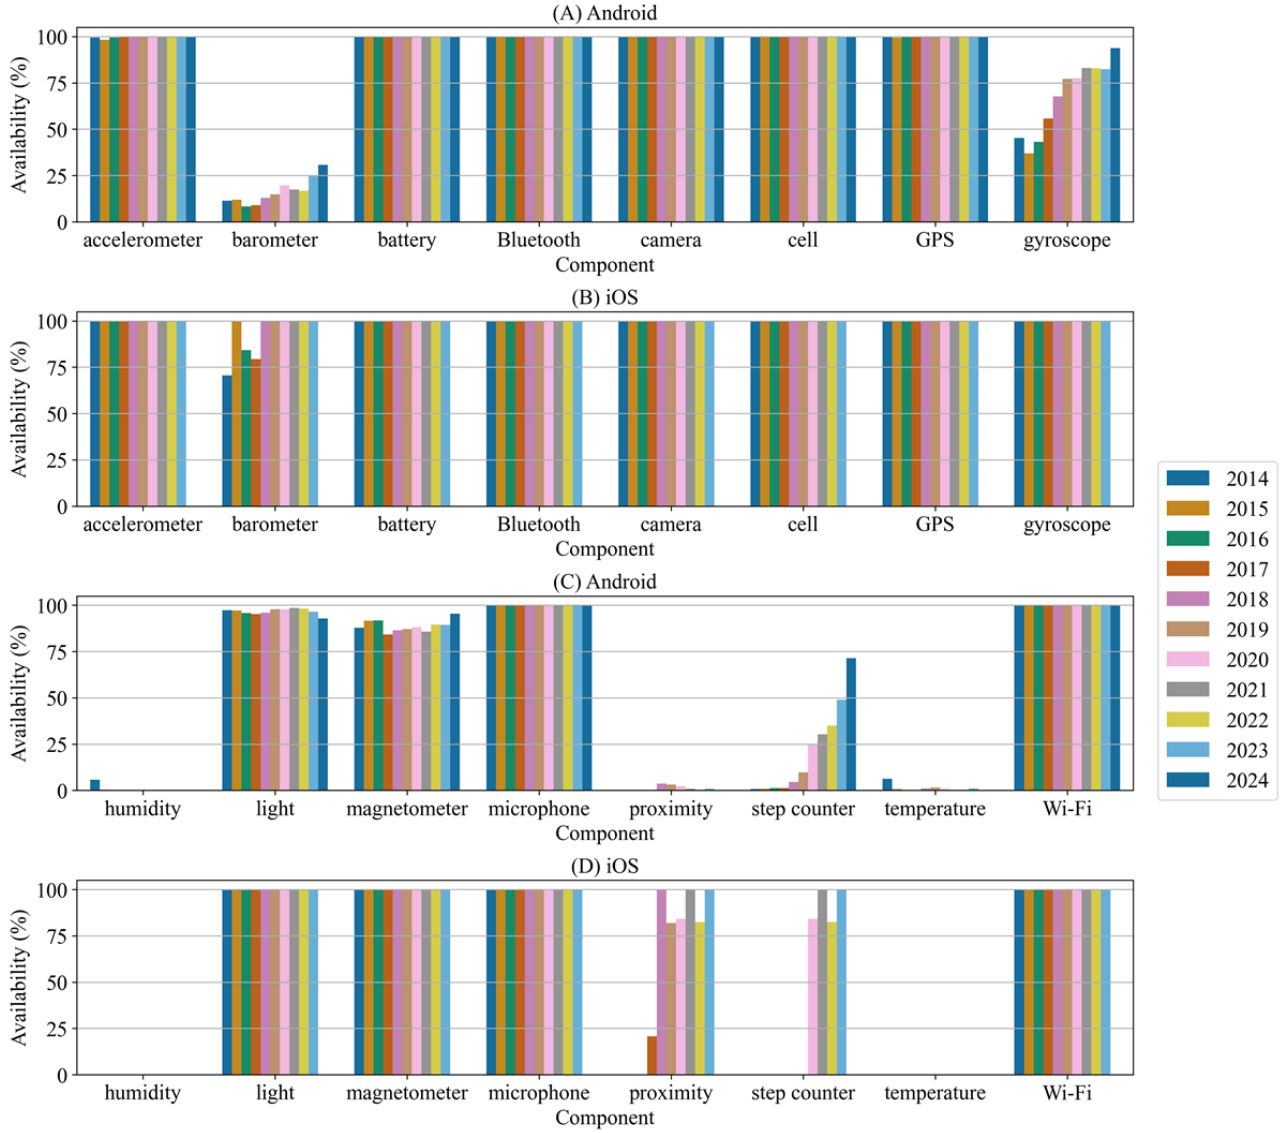
To estimate real-world smartphone usage in Germany before the start of the MENTINA trial, the top 5 best-selling smartphones in the country for September 2024 were extracted from Counterpoint [30]. The Apple iPhone 15 Pro Max ranked first, accounting for 10% of sales, followed by the Apple iPhone 15 Pro (9%) and the Apple iPhone 16 Pro Max (6%). The list also included Android devices, with the Samsung Galaxy A55 5G ranking fourth (6%) and the Samsung Galaxy S24 ranking fifth (5%).

Due to the worldwide market dominance of Android and iOS smartphones, PhoneDB was only queried for hardware component availability on Android and iOS systems. Table 5 shows the fields and values of PhoneDB's search tool, combinations of which were used to estimate the trends of hardware component availability for Android and iOS smartphones over the past 10 years.

Table 5. Relevant PhoneDB fields and input values to meet the search criteria.

Search criteria	Field	Input values
General		
Year	Release Date	Dates spanning complete years from 2014 to 2024 (eg, from 2020-01-01 to 2020-12-31)
Smartphone	Device category	Smartphone
Operating system	Platform	Android or iOS/iPadOS
Data stream		
Accelerometer	Built-in accelerometer	Any
Barometer	Barometer checkbox	Checked
Battery	Battery	Any
Bluetooth	Bluetooth	Any
Camera	Camera image sensor	Any
Cellular network	Supported cellular bands	Any
GPS	GPS checkbox	Checked
Gyroscope	Built-in gyroscope	Any
Humidity	Humidity sensor checkbox	Checked
Light	L sensor checkbox	Checked
Magnetometer	Built-in compass	Any
Microphone	Microphone(s)	Any
Proximity	IR[a] face sensor or LiDAR[b] checkbox	Checked
Step counter	Step counter checkbox	Checked
Temperature	T sensor checkbox	Checked
Wi-Fi	Wireless LAN[c]	Any

[a]IR: infrared.



[b]LiDAR: light detection and ranging.

[c]LAN: local area network.

XSL•FO
RenderX

The raw data derived from the PhoneDB queries can be viewed in Multimedia Appendix 2. The appendix also contains the availability results for Android and iOS. Figure 2 depicts a condensed version of these results by showing the availability of 16 hardware components on Android and iOS smartphones from 2014 to 2024 as of September 2024.

Figure 2. Annual hardware component availability on Android and iOS smartphones from 2014 to 2024 as of September 2024. (A and B) Availability of accelerometer, barometer, battery Bluetooth, camera, cellular network, GPS, and gyroscope components on (A) Android and (B) iOS. (C and D) Availability of humidity, light, magnetometer, microphone, proximity, step counter, temperature, and Wi-Fi components on (C) Android and (D) iOS. The data for each hardware component are plotted in chronological ascending order to depict the availability trend throughout the years. The charts in B and D are missing a bar for 2024 because there were no existing iOS specifications for 2024 as of September 22, 2024.

As seen in Figure 2, hardware components such as accelerometers, batteries, Bluetooth, cameras, cellular network support, GPSs, microphones, and Wi-Fi were available on almost every Android and iOS smartphone released in the 10-year period. Since 2018, iOS smartphones have been equipped with barometers. In contrast, only 31% of Android devices came with barometers in 2024, but a positive trend was observed. Similarly, iOS smartphones have provided gyroscopes for the last 9 years, while not all Android devices were shipped with gyroscopes in 2024. With more than 80% of Android smartphones having gyroscopes installed from 2021 to 2023 and approximately 94% in 2024, a positive trend was visible. Besides a few recognizable Android devices in 2014, almost no Android or iOS smartphone provided a humidity sensor in the period studied. Almost the same pattern applied to temperature sensors, with several years seeing low availability on Android systems and no coverage on iOS systems. For light sensors, iOS devices provided full coverage from 2014 to 2023. For Android, 95% of devices provided light sensors from 2014 to 2023 and an all-time low of approximately 93% did so in 2024. Similarly, while magnetometers were found on every iOS smartphone, not every Android device came with magnetometers. The trend of magnetometer availability on Android phones experienced a slow increase from 2017 to 2023, reaching 95% availability in 2024. From 2018 to 2023, iOS smartphones came with a proximity sensor approximately 80% of the time, whereas almost no Android phones provided a proximity sensor during the studied period. Step counters are

XSL•FO
RenderX

usually derived by sensor fusion of multiple other hardware sensors, but modern smartphones are equipped with dedicated motion coprocessors to perform this task in a more energy-efficient manner [35]. Coprocessors for efficiently estimating step counts were present on iOS phones more than 80% of the time since 2017; Android systems have rapidly caught up, with an average availability of 71% in 2024.

For transparency, Multimedia Appendix 3 provides a comprehensive list of the smartphones considered in this study, including hardware component availability and price information sourced from PhoneDB. Among the top-selling iOS models, the Apple iPhone 15 Pro Max, iPhone 15 Pro, and iPhone 16 Pro Max include all hardware components listed in Table 5 except for humidity and temperature sensors. In contrast, the top-selling Android models, the Samsung Galaxy A55 5G and Galaxy S24, are equipped with fewer sensors than their iOS counterparts. The more expensive Samsung Galaxy S24 lacks sensors for measuring humidity, proximity, and temperature, while the most affordable among the 5 best-selling models, the Samsung Galaxy A55 5G, is missing additional components, including a barometer, humidity sensor, proximity sensor, step counter, and temperature sensor.

Discussion

Principal Results

To highlight the potential of sensors for building reliable mental health monitoring systems across smartphone platforms, we focused on answering three research questions in the course of this work: (1) Which data streams provided by smartphones have been used in the literature to build models for depression monitoring? (2) Which smartphone data streams are available across smartphone vendors and operating systems to build robust platform-independent software systems for depression monitoring? (3) Which proxies have been constructed from raw smartphone data streams to build key figures for depression models?

To address research question (1), an umbrella literature review aligned with the PRISMA workflow was conducted, and 9 articles were included that ensure high methodological quality according to the AMSTAR checklist. From each of the included articles, the mentioned smartphone data streams were extracted, resulting in a list of 16 hardware data streams and 3 software data streams.

To consider research question (3), the purposes of each data stream regarding mental health monitoring were extracted from the literature and assigned to similar purpose clusters. In summary, smartphone data were used in the literature to build key figures for circadian rhythm, the environment, mobility, mood, physical activity, sleep, social activity, speech, stress, and well-being to provide insights into the mental state of individuals.

To provide answers to research question (2), the identified smartphone hardware data streams were assessed regarding their availability on Android and iOS platforms.

In sum, hardware components including accelerometers, batteries, Bluetooth, cameras, cellular network receivers, GPSs, microphones, and Wi-Fi were available on every Android and iOS device released in the past decade. Due to their presence on every smartphone, data streams from these components are promising candidates for the construction of robust cross-platform software systems.

The same applies to data on gyroscopes, light sensors, and magnetometers, which were installed on every iOS and almost every Android smartphone. Despite the fact that step counts are already provided by the operating systems through sensor fusion of other hardware components, the availability of motion coprocessors for more accurate step counters on Android and iOS smartphones increased significantly throughout the studied period, making it another promising candidate for the establishment of robust software systems.

As of September 2024, barometers, humidity sensors, proximity sensors, and temperature sensors had not been consistently installed across Android and iOS mobile phones, and therefore have limited use for reliable cross-platform mental health monitoring systems.

Limitations

While this work strives to provide a complete picture of the smartphone data available for the development of reliable cross-platform depression indication systems, it does not consider the quality and uniformity of data streams. This work considers a data stream for a particular hardware component to be available if any type of hardware component has been installed. Due to the broad spectrum of installed hardware components in the considered time frame, the data stream signals will vary significantly, thus limiting the comparability and interpretability of raw values across mobile phones. Therefore, future work may focus on improving operating systems and middleware to provide comparable data streams derived from different hardware component types. Some studies have already attempted to address the integration of diverse sensor signals across mobile devices by providing cross-platform frameworks to facilitate the development of stable mobile apps [36,37].

Furthermore, this work lacks an in-depth analysis of how the extracted data streams were specifically used in the literature to compute key metrics for representing mental health. While the studies included in the umbrella review provide a high-level description of the use of smartphone data streams, more detailed research is needed for each data stream individually. An example of in-depth analysis is the investigation of human voice signals derived from smartphones for mood and depression monitoring, which plays a crucial role in the development of mental health monitoring systems [38,39]. Future research should further explore the preprocessing and integration of smartphone data streams to construct representative mental health metrics across platforms.

Although this study primarily focuses on the cross-platform availability of hardware sensors, the umbrella review also identified several software data streams relevant to mental health monitoring, including app usage, call and message logs, and screen status information. However, the included studies do not

XSL•FO
RenderX

provide a comprehensive overview of all available data streams offered by operating systems, as they do not account for data accessible through additional operating system functionalities or external application programming interfaces (APIs). For example, a study by Jacobson and Chung [40] illustrates how GPS location data can be enriched with weather conditions by retrieving temperature, humidity, and precipitation data from the National Weather Service API at a specific time and location. Given that humidity and temperature sensors are rarely integrated into Android and iOS smartphones, as indicated by our cross-platform sensor availability analysis, leveraging operating system internal or external APIs could help compensate for these hardware limitations by providing the necessary environmental data. Future research should investigate additional data streams that can be accessed via operating system APIs and external APIs, expanding the range of available information for mental health monitoring.

This umbrella review was designed to support the subsequent cross-platform availability analysis. Given the considerable redundancy observed across the included reviews, a broader search strategy would likely not have materially influenced the main findings, namely the smartphone data streams and their mental health purposes identified in recent years. Nevertheless, the comprehensiveness of the search strategy might be enhanced by the inclusion of additional keyword synonyms. In addition, the time frame for study inclusion was limited to the last 5 years, which may have led to the exclusion of earlier relevant reviews, particularly those covering foundational work or less frequently updated areas. Another limitation concerns the study selection process—while the selection criteria were clearly defined and straightforward to apply, full-text selection was performed by only 1 author (JL), which may have introduced a risk of selection bias. Furthermore, the umbrella review approach, which enabled a high-level synthesis of existing systematic reviews, comes with inherent limitations. As it depends on the scope and quality of the included reviews, any omissions or biases in those sources are carried forward. This may lead to underrepresentation of newer sensor types or recent primary studies not yet covered. Inconsistent reporting across reviews posed a challenge, but relevant information was systematically extracted and harmonized into a unified comparison table, enabling cross-review analysis of sensor modalities and mental health outcomes. Despite these constraints, the method provides a critically appraised foundation to inform future research and application design.

Comparison With Prior Work

Through the course of this work, plenty of reviews were found that already summarize the potential of smartphone data for mental health monitoring [7-15,41-44]. To our knowledge, there is no umbrella review providing a complete picture of the research in this field. Therefore, this work consolidates the literature findings with respect to the development of cross-platform mental health monitoring systems. The studies of the umbrella review [7-15] mostly highlight the potential of smartphone data for mental health monitoring, but little research has been performed on the availability of underlying data sources across mobile platforms. The availability of data streams is highly dependent on the smartphone operating system [42]. Therefore, this work closes that research gap by providing the availability of smartphone hardware data streams on the predominating smartphone platforms, Android and iOS, over the last 10 years. Vendors and researchers may make use of the availability results to build reliable and robust mental health monitoring software systems in the future.

Conclusions

Research in the field of digital phenotyping for mental health and depression modeling is an emerging and complex field that integrates insights from psychiatry, technology, and health informatics [45]. Currently, the literature lacks information on passive smartphone data for reliable key figures that represent mental health. This work has started to address this gap by analyzing the cross-platform availability of relevant smartphone data. The results are expected to support the informed decisions concerning the best data collection setup for apps and trials focusing on the value of long-term complex time series analyses of such data in people living with depression and other mental health issues. Nevertheless, further research is needed to streamline smartphone data across varying mobile hardware and software configurations to provide reliable digital mental health for everyone. Therefore, future work may investigate improving frameworks and operating systems to easily provide comparable data streams for mental health monitoring independent of the underlying smartphone.

Acknowledgments

This work was funded by the European Union (grant 101080651).

Authors' Contributions

JL conducted the cross-platform availability analysis, and the main writing of the manuscript. JL, MP and UH worked on the overall study design, conducted the umbrella review, and fine-tuned the manuscript. AD, DH, and UH supervised and reviewed the work from technical and medical perspectives.

Conflicts of Interest

Abstract

Background: Metabolic syndrome (MetS) represents a complex and multifaceted health condition characterized by a clustering of interconnected metabolic abnormalities, including central obesity, insulin resistance, dyslipidemia, and hypertension. Effective management of MetS is crucial for reducing the risk of cardiovascular diseases and type 2 diabetes.

Objective: This study aimed to assess the effectiveness of combining glucagon-like peptide-1 (GLP-1) and dual gastric inhibitory polypeptide (GIP)/GLP-1 agonists with a continuous, digitally delivered behavioral change model by an integrated care team, in treating MetS among individuals with obesity.

Methods: The 6-month Zone.Health (meta[bolic]) weight loss program involved 51 participants (mean age 45, SD 10 years; mean BMI 35, SD 5 kg/m²), categorized by gender, and treated with either tirzepatide or semaglutide. Participants received continuous support via a digital health platform, which facilitated real time monitoring and personalized feedback from an integrated care team. Engagement levels with the digital platform, measured by the frequency of inbound interactions, were tracked and analyzed in relation to health outcomes.

Results: Tirzepatide reduced waist circumference (WC) by −18.08 cm, compared with −13.04 cm with semaglutide (P<.001). Triglycerides decreased significantly with both drugs, with tirzepatide showing a reduction of −64.42 mg/dL and semaglutide −70.70 mg/dL (P<.001). Tirzepatide generally showed more pronounced improvements in fasting glucose, blood pressure (BP), low-density lipoprotein, and total cholesterol compared with semaglutide. Higher engagement with the digital health platform showed significant difference among the 3 groups; the group with the highest level of app-based interactions (≥25 interactions) had the greatest WC reduction (mean −19.04, SD 7.40 cm) compared with those with ≤15 interactions (mean −9.60, SD 5.10 cm; P=.002). Similarly, triglycerides showed the greatest reduction in the group with ≥25 interactions (mean −108.56, SD 77.06 mg/dL) compared with those with ≤15 interactions (mean −44.49, SD 50.85 mg/dL; P=.02). This group also exhibited the largest reduction in diastolic BP (mean −10.33, SD 7.40 mm Hg) compared with those with ≤15 interactions (mean −0.83, SD 7.83 mm Hg; P=.004), and the most substantial decrease in fasting glucose levels (mean −18.60, SD 10.82 mg/dL) compared with those with ≤15 interactions (mean −2.49, SD 27.54 mg/dL; P=.02). Participants in the highest quartile of digital engagement had a 60% greater likelihood of MetS reversal compared with those in the lowest quartile.

Conclusions: This study shows that combining GLP-1 and dual GIP/GLP-1 agonists with a digital behavioral change model significantly improves MetS markers in individuals with obesity. Tirzepatide proved more effective than semaglutide, leading to greater reductions in WC and triglyceride levels, along with better improvements in fasting glucose, BP, and lipid profiles. Higher app-based engagement was linked to better health outcomes, with participants in the highest engagement group having a 60% greater likelihood of treating MetS compared with those with the lowest engagement.

Introduction

Metabolic syndrome (MetS) represents a complex and multifaceted health condition characterized by a clustering of interconnected metabolic abnormalities, including central obesity, insulin resistance, dyslipidemia, and hypertension [1]. Individuals diagnosed with MetS face an elevated risk of developing cardiovascular disease [2], type 2 diabetes [3], and other related complications [4]. Understanding the intricate mechanisms underlying MetS is crucial for optimizing patient management and outcomes. In the United Arab Emirates, the prevalence of MetS was 33.6% (269/801) in the Emirati population, 34.5% (214/620) in the Arab non-Emirati population, and 40.7% (695/1709) in the Asian non-Arab population [5].

Obesity serves as a primary contributing factor to the development and progression of MetS. Excess adipose tissue, particularly visceral fat, contributes to chronic low-grade inflammation and the release of adipokines, cytokines, and free fatty acids, all of which play vital roles in insulin resistance and metabolic dysregulation [6]. Central obesity, characterized by an accumulation of adipose tissue around the abdomen, is particularly indicative of MetS and poses a heightened risk for cardiovascular complications [7]. The management of MetS revolves around lifestyle modifications and pharmacological interventions aimed at addressing its components and reducing overall cardiovascular risk [8]. Lifestyle interventions, including dietary changes, regular physical activity, and weight management, form the cornerstone of treatment [9]. In patients with MetS, dietary strategies emphasizing a balanced intake of macronutrients and lifestyle modification such as smoking cessation, regular exercise, and proper eating habits may improve profiles of each component of MetS and reduce the risk of developing diabetes and cardiovascular disease [9].

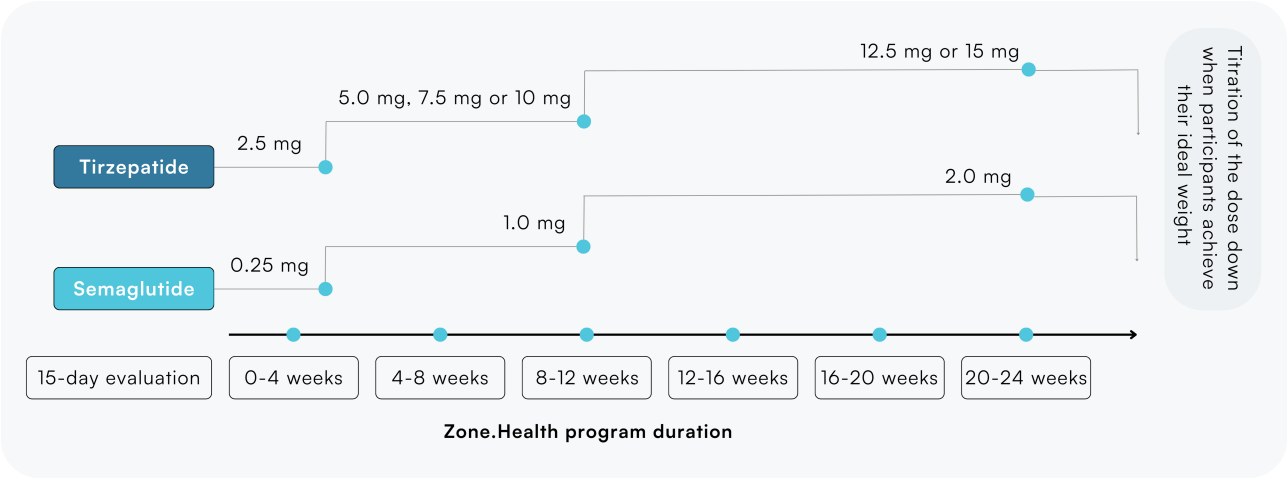
Pharmacotherapy plays a complementary role in the management of MetS, with medications targeting specific components of the syndrome. This may include statins to address dyslipidemia, antihypertensive agents to manage elevated blood pressure (BP), and insulin-sensitizing drugs to improve glucose metabolism [8]. Notably, emerging therapeutic agents such as glucagon-like peptide-1 (GLP-1) receptor agonists have shown promise in addressing multiple aspects of MetS, including glycemic control, weight reduction, and cardiovascular risk reduction [10]. By mimicking the action of endogenous GLP-1, these medications stimulate glucose-dependent insulin secretion, suppress glucagon release, and delay gastric emptying, resulting in improved glycemic control and reduced appetite [10]. Furthermore, GLP-1 receptor agonists have been associated with favorable effects on body weight, BP, and lipid profiles, making them attractive therapeutic options for individuals with MetS [10].

MetS poses a significant challenge to public health, necessitating comprehensive and more engaging approaches for prevention and management. Integrating dietary modifications, lifestyle interventions, and pharmacological treatments targeting specific components of the syndrome are essential for mitigating its adverse outcomes. The Zone.Health's meta[bolic] program, which combines pharmacotherapy with continuous engagement and monitoring to enable sustainable lifestyle modifications, demonstrated significant improvements in weight, body composition, and metabolic markers [11]. Enhancing traditional treatment paradigms by integrating continuous digital health monitoring with tailored pharmacotherapy. This program leverages advanced analytics and real time data to dynamically adjust treatment plans, fostering deeper patient engagement and more precise management of MetS components. Compared with traditional models that often rely on intermittent follow-ups and generalized treatment approaches, Zone.Health's continuous care model ensures long-term lifestyle modifications and pharmacological adherence, which are critical for long-term management of MetS. This integration of technology and personalized care is designed to significantly improve clinical outcomes by providing consistent, supportive, and adaptive interventions tailored to individual patient needs. Therefore, the aim of this study is to measure the effectiveness of GLP-1 and GLP-1/gastric inhibitory polypeptide (GIP) medications when combined with a continuous, digitally delivered behavioral change model involving a multidisciplinary team in the treatment of MetS components and weight among individuals with obesity in the UAE population.

Methods

Zone.Health Program

Zone.Health, introduced by meta[bolic] [12] in 2023, is a value-based 6-month weight loss program designed to be used in combination with pharmacotherapy. This innovative initiative offers hyperpersonalized insights, and monitoring in order to have patients adopt realistic, bite-sized behavioral change decisions over the duration of the program. The program's "value-based" approach underscores its commitment to efficacy, promising partial refunds to participants who fulfill specified compliance metrics but do not achieve a minimum 10% weight loss within the program's timeframe. This ensures accountability while prioritizing the participant's progress and well-being. Hyperpersonalization lies at the core of Zone.Health, where each participant's unique physiological, behavioral, and psychological profile is considered. When focusing on physiological factors, parameters like age, fat mass, muscle mass, and physical activity levels are considered. Whereas the behavioral and psychological aspect includes mental health, goal setting, and psychological beliefs. Furthermore, using continuous glucose monitoring (CGM), alongside activity and sleep tracking, and other digital biomarkers, the health care team dynamically tailors dietary recommendations, exercise plans, and medication regimens to suit each participant needs. The ongoing engagement between participants and the health care team is necessary. Biweekly sessions by the health coach comprehensive provides support, addressing progress, challenges, and evolving needs. As participants advance, engagement frequency adjusts to monthly sessions, focusing on maintaining achievements and adapting strategies for long-term success. Zone.Health's multifaceted approach extends beyond face-to-face interactions, incorporating an intuitive app called "Zone.Health" supported by the health care team including coaches, sports scientists, dietitians, physicians, and



XSL•FO
RenderX

diabetes educators. The app is integrated with a nutrition artificial intelligence food logging tool used by participants for food logging as well as integration with wearable data from Apple healthkit or Google fit. Participants are educated by dietitians to ensure correct food logging and minimize errors, by diabetes educators to interpret CGM data, and by health coaches to ensure integrating all other digital wearables (including Apple watch, Google Fitbit, or ŌURA ring [Oura Health Ltd]) into the app and educate the participants data collected from these wearables. Data integration is seamless, with unified and time-synchronized information accessible through a single clinician portal, facilitating effective patient monitoring and engagement. Medication adjustments are made monthly, guided by assessments of fat versus muscle loss ratio, weight fluctuations, and reported side effects. Regular measure of body composition analysis using (Seca mBCA 514, Seca GmbH & Co. KG) ensures a comprehensive understanding of each participant's progress, with evaluations conducted both at the program's onset and quarterly thereafter for comparison. The effectiveness of the Zone.Health's hybrid approach is supported by previous research, particularly in diabetes management, demonstrating its potential to revolutionize weight loss strategies and improve overall health outcomes [11,13,14].

Study Design

A retrospective, real world evidence observational study was conducted among participants with MetS that signed up to the Zone.Health weight loss program. A comprehensive examination of medical records was undertaken to explore the occurrence and factors contributing to MetS among patients who were prescribed GLP-1 medications. This study encompassed 51 adult patients from diverse ethnic backgrounds who had completed a 6-month program duration with all MetS parameters collected. Medication administration followed a thorough assessment, including a 15-day evaluation period and initial dietary analysis, to confirm participant eligibility. Treatment selection, whether semaglutide or tirezepatide, was determined by physicians based on clinical suitability. Following the standard practice, tirzepatide was started with an initial dose of 2.5 mg, gradually increasing to either 5.0 mg, 7.5 mg, or 10 mg by the 3-month mark and reaching 12.5 mg or 15 mg by 6 months. Semaglutide started at 0.25 mg, escalating to 1 mg at 3 months and reaching to 2.0 mg at 6 months (Figure 1). All participants adhered to the criteria, ensuring the continued validity of contractual agreements. The study strictly followed the ethical guidelines of the Declaration of Helsinki, ensuring each participant gave signed consent. The UAE health care authority monitored the clinical protocols, ensuring they met international ethical standards for research involving human subjects. All study procedures, including data collection and analysis, respected participant rights and privacy.

Figure 1. Tirzepatide and semaglutide dose titration throughout the Zone.Health program.

Study Outcomes

Primary Objective

Reduction in MetS markers (waist circumference [WC], triglycerides, and fasting glucose levels) among individuals with obesity over a 6-month period when treated with GLP-1 (semaglutide) and dual GIP/GLP-1 agonists (tirzepatide).

Secondary Objectives

First, changes in BP (systolic and diastolic) and lipid profiles (total cholesterol, low-density lipoprotein [LDL], and high-density lipoprotein [HDL]) in participants receiving tirzepatide versus those receiving semaglutide.

Second, association between levels of digital engagement with the health platform and improvements in MetS markers.

Criteria for Diagnosing MetS

International Diabetes Federation (IDF) definition of MetS was used accordingly to classify participants with MetS [15]. In this study, females and males were included in the study if they had the MetS if the following criteria were met.

First, waist circumference of ≥94 cm for males and ≥80 cm for females, based on ethnic-specific values, such as Europids, Sub-Saharan Africans, Ethnic South and Central Americans, and Middle Eastern individuals.

Second, any two of the following four factors: (1) raised triglycerides ≥150 mg/dL (1.7 mmol/L) or specific treatment

XSL•FO
RenderX

for this lipid abnormality; (2) reduced HDL cholesterol (males <40 mg/dL [1.03 mmol/L], females <50 mg/dL [1.29 mmol/L]), or specific treatment for this lipid abnormality; raised blood pressure (systolic BP ≥130 mm Hg or diastolic BP ≥85 mm Hg), or treatment for previously diagnosed hypertension; (4) raised fasting plasma glucose ≥100 mg/dL (5.6 mmol/L), or previously diagnosed type 2 diabetes.

Data Collection and Participants

Data were collected from physicians' patient records at baseline and at 6 months using the electronic medical record (Diamond, Hicom). Patients' gender, age, ethnicity, medication, WC (cm), weight kg, BP (mm Hg), and BMI (kg/m²) variables were collected. Laboratory variables were collected including total cholesterol (mg/dL), LDL cholesterol (mg/dL), HDL cholesterol (mg/dL), triglycerides (mg/dL), and fasting glucose (mg/dL). Engagement interactions were collected from the app portal. Inbound interactions refer to interactions or messages received from the participants related to dietary advice or modifications, medication dosage and side effects, coaching-related queries, and inquiries directed at any of the health care team. The outbound interactions refer to the interactions or messages initiated by the health care team to the participants, which consists of (1) biweekly reminders of food logging, weight recording, data integration, and monthly workout schedules (dietitians, coaches, and sport scientists); (2) biweekly physicians follow-up on the side effect of the medications; and (3) CGM data feedback provided by the diabetes educator.

Participant Inclusion Criteria

Eligible participants were adults (aged 18 years and older) diagnosed with MetS and obesity, who met the IDF criteria for MetS, which includes central obesity (WC specific to population and gender) plus at least 2 of the following: raised triglycerides, reduced HDL cholesterol, raised BP, or raised fasting plasma glucose. Participants had been prescribed GLP-1 or GIP/GLP-1 therapies as part of their treatment regimen. Individuals with incomplete records or those who did not engage with the digital platform were excluded from the analysis.

Ethical Considerations

Ethical approval was obtained from the Dubai Health Authority (DHA; DSREC-02/2025_09), and patient data were anonymized to maintain confidentiality. To protect participant privacy, all data collected were anonymized, and measures were taken to safeguard sensitive information, including data encryption and restricted access. It is important to note that no compensation was provided to participants for their involvement in this study.

Statistical Analysis

Data analysis performed using SPSS software version 29.0 (IBM Corp). Continuous data (such as age, weight, and laboratory parameters) were presented as means and SDs, and categorical variables (such as gender, medication type, Total n° of IDF criteria met, and ethnicity) were expressed as counts and percentage. The paired *t* test was used to compare variables at baseline and at 6 months and ANOVA test was used to see the baseline characteristics between female and male. One-way ANOVA test was conducted to test differences in baseline characteristics across medication types. ANOVA was also used to assess differences between app-based interaction groups and their impact on improvements in MetS markers. $P<.05$ was considered significant. Furthermore, post hoc Bonferroni test was conducted to measure the difference between app-based engagement groups.

Results

Basic Demographics and Baseline Characteristics Stratified by Sex (N=51)

The study population is almost evenly divided between individuals of Middle Eastern (23/51, 45%) and European (28/51, 55%) ethnicities (Table 1 and Table 2). Majority of participants are treated with tirzepatide (31/51, 61%) as opposed to semaglutide (20/51, 39%). In terms of the number of MetS parameters met, all patients met the IDF criteria with most participants (34/51, 67%) meeting 3 criteria, 27% (14/51) meeting 4, and a small group of 6% (3/51) meeting all 5 criteria. Differences between the tirzepatide and semaglutide groups are evident in several baseline characteristics. There is a significant difference in age, with the tirzepatide group being older ($P=.02$). Notable disparities also exist in weight and WC, with the tirzepatide group being significantly heavier ($P=.01$) and having a larger WC ($P=.002$). The tirzepatide group also has a higher BMI ($P=.02$). BP measurements between the groups are similar, without significant differences in either systolic or diastolic BP. Cholesterol profiles are comparable, with no significant differences in total cholesterol, LDL cholesterol, or HDL cholesterol levels. In addition, there are no significant differences in triglycerides or fasting glucose levels between the 2 groups.

[c]LDL: low-density lipoprotein.

[d]HDL: high-density lipoprotein.

Improvements of Diagnostic Criteria of MetS After 6 Months of Zone.Health Program

Table 3 illustrates significant improvements in the criteria used to diagnose MetS after a 6-month program, comparing the effects of tirzepatide and semaglutide (N=51). Tirzepatide showed greater reductions in WC (–18.08 cm) compared with semaglutide (−13.04 cm), both statistically significant (*P*<.001). Triglyceride levels decreased significantly with tirzepatide (−64.42 mg/dL) and even more with semaglutide (−70.70 mg/dL; *P*<.001). HDL cholesterol increases were modest and not statistically significant for both drugs. Significant reductions were observed in fasting glucose, systolic and diastolic BP, and LDL cholesterol, with tirzepatide generally showing more pronounced improvements than semaglutide. Overall cholesterol levels also decreased significantly in both treatment groups.

Treatment of Remaining MetS Markers in Patients With Increased WC (n=26)

In participants who did not reverse MetS due to persistently increased WC, improvements were observed with the remaining MetS markers. For instance, 85% (22/26) of participants successfully treated their elevated triglyceride levels to within normal ranges. HDL saw a significant improvement with 73% (19/26) of participants elevating their levels to the desired range. In addition, BP was stabilized in 89% (23/26) of these participants, and blood sugar levels were brought back to healthy levels in 96% (25/26) of those who did not treat MetS due to persistent increased WC.

Change in MetS Risk Factors by App-Based Interaction Groups

Table 4 and Table 5 presents the difference between patient engagement and improvements in MetS markers over a 6-month period among all participants. Engagement is quantified as both inbound and outbound interactions; inbound interactions (received from participants) average at 28.86 (SD 21.32), outbound (sent to participants from the health care team) at 58.57 (SD 25.26), and the total number of interactions at 84.00 (SD 45.76). Significant improvements were observed in several markers. WC, triglycerides, diastolic BP, and fasting glucose showed significant changes, with *P* values of .003, .01, .003, and .03, respectively. Changes in HDL and systolic BP were profound but not statistically significant. The post hoc analysis showed significant differences among interaction groups, indicating that higher app-based interactions are associated with better outcomes (Table 6). A significantly increased reduction in WC was found in individuals with ≥25 interactions (mean −19.04, SD 7.40) compared with individuals with ≤15 interactions (mean −9.60, SD 5.10 cm, *P*=.002). In addition, individuals with ≥25 interactions showed a significant reduction in triglycerides (mean −108.56, SD 77.06 mg/dL) compared with those with ≤15 interactions (mean −44.49, SD 50.85 mg/dL, *P*=.02) and a significant reduction when compared with those with 16 - 24 interactions (mean −55.77, SD 44.52 mg/dL, *P*=.03). Diastolic BP also significantly decreased in individuals with ≥25 interactions (mean −10.33, SD 7.40 mm Hg) compared with those with ≤15 interactions (mean −0.83, SD 7.83 mm Hg, *P*=.004). Fasting glucose levels were significantly lower in individuals with ≥25 interactions (mean −18.60, SD 10.82 mg/dL) compared with those with ≤15 interactions (mean −2.49, SD 27.54 mg/dL, *P*=.02).

[d]FG: fasting glucose.

Discussion

Principal Findings

This study examines the effect of GLP-1 and dual GIP/GLP-1 agonists when combined and integrated with a tech-enhanced, continuous feedback cycle on lifestyle modifications in treating MetS. MetS is intricately linked to central obesity and excessive weight, with studies illustrating that increased adiposity, particularly in the abdominal region, is a major risk factor for developing MetS [16]. Central obesity is associated with increased insulin resistance, which plays a pivotal role in the pathogenesis of MetS [16].

Studies have shown that even a modest amount of weight loss is associated with improvement in MetS parameters and related cardiovascular disease risk components. Losing weight is associated with a decrease in insulin resistance and insulin level, decreasing the risk of type 2 diabetes or improving previously diagnosed diabetes [17]. Losing weight also causes a positive impact on dyslipidemia by an increase in the HDL level and a drop in the LDL level [18,19]. GLP-1 and GIP agonist use has

XSL•FO
RenderX

been shown to reduce MetS severity, abdominal obesity, and inflammation [20].

Over a 6-month period, the comparative analysis of tirzepatide and semaglutide in the Zone.Health program showed significant improvements in MetS markers. Tirzepatide led to greater reductions in WC and LDL cholesterol, with slightly better results in fasting glucose and BP than semaglutide. While both treatments modestly increased HDL cholesterol without significance, semaglutide had a slightly better effect on lowering triglycerides. This suggests the treatment choice may vary based on individual patient needs and goals.

Despite significant improvements in WC observed in the study, it is noted that the rate of change might be perceived as low relative to other MetS markers. This could be attributed to several factors. First, central obesity, characterized by high WC, is often more stubborn and resistant to reduction through conventional weight loss measures alone [21]. This resistance could be partly due to the physiological characteristics of adipose tissue in the abdominal area, which is more metabolically active and sensitive to hormonal influences [21]. This may be attributed to the physiological characteristics of abdominal adipose tissue, which is highly metabolically active and hormonally sensitive, making it particularly challenging to reduce through pharmacotherapy and lifestyle changes alone. In addition, the IDF criteria consider an increased WC as a mandatory component for the diagnosis of MetS, which could preserve the perceived low reversal rate in study participants despite other significant improvements. The other MetS markers such as triglycerides, fasting glucose, and BP showed more substantial improvements even with persistent increased WC. These markers often respond more dynamically to metabolic improvements induced by GLP-1 agonists and lifestyle interventions. GLP-1 agonists improve insulin sensitivity and secretion, which directly impacts glucose control and lipid metabolism [18,19]. This improvement in insulin dynamics could explain the significant decrease in triglycerides and fasting glucose [22]. Similarly, the improvements in BP may be due to the weight loss itself as well as the improvement in arterial stiffness and endothelial function resulting from better metabolic control [23]. Furthermore, the baseline WC of our participants was significantly higher than the general thresholds for MetS, suggesting that longer-term or more intensive treatment strategies might be necessary to achieve meaningful reductions in WC. Challenges in reducing WC in this study align with findings from the Look AHEAD trial, where intensive lifestyle interventions resulted in significant weight loss but less pronounced reductions in WC [24]. This discrepancy highlights the complexity of central obesity as a metabolic entity and underscores the need for targeted strategies that specifically address this component of MetS.

Integrating Digital Solutions in Weight Loss Management and MetS Markers

The integration of hybrid care models in chronic disease management, such as diabetes mellitus, has shown promising results in reducing key metrics like HbA1c levels [11,13,14]. Our study also explores the perspective of people with MetS receiving treatment with medication such as semaglutide or tirzepatide along with feedback relating to their health in a real world environment. The long-term treatment of obesity, diabetes, and other chronic diseases requires that health care professionals shift away from episodic care and keep patients continuously engaged. The integration of digital tools as part of a standard care pathway allows health care practices to monitor and communicate with patients by observing personal data received from patients, whether it be activity, sleep habits, or information on dietary choices. Together, they are collectively able to take action regarding medication titration or a more consolidated plan during treatment [25]. The association between patient engagement and improvements in MetS markers, as presented in Table 3 of our study, further underscores the potential of digital health solutions in chronic disease management, particularly when combined with pharmacotherapy. Our findings indicate that higher engagement in inbound interactions is linked to better outcomes in key MetS parameters such as WC, triglycerides, and diastolic BP, and are supported by previous studies around engagement and outcomes in diabetes [13]. The significant reduction in these MetS markers with increased digital interaction suggests that patient engagement may be as critical as medication adherence in the management of MetS. This aligns with the broader trend in health care that emphasizes patient-centered models where ongoing patient engagement and personalized interaction play pivotal roles. The integration of digital tools facilitates this by providing continuous monitoring and real time feedback, which are essential for sustaining behavior changes over time. Furthermore, the Peterson Report emphasizes that purely digital solutions often fall short in achieving long-term patient engagement and effective disease management, citing a lack of personalization and direct human interaction as key shortcomings [26]. This finding supports the adoption of a hybrid care model, which combines the scalability of digital tools with the tailored support and expertise of the treating health care professionals.

To our knowledge, this study is the first to examine the effectiveness of GLP-1 medications alongside lifestyle interventions under a hybrid model of care in improving MetS markers. However, this study has a few limitations. First, the sample size, although adequate for detecting significant changes, is not large enough to ensure the generalizability of the findings across diverse populations or to detect more subtle effects. Second, the absence of a control group makes it difficult to definitively attribute the improvements in MetS markers to the interventions, as comparisons with a nonintervention baseline are lacking. In addition, Zone.Health is a paid program, and monetary investments into the program may have influenced participant outcomes, as those who have paid for the program might be more likely to participate actively and follow instructions. What can be concluded is that GLP outcomes on certain MetS parameters can be enhanced when delivered in a hybrid care model, as demonstrated in previous studies, thereby leading to better outcomes, an important factor considering the cost of GLP treatments.

Conclusions

In conclusion, this study highlights the effective role of combining GLP-1 and GIP/GLP-1 agonists with a continuous,

XSL•FO
RenderX

digitally delivered behavioral change model by an integrated care team in managing MetS, particularly in reducing WC, improving lipid profiles, and enhancing glycemic control across different genders. Despite notable improvements in most MetS markers, the persistence of increased WC suggests a need for strategies specifically targeted at abdominal obesity. Future research should focus on optimizing interventions that specifically address this resistant aspect of MetS, potentially incorporating new digital biomarker monitoring to enhance engagement even further due to the relationship between engagement and outcomes, as shown in this study.

Abstract

Background: Mobile health (mHealth) apps are increasingly used for health promotion, particularly for managing noncommunicable diseases (NCDs) through behavior modification. Understanding the factors associated with successful weight loss in such interventions can improve program effectiveness.

Objective: This study examined factors influencing weight change and the relationship between weight recording frequency and chat volume with health care professionals on weight loss in individuals with obesity and NCDs.

Methods: The participants had obesity (BMI ≥25 kg/m²) and were diagnosed with NCDs (eg, hypertension, diabetes, dyslipidemia). The program included 12 telephone consultations with health care professionals. Only participants who completed the full 6-month program, including all 12 telephone consultations, and provided an end-of-study weight were included in the analysis. The primary outcome was the rate of weight change, defined as the percentage change in weight from the initial period (first 14 days) to the final period (2 weeks before the last consultation), relative to the initial weight. The key independent variables were proportion of days with weight recording and chat communication volume (total messages exchanged). An interaction term between these variables was included to assess moderation effects in the regression analysis. The volume of communication was measured as the total number of messages exchanged, with each message, regardless of who sent it, being counted as 1 interaction. Health care staffs were instructed to send a single scheduled chat message per week following each biweekly phone consultation. These scheduled messages primarily included personalized feedback, reminders, and motivational support. In addition, providers responded to participant-initiated messages at any time during the program. Furthermore, 1 professional responded to each participant. Hierarchical multiple regression and simple slope analyses were conducted to identify relationships and interactions among these variables.

Results: The final analysis of this study included 2423 participants. Significant negative associations were found between the rate of weight change and baseline BMI (β=−.10; *P*<.001), proportion of days with weight recording (β=−.017; *P*<.001), and communication volume (β=−.193; *P*<.001). The interaction between proportion of days with weight recording and chat frequency also showed a significantly negative effect on weight change (β=−.01; *P*<.001). Simple slope analysis showed that when the proportion of days with weight recording was +1 SD above the mean, frequent chats were associated with greater weight reduction (slope=−0.60; *P*<.001), whereas no significant effect was observed at −1 SD (slope=−0.01; *P*=.94)

Conclusions: The findings suggest that both the proportion of days with weight recording and communication volume independently and interactively influence weight change in individuals with obesity and NCDs.

Introduction

Obesity is a major public health challenge and a well-established risk factor for noncommunicable diseases (NCDs), such as hypertension, diabetes, and dyslipidemia. Effective weight management is crucial not only for obesity prevention but also for reducing the risk of NCD-related complications. Obesity is recognized as one of the contributing factors to the onset of NCDs, such as ischemic heart disease, cerebrovascular disease, hypertension, and diabetes mellitus. It was found that 43% of individuals aged 18 years and older were overweight and 16% were living with obesity in 2022 over the world [1,2]. Several guidelines for primary and secondary prevention of NCDs recommend weight loss for managing risk factors derived from insulin resistance [3-6]. Interventions causing any weight loss significantly reduce systolic and diastolic blood pressure, low-density lipoprotein cholesterol, triglycerides, fasting plasma glucose, and HbA_{1c} in a period of over 6 - 12 months, and lasting benefits persist for at least 2 years [7]. Furthermore, other studies have shown that patients with diabetes who achieved ≥10% weight loss in the first year after diagnosis had a significantly higher likelihood of remission [8]. Thus, effective strategies for weight reduction are important for managing and preventing NCDs.

The use of mobile health (mHealth) apps is an emerging approach, which has been proven to promote weight loss through lifestyle modifications [9]. One of the key functions of mobile apps is daily lifestyle records and health status monitoring, which empower individuals to actively manage their health and enhance efficiency for health care providers [10]. These apps offer tools for self-monitoring, allowing users to record their weight, dietary intake, and physical activity. Study has confirmed the effectiveness of self-monitoring in promoting weight loss [11], with frequent weight recording being particularly associated with greater weight loss [12,13].

Recently, interactive approaches that include communication with health care professionals are considered highly effective in mHealth intervention [14,15]. These involve phone consultations, chat messaging, and personalized feedback, supporting swifter information exchange between the user and health care professionals. Studies have also shown that personalized advice and social support from health care professionals enhance adherence to weight loss programs and improve outcomes [14,15]. The success of these mHealth interventions is due to user engagement, specifically, the frequency of users recording their data in the app. High engagement rates are crucial for effective self-monitoring and allow health care professionals to provide relevant feedback.

Various opinions exist on what constitutes the most effective form of interactive support within these programs. Although some argue for the quality of interactions, such as the content and personalization of messages, others have focused on the importance of the quantity of interactions. Our review of the literature suggests that the volume of communication between users and health care professionals could be a critical factor in the effectiveness of weight loss interventions [16-20]. However, only limited evidence can confirm the interactive effect of adherence to self-monitoring and the quantity of app-based communication volume on achieving weight reduction.

Therefore, this study aims to investigate the relation of weight recording frequency and app-based communication volume with weight reduction and determine their interactive effects on the participants of the app-based lifestyle modification.

Methods

Study Design and Setting

This retrospective observational study used data from PREVENT Inc., a company providing medical data analysis and mobile app-based lifestyle modification support programs for individuals with NCDs. PREVENT Inc. predicts the risk of the onset of cerebrovascular and cardiovascular diseases using health insurance claims and health checkup data. Furthermore, employees or their dependents who are at high risk of onset could be provided with an individualized support program by health care professionals.

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki, and was approved by the Research Ethics Committee of Nagoya University (approval 2022 - 0453). Participants agreed to a privacy policy at the start of the program, which stated that the data gathered in the app may be used for future study. All participants provided informed consent before participating in the study. No financial compensation was provided to participants, who were free to withdraw at any time. All data presented were anonymized, and there are no images in the paper or the Multimedia Appendix that could identify individual participants.

Study Population and Procedure

PREVENT, Inc provides a mobile app-based lifestyle modification support program called Mystar to individuals at a high risk of cerebrovascular and cardiovascular diseases with NCDs, commissioned by the health insurance association. The selection of the target population was performed objectively using health insurance claims and health checkup data provided by the health insurance association. The principal approach to participation in these targeted population programs was for the health insurance association or PREVENT, Inc to send an invitation to participate in the program, or for the health insurance association to contact the individual. This study analyzed data from individuals who participated in the program from December 2018 to November 2023.

Participants eligible for this study were required to meet specific inclusion criteria. These criteria included a diagnosis of hypertension, diabetes, or dyslipidemia, with participants either receiving medication or having a history of coronary artery disease or stroke. Furthermore, participants needed to be classified as having obesity, defined by a BMI of 25 kg/m^2 or higher. Only individuals who agreed to participate in the 6-month program and provided informed consent for the use of their data in study were included. Exclusion criteria were applied to ensure the integrity of the study. Participants who failed to complete the full 6-month program (dropouts) or whose BMI

XSL•FO
RenderX

was below 25 kg/m² at the time of enrollment were excluded. In addition, individuals with medical conditions that could interfere with participation, such as severe cardiac diseases (eg, arrhythmia or cardiomyopathy), end-stage kidney disease, or mental disorders, were not eligible. The study also excluded participants who were taking medications that might affect weight management interventions, such as cardiotonic agents, immunosuppressive drugs, or antipsychotics. Finally, participants deemed unsuitable for inclusion by the health insurance association were excluded based on predefined criteria.

Disease Management Program

The disease management program was implemented with the approval of the participants' attending physicians. The program's objective was to improve the management of certain conditions, such as hypertension, diabetes, and dyslipidemia, through lifestyle improvements, to prevent the onset of conditions, such as stroke and myocardial infarction. Participants were provided with a mobile app account, which allowed them to record their lifestyle habits and exchange chat messages with health care professionals assigned to them. The program lasted 6 months, during which the participants had 12 telephone consultations with health care professionals. Nurses, registered dietitians, physical therapists, and other health care professionals provided individual advice through phone calls and chats based on the participants' lifestyle and disease management conditions. During telephone consultations, the participants set behavioral goals for the next 2 weeks and worked on improving lifestyle habits, such as exercise and diet by recording self-monitoring of health behaviors. Using the chat feature, not only could the participants ask health care professionals questions anytime but health care professionals could also provide individual advice. Further details of the program are described in a previous study [21].

Measurement of the Study Outcome: Weight Change

This study's primary outcome was that the rate of weight loss because the rate of weight change has been shown to be important for health improvement in individuals with obesity in Japan [22]. The rate of weight loss was calculated as the percentage change in weight over the program duration. Specifically, it was determined by dividing the difference between the initial average weight (recorded during the first 14 days of the program) and the final average weight (recorded during the 2 weeks before the last consultation) by the initial average weight, and then multiplying by 100 to express it as a percentage. This approach ensures that weight change is represented as a proportion of the initial weight, rather than just an absolute difference.

Proportion of Days With Weight Recording

Weight recording was measured as the proportion of days during the program on which participants recorded their weight at least once. If a participant recorded their weight more than once on a single day, only the first entry was used to calculate daily adherence. Units are reported as the percentage of days with weight recording relative to the total number of days in the program.

Communication Volume

Communication volume was assessed by counting the total number of chat messages exchanged between participants and health care staff throughout the program. Each chat message, whether initiated by the participants or health care staff, was considered as 1 interaction. In addition, 1 professional responded to each participant. The participants received advice from their assigned health care staff a week after each of the biweekly phone consultations, which was implemented over 6 months, totaling 12 sessions. Chat interactions included responses to participant inquiries, personalized feedback, and reminders for weight tracking when participants failed to log their weight. Health care professionals involved in these interactions included nurses, registered dietitians, and physical therapists, and messages were tailored based on participants' conditions and progress. Apart from these scheduled messages, the participants and health care professionals could freely engage in chat exchanges at any time during the program. In these chat communications, the health care staff provided feedback, lifestyle modification guidance, and information that encouraged continued healthy behaviors based on the participants' self-monitoring of health behaviors data. The participants could report the details of their daily activities and ask the health care staff about any questions or concerns. Each chat message, whether initiated by the participants or health care staff, was considered as 1 interaction.

Other Variables

We collected comprehensive demographic data (eg, age, gender, height, weight, and BMI), medical information, self-monitoring of health behaviors data, and app usage statistics from the participants. In addition, medical history information was obtained from health insurance claims data before the program began. Demographic and medication data were collected at program enrollment, while self-monitoring and app usage data were recorded throughout the program.

Independent Variables

The key independent variables in this study were the proportion of days with weight recording and chat communication volume. In addition, age, gender, and BMI were included as independent variables to control for demographic and physiological factors. An interaction term between the proportion of days with weight recording and chat communication volume was introduced in Model 2 to examine their combined effect on weight change.

Statistical Analysis

To handle missing data, a listwise deletion method was used, ensuring that only complete cases were analyzed. Descriptive statistics were used to summarize the basic demographic and clinical characteristics of the study population, including age, gender, BMI, proportion of days with weight recording, and volume of communication with health care professionals. To assess potential selection bias, we compared baseline characteristics between participants who completed the program and those who were excluded due to missing data. Independent *t* tests were used for continuous variables, and χ^2 tests were applied for categorical variables. A hierarchical multiple regression analysis was performed to investigate the relation

XSL•FO
RenderX

between the dependent variable—the rate of weight change—and various independent variables. Model 1 included age, gender, BMI, proportion of days with weight recording, and communication volume as the independent variables. Model 2 expanded upon Model 1 by introducing an interaction term between proportion of days with weight recording and chat count to examine their combined effect on weight change. The fit of Models 1 and 2 was compared to assess the contribution of the interaction term in explaining the variability in weight change. Upon identifying a significant interaction effect, a simple slope analysis was performed to further investigate the nature of this interaction. The proportion of days with weight recording was categorized into 3 groups based on SD, which included values more than one SD above the mean (+1 SD group), the mean itself (mean group), and one SD below the mean (−1 SD group). All statistical analyses were performed using R (version 4.1.0; R Foundation for Statistical Computing).

Results

Baseline Characteristics of the Study Participants

A total of 3999 participants were assessed for eligibility, and 90 dropped out during the program. Thus, 3909 participants (97.7%) completed the 6-month programme. Of these, 1486 were excluded from the analysis due to missing data, including those who did not provide data at the end of the study. Consequently, the final analysis was restricted to 2423 participants who met the criteria for the complete-data analysis. Table 1 shows the characteristics of the 2423 participants included in this study. Baseline characteristics were compared between completers (n=2423) and excluded participants (n=1486). Participants with complete data were older, more likely to be male, and had a higher prevalence of hypertension, while excluded participants had a higher prevalence of diabetes mellitus (P<.01 for all). Participants with complete data also had lower BMI, lower HbA_{1c}, and greater app engagement (higher chat volume and proportion of days with weight recording; P<.01). Detailed results were provided in Multimedia Appendix 1.

Table . Participants' characteristics. Values are shown as mean (SD) for ordinal variables and counts (%) for categorical variables.

Participants' characteristics	Results (n=2423)
Age (years), mean (SD)	54.9 (6.8)
Gender, n (%)	
Men	2144 (88.5)
Women	279 (11.5)
NCDs[a]	
Hypertension, n (%)	1842 (76)
Diabetes mellitus, n (%)	1199 (49.5)
Dyslipidemia, n (%)	1510 (62.3)
Previous stroke, n (%)	79 (3.3)
Previous ischemic heart disease, n (%)	151 (6.2)
Condition at the start of the program, mean (SD)	
Body weight (kg)	83.4 (12.7)
BMI (kg/m^2)	29.2 (3.7)
Systolic blood pressure (mmHg)	130.9 (12.2)
Diastolic blood pressure (mmHg)	84.5 (9.4)
HbA_{1c} (%)	6.5 (1.1)
HDL[b] cholesterol (mg/dL)	51.5 (11.9)
LDL[c] cholesterol (mg/dL)	121.8 (30.3)
App-related factor, mean (SD)	
Chat volume (chats per week)	1.9 (1.8)
Proportion of days with weight recording (%)	78.6 (26.7)

[a]NCD: noncommunicable disease.

[b]HDL: high-density lipoprotein.

[c]LDL: low-density lipoprotein.

Factors Associated With the Rate of Weight Change

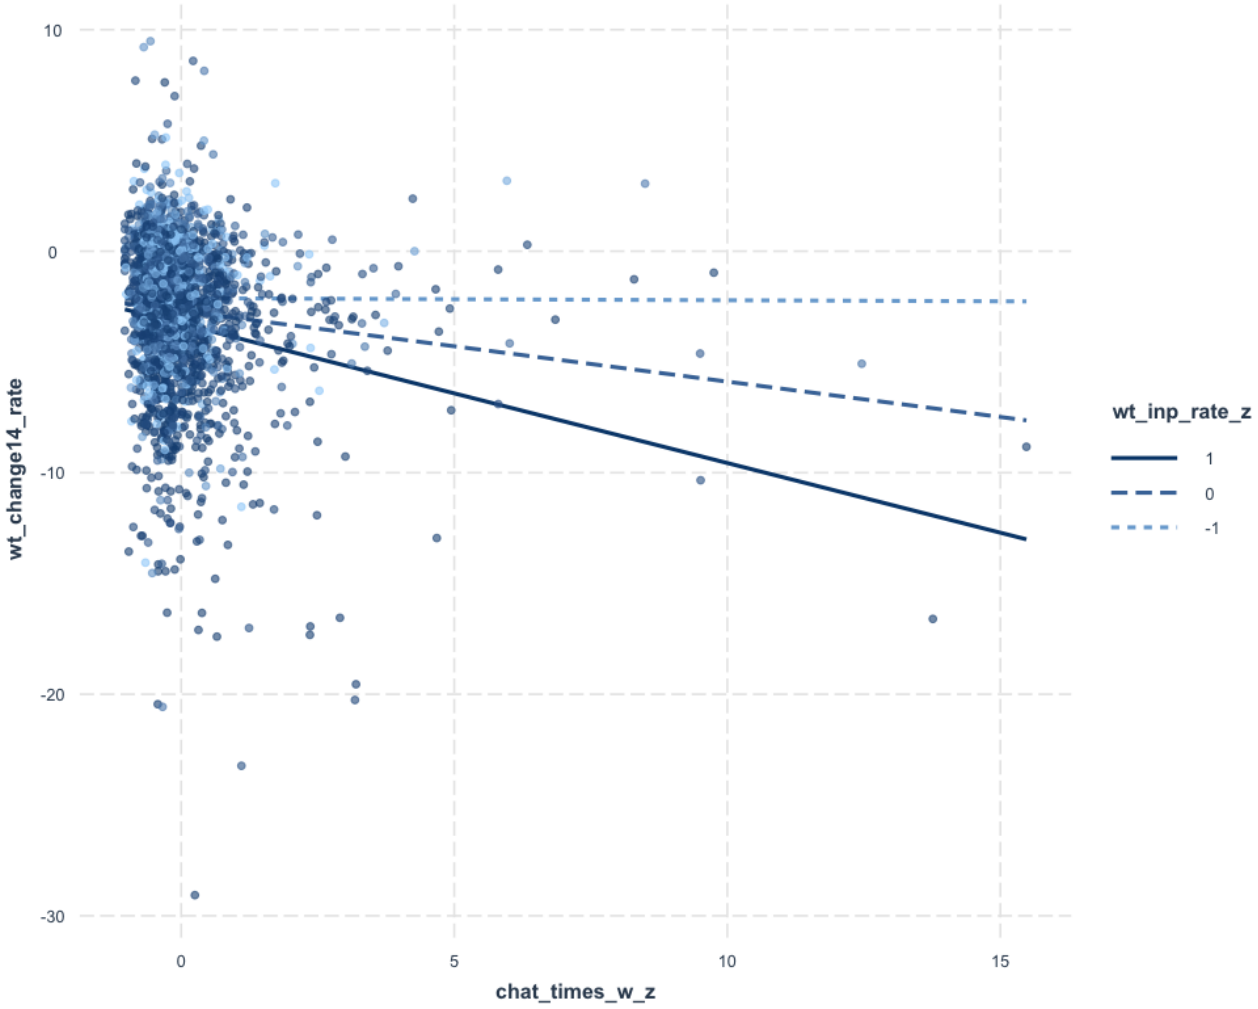
Hierarchical multiple regression analyses were conducted to determine the factors associated with the rate of weight change among the participants. In Model 1, the independent variables included age, gender, baseline BMI, proportion of days with weight recording, and communication volume. The analysis identified significant negative coefficients for baseline BMI (β=−.097; *P*<.001), proportion of days with weight recording(β=−.017; *P*<.001), and communication volume (β=−.193; *P*<.001). Model 2 extended Model 1 by incorporating an interaction term between proportion of days with weight recording and chat frequency, which assesses their combined effect on weight change. The results of Model 2 showed a significant negative interaction effect (β=−.006; *P*<.001), suggesting that higher proportion of days with weight recording combined with frequent chats substantially enhance weight loss. Furthermore, Models 1 and 2 have shown that the addition of the interaction term significantly enhanced model performance (Δ*F*=13.97; *P*<.001). Table 2 has more details.

Table . Results of hierarchical linear regression analysis for weight change.

	Model 1[a] (Adjusted R^2=0.06)		Model 2[b] (Adjusted R^2=0.06)	
	β	*P* value	β	*P* value
Age	.016	.07	.02	.06
Gender (reference: Men)	.398	.02	.39	.03
BMI	−.097	<.001	−.10	<.001
Proportion of days with weight recording	−.017	<.001	−.02	<.001
Volume of chat communication	−.193	<.001	−.15	<.001
Proportion of days with weight recording × volume of chat communication (interaction)	—[c]	—	−.01	<.001

[a]Model 1 includes age, gender, BMI, proportion of days with weight recording, and volume of chat communication as independent variables.

[b]Model 2 extends model 1 by adding an interaction term between proportion of days with weight recording and volume of chat communication.



[c]Not applicable.

Simple Slopes Analysis

When the proportion of days with weight recording is −1 SD below the mean, the slope of weekly chat times on weight change rate is −0.01; this result is not statistically significant (*P*=.94). When the proportion of days with weight recording is at the mean (0 SD), the slope of weekly chat times on weight change rate is −0.32; this result is significant (*P*<.001). When the proportion of days with weight recording is +1 SD above the mean, the slope of weekly chat times on weight change rate is −0.6; this result is significant (*P*<.001) (see Figure 1).

XSL•FO
RenderX

Figure 1. The figure illustrates the interaction between proportion of days with weight recording (wt_inp_rate_z) and communication volume (chat_times_w_z) on weight change rate (wt_change14_rate).

Discussion

Principal Findings

This study aims to determine the factors associated with weight change rates in mHealth and assess the interaction of proportion of days with weight recording and communication volume on weight change rates. As a result, the regression analysis indicated that chat communication volume had a stronger association with weight change rates compared with the proportion of days with weight recording. Furthermore, the higher chat communication volume was associated with greater weight reduction in the case of high proportion of days with weight recording, whereas it was not significant when the proportion of days with weight recording were low.

The primary findings of this study were that the volume of chat communication and proportion of days with weight recording were associated with the weight change rate and that a significant interactive effect on weight loss was observed during the lifestyle modification program. Chat messages included both generic reminders, such as prompts to log weight, and personalized feedback based on participant progress and health data, as reflected by the high proportion of days with weight recording and the regular chat-based communication (1.9 exchanges per week) throughout the program. These interactions, combining standardized guidance and tailored support, may have helped participants stay motivated and accountable. In this study, the average proportion of days with weight recording over 6 months was 78.6% (1902/2423), indicating a higher user engagement. The lifestyle modification program in this study required biweekly telephone consultations based on the lifestyle data including weight and provided personalized feedback. Furthermore, this interactive approach likely contributed to encouraging the participants' proportion of days with weight recording. Previous studies have reported on the relationship between each indicator, proportion of days with weight recording, and communication volume, as well as the achievement of weight loss [11,12,14,15]. Weight measurement has been considered as one of the key indicators reflecting the user's engagement, which is related to weight loss outcomes in a mobile app intervention [12]. A study suggested that regular self-weighing patterns, particularly high and consistent self-weighing, are associated with greater weight loss and maintenance, as well as better adherence to energy intake and step goals in a 12-month behavioral weight loss intervention [13]. Another study of physical activity promotion determining the effectiveness of behavior modification support through gamified mobile apps has found that users with high engagement

XSL•FO
RenderX

showed greater improvements in physical activity [23]. However, it is still unclear how the interaction between the proportion of days with weight recording and the amount of communication affects weight loss due to lifestyle modifications. In this study, the interaction between the amount of communication and the effect of weight loss was higher when the proportion of days with weight recording was high, whereas no significant relation was observed between the amount of communication and the effect of weight loss when the proportion of days with weight recording was low. These findings suggest that frequent weight recording tends to increase the impact of communication with health care professionals, making personalized feedback more effective and contributing to greater weight loss.

Mainly 2 potential reasons could explain the findings of this study. First, a high proportion of days with weight recordings likely result in a richer and more continuous stream of data, allowing health care professionals to better understand the participants' condition and provide more tailored and precise advice. Conversely, a low proportion of days with weight recording tend to provide fragmented data, possibly resulting in more general feedback that may not be as effective. A systematic review by Berry et al [24] has reported that tailored advice in digital self-monitoring of physical activities and diet is an effective intervention for promoting weight loss in adults with obesity or overweight. Another study has reported that individualized text messages and treatment information provision tend to facilitate user behavioral change and the development of healthy behaviors [25]. The assumption from this study is that if health care providers can obtain large amounts of self-monitoring of health behaviors data from participants, it will be possible to provide highly personalized health plans and advice. This concept is in line with the studies reporting that lifestyle modification was promoted more by individualized feedback, reminders, and messages compared with standardized communication [26,27]. If only limited self-monitoring of health behaviors data were available, health care professionals would be unable to provide personalized advice, and the advice given would predominantly be general. Furthermore, a second possible explanation is the theory that frequent weight monitoring will foster the habit of self-monitoring, which will motivate participants to be more consistent in achieving their weight loss goals, thereby maximizing the effectiveness of communication with their instructors. A study by Conroy et al [28] investigated the relation between physical activity self-monitoring and weight loss and found that frequent self-monitoring led to increased physical activity and weight loss. Another study has found that users who stopped tracking their weight experienced weight gain and a decline in both their physical activity and activity tracking frequency [29]. These results suggest the association between weight monitoring and the motivation to achieve lifestyle modifications. Furthermore, patient–provider communication has been reported to affect adherence through trust and motivation [30]. This heightened motivation enhances the impact of communication with health care professionals as participants are more likely to heed the advice seriously and act upon it.

The findings emphasize the critical role of self-monitoring in the context of mHealth interventions. As digital health technologies become increasingly integrated into daily life, understanding the mechanisms and effects of self-monitoring on behavioral change is important. Self-monitoring is acknowledged as a cornerstone of behavioral change including lifestyle modification [31], involves individuals in self-care management, and enhances self-feedback through learning the link between daily lifestyle changes and health outcomes. The effectiveness of weight and lifestyle monitoring for weight reduction has been widely accepted even before the development of mHealth [24]. This study on mHealth intervention has confirmed the potential role of self-monitoring in the relation between mobile app-based communication and lifestyle modification, emphasizing the unique role of self-monitoring in the mHealth era. Thus, lifestyle monitoring using mobile apps may facilitate the positive cycle of behaviors and outcomes caused by personalized communication, which is a determinant of the effectiveness of lifestyle modifications in mHealth [24,32]. However, the high proportion of days with weight recording in this study may indicate the high readiness of the users for the program or their intrinsic motivation for lifestyle modification. Furthermore, the potential burden on the participants to consistently record their weight in daily living should also be considered to monitor long-term adherence. Therefore, further study is needed to investigate the causal relation between self-monitoring passively promoted by mHealth intervention, improved health care communication with health professionals, and subsequent behavioral change. In addition, future study should explore how chat interactions influence participant retention, particularly among those who do not experience early weight loss. Understanding whether chat engagement can help maintain motivation in these individuals could provide further findings for optimising mHealth interventions for long-term adherence.

Limitations

This study performed a retrospective analysis targeting participants in health programs provided by health insurance unions. Consequently, the participants were predominantly those who voluntarily joined the programs, the majority being males. This demographic imbalance may limit the generalizability of the findings. Future study should investigate whether similar trends are observed in more diverse populations, including elderly individuals and females. In addition, our analysis was conducted using a completers-only approach, meaning that participants who dropped out before completing the program were not included in the final analysis. Since previous study has shown that individuals who drop out of weight loss interventions tend to have poorer outcomes, our findings may not fully reflect the weight loss trajectories of all participants [33]. In fact, baseline characteristics differed significantly between participants with complete data and those with missing data. These differences suggest that participants with complete data may have been more intrinsically motivated or in better health, potentially influencing weight loss outcomes. Furthermore, this study measured the communication volume solely based on the number of chat messages sent and received, without considering the length or content of the messages. While

XSL•FO
RenderX

message frequency is a useful measure of engagement, we did not differentiate between participant-generated and provider-generated messages. Participant messages may indicate engagement and self-motivation, while provider messages likely focus on feedback and support. This lack of differentiation limits the ability to fully interpret the specific roles and contributions of each message type in the observed outcomes. Additional factors such as the duration of interactions, the frequency of health-related queries, and the number of proactive messages sent can provide further context into how communication affects weight loss outcomes. This limitation may affect the accuracy of assessing the impact of communication on weight change rate. Thus, future studies should develop and use more comprehensive methods for evaluating communication, including qualitative assessments of message content and context. Furthermore, determining the effectiveness of different communication strategies, such as personalized feedback and motivational interviewing techniques, could provide insights into optimizing engagement and outcomes. Another limitation is that the proportion of days with weight recording in this study was calculated as the proportion of days on which participants recorded their weight over the entire 6-month period. While this measure provides an overall indicator of engagement, it does not capture temporal variations in engagement patterns, such as whether participants maintained consistent recording behavior throughout the intervention or showed high initial engagement followed by decline. This distinction is important because sustained engagement is often a critical factor for achieving successful behavior modification in mHealth interventions. Future study should explore longitudinal patterns of weight recording behavior to provide a more nuanced understanding of compliance and engagement trends in mHealth-based weight management programs.

Conclusions

The results of this study have revealed an association between weight change rate and the interaction of proportion of days with weight recording and communication volume between health care staff and participants in a lifestyle modification program. When the proportion of days with weight recording was high, the relation between communication volume and weight change rate was strong. Conversely, when the proportion of days with weight recording was low, the relation between communication volume and weight change rate was weak. These findings suggested that the acquisition of self-monitoring of health behaviors and lifelog data was crucial for maximizing the effectiveness of the health care professional's support. Furthermore, these insights would be beneficial in the development and process management of lifestyle modification programs using mHealth.

Acknowledgments

The authors thank the participants of the mobile app-based program for their contributions. Special thanks to the study team at PREVENT Inc. for their support in data collection and management. This work was supported by JSPS KAKENHI (grant 23K16769) and the Taiju Life Social Welfare Foundation.

Data Availability

The data that support the findings of this study are available from the corresponding author upon reasonable request.

Authors' Contributions

YH conceptualized the study, supervised data analysis, and drafted the manuscript. KS performed statistical analysis and contributed to manuscript preparation. SI performed statistical analysis and contributed to manuscript preparation. TA provided expertise on study design and critically revised the manuscript. MK assisted in data collection, manuscript writing, and revisions. TM provided oversight on methodology and reviewed the final manuscript.

Conflicts of Interest

This study was conducted as part of PREVENT, Inc's internal research activities. No external funding was received for this work. PREVENT, Inc provided access to anonymized program data and other necessary resources for the research. The company had no influence on the study design, data analysis, interpretation of findings, or the preparation of the manuscript, which were conducted independently by the authors.

Abstract

Background: The global targets for HIV testing for achieving the Joint United Nations Programme on HIV/AIDS (UNAIDS) 95-95-95 targets are still short. Identifying gaps and opportunities for HIV testing uptake is crucial in fast-tracking the second (initiate people living with HIV on antiretroviral therapy) and third (viral suppression) UNAIDS goals. Machine learning and health technologies can precisely predict high-risk individuals and facilitate more effective and efficient HIV testing methods. Despite this advancement, there exists a research gap regarding the extent to which such technologies are integrated into HIV testing strategies worldwide.

Objective: The study aimed to examine the characteristics, citation patterns, and contents of published studies applying machine learning and emerging health technologies in HIV testing from 2000 to 2024.

Methods: This bibliometric analysis identified relevant studies using machine learning and emerging health technologies in HIV testing from the Web of Science database using synonymous keywords. The Bibliometrix R package was used to analyze the characteristics, citation patterns, and contents of 266 articles. The VOSviewer software was used to conduct network visualization. The analysis focused on the yearly growth rate, citation analysis, keywords, institutions, countries, authorship, and collaboration patterns. Key themes and topics were driven by the authors' most frequent keywords, which aided the content analysis.

Results: The analysis revealed a scientific annual growth rate of 15.68%, with an international coauthorship of 8.22% and an average citation count of 17.47 per document. The most relevant sources were from high-impact journals such as the *Journal of Internet Medicine Research*, *JMIR mHealth and uHealth*, *JMIR Research Protocols*, *mHealth*, *AIDS Care-Psychological and Socio-Medical Aspects of AI*, and *BMC Public Health*, and *PLOS One*. The United States of America, China, South Africa, the United Kingdom, and Australia produced the highest number of contributions. Collaboration analysis showed significant networks among universities in high-income countries, including the University of North Carolina, Emory University, the University of Michigan, San Diego State University, the University of Pennsylvania, and the London School of Hygiene and Tropical Medicine. The discrepancy highlights missed opportunities in strategic partnerships between high-income and low-income countries. The results further demonstrate that machine learning and health technologies enhance the effective and efficient implementation of innovative HIV testing methods, including HIV self-testing among priority populations.

Conclusions: This study identifies trends and hotspots of machine learning and health technology research in relation to HIV testing across various countries, institutions, journals, and authors. The trends are higher in high-income countries with a greater focus on technology applications for HIV self-testing among young people and priority populations. These insights will inform future researchers about the dynamics of research outputs and help them make scholarly decisions to address research gaps in this field.

Introduction

HIV remains a global public health burden, affecting more than 39 million people living with HIV, with approximately 60% of people living with HIV living in sub-Saharan Africa (SSA) [1,2]. HIV/AIDS has claimed 42.3 million lives since the beginning of the epidemic and 630,000 lives in 2023 alone [1]. In addition, the continuous transmission and heightened rates of new HIV infections across different countries remain a significant concern [1,2]. There have been ongoing efforts to curb HIV as a public health threat, among which is the Joint United Nations Programme on HIV/AIDS (UNAIDS) goal of ending AIDS by 2030 [3]. UNAIDS and the World Health Organization (WHO) highlight the significance of prioritizing HIV testing for the realization of this goal [3,4]. Getting tested is the only way to identify people living with HIV for early initiation of antiretroviral therapy to reduce HIV transmission rates [3,4].

Current trends indicate a significant gap in the uptake of HIV testing globally, as only 86% of people living with HIV knew their HIV status by the end of 2023 [2]. This leaves approximately 5.4 million people living with HIV untested, which falls short of the UNAIDS interim target of testing 95% of people living with HIV by 2025 [2,3]. Conventional HIV testing and prevention programs have shown progress, but they fail to address stigma and social discrimination among key populations (KPs) [2-5]. Due to this challenge, HIV testing rates remain low among KPs, who bear the highest burden of HIV incidence [2,5]. In response to this issue, the WHO released updated comprehensive guidelines in 2016 to improve HIV testing coverage while using new strategies, including HIV self-testing (HIVST) [5]. The guidelines are continuously updated to integrate emerging technologies, providing more convenient options for HIV testing and helping to fast-track the UNAIDS 2030 goal.

The emergence of technology-driven health care interventions in recent years has resulted in remarkable advancements, especially in the realm of HIV testing [6]. Among these innovations, machine learning emerged as a noteworthy tool for enhancing the efficacy, accuracy, and accessibility of HIV testing services [7-10]. Machine learning involves the use and development of computer systems that can learn and adapt without explicit instructions by using algorithms to analyze and draw conclusions from data patterns [10].

Machine learning can improve HIV testing in a variety of ways. This methodology accurately predicts latent factors influencing HIV testing by analyzing complex data that could not be explored by the common approaches. Precisely, machine learning identifies individuals at the highest risk of HIV for tailored and cost-effective HIV testing programs to optimize resource allocation [7-11]. This is extremely beneficial, especially for low-income countries with limited resources to combat high HIV rates and other prevailing health issues. A study by Xu et al [11] confirmed that machine learning models such as logistic regression, support vector machines, random forest (RF), Extreme Gradient Boosting (XGBoost), elastic net, and k-nearest neighbor, among other algorithms, were reliable in predicting future HIV risk using complex datasets. Similarly, a retrospective analysis conducted in the United States [12] discovered that RF models seem promising for identifying important predictors of HIV testing uptake. The model's integration into future HIV prevention and treatment research, as well as intervention program evaluations, was highly encouraged [12]. Datasets from 4 SSA countries were analyzed by XGBoost, support vector machines, RF, elastic net, k-nearest neighbor, and light gradient boosting machine algorithms to accurately identify high-priority groups susceptible to HIV for enhancing targeted HIV testing [7].

Recently, more advanced machine learning technologies have emerged as a game changer for HIV testing concerns such as privacy and accessibility issues with high rates of false positivity/negativity. For instance, the integration of HIVST into machine learning, digital health, and mobile devices is gaining popularity, especially among KPs who usually avoid public services due to stigma [13]. Consistently, the WHO recommends HIVST as a convenient and discrete choice for HIV testing, citing its dependability and excellent performance as key factors for its success [5]. In 2017, van Heerden et al [14] installed artificial intelligence (AI) conversational agents into Android devices to facilitate HIVST and counseling. It was interesting to find out that the South Africans who participated in the study felt the device was more convenient for HIV counseling and testing than the usual procedure. Mobile health (mHealth), which involves using mobile devices to enhance health care services and research, has proven advantageous when incorporated with machine learning [15]. A machine learning mHealth technique was used to detect false-positive HIV test results in another South African study [15]. The technology demonstrated high levels of sensitivity (97.8%) and specificity (100%) compared to conventional visual interpretations of HIV rapid diagnostic tests [15]. Similar advancements were made by [16,17] with their HealthPulse AI technologies, which outperformed human interpretation of HIV test results and provided an opportunity to reduce mental health disturbances associated with false-positive test results.

Leveraging machine learning methods and health technologies can improve HIV testing outcomes by prioritizing high-risk individuals and enhancing the accuracy of HIV testing devices. Despite these advancements, a research gap remains regarding the integration of machine learning techniques into HIV testing interventions. This bibliometric analysis aims to address this gap by examining trends in published studies, journal performances, and collaboration networks among researchers, institutions, and countries regarding using machine learning and emerging health technologies in HIV testing from 2000 to 2024. By identifying key patterns and gaps, the findings will inform future research directions and support more effective

XSL•FO
RenderX

implementation of machine learning and emerging health technologies in HIV testing.

Methods

Study Approach and Search Strategy

This bibliometric analysis was conducted to understand trends, patterns, and collaboration networks in published studies focused on using machine learning and emerging health technologies in HIV testing from 2000 to 2024. A search string was developed using synonyms of "machine learning" OR "health technologies" and "HIV testing" with Medical Subject Headings (MeSH) terms in PubMed and published keywords from related studies. The articles used for this bibliometric analysis were gathered from the Web of Science (WoS) database. The WoS is one of the world's top databases for scientific research and citation data, encompassing a wide range of areas such as medicine and health care [18-20]. It has been recognized as a legitimate platform for bibliometric analysis [19-23].

The search query was entered into the WoS search box and filtered by topics, which captured a total of 708 articles at the initial search, and the article list was refined by the inclusion and exclusion criteria listed in Table 1. The study analyzed 266 articles that met the inclusion criteria.

Table . Inclusion and exclusion criteria.

	Inclusion criteria	Exclusion criteria
Document type	Original and review articles	Proceedings, early access, letters, meeting abstracts, letters, editorial materials, data papers, retracted materials, and corrections.
Years of publication	January 2000 to December 2024	Before January 2000
Language	English	Catalan, French, German, and Spanish
Context	Machine learning and emerging health technologies in HIV testing	Machine learning and emerging health technologies in pre-exposure prophylaxis, antiretroviral therapy, postexposure prophylaxis, voluntary medical male circumcision, HIV education, and unrelated topics.
Research area	Human medicines and health care–related subjects	Religion, government law, history, philosophy of science, arts, humanities, and other topics

The search string that was used to retrieve studies that used machine learning and emerging health technologies in HIV testing from the WoS is detailed here:

("HIV testing" OR "AIDS Testing" OR "HIV Diagnosis" OR "Rapid HIV testing" OR "HIV Self-Testing" OR "HIV Screening" OR "Human Immunodeficiency Virus Testing" OR "HIV counsel$ing and testing")

AND

("Machine Learning" OR "Artificial Intelligence" OR "Unsupervised Learning" OR "Supervised Learning" OR "Model* Algorithm*" OR "Deep Learning" OR "Neural Network*" OR "Support Vector Machine*" OR "Random Forest" OR "Decision Tree*" OR "Convolutional Neural Networks" OR "Recurrent Neural Networks" OR "artificial neural networks" OR "LASSO" OR "XGBoost" OR "ensemble learning" OR "reinforce* learning" OR "Naive Bayes*" OR "AI chatbot" OR "Large language model*" OR "principal component analysis" OR "natural language processing" OR "Health technology" OR "health informatics" OR "Bayesian network*" OR "mHealth" OR "Digital Health" OR "eHealth" OR "Video gam*" OR "Telehealth" OR "Telemedicine" OR "mobile app*")

Inclusion and Exclusion Criteria

The inclusion and exclusion criteria outlined in Table 1 were carefully selected to ensure a relevant and comprehensive dataset. Studies were considered for this bibliometric analysis if they applied machine learning and health technologies in HIV testing, diagnosis, or predictive models. Articles that used machine learning and emerging health technologies in other HIV interventions, such as treatment and education programs, were excluded. Moreover, the analysis focused on original and published studies between January 2000 and December 2024. The criteria used in this study were to align the focus of this analysis with the study objective.

Data Processing and Analysis

Data Cleaning and Screening

The bibliographic data were initially cleaned to remove duplicates and exclude studies that fell outside the scope of this study (refer to Table 1). Filters on the WoS database were used to remove articles published before 2000, studies conducted in languages other than English, and studies that were not original or reviewed. Of the 356 articles, 342 remained in the sample and were exported into the Covidence web software for screening. The Covidence software automatically removed 5 duplicates, and 2 independent reviewers (MJ and EP) conducted a comprehensive screening to retain eligible articles in the sample. Articles were screened by title and abstract, and 56 ineligible articles were removed. The full text of the remaining articles was also screened; of these, 266 were selected for the final sample for analysis. The two reviewers independently screened the articles at each stage and resolved disagreements through consensus. The screening process is presented in the Results section.

XSL•FO
RenderX

Data Analysis

This bibliometric analysis was performed using the Biliometrix R package (version 4.3.2; Posit Software, PBC) [24], while the VOSviewer software (version 1.6.20) was used for network visualization.

After the data were screened, cleaned, and refined according to the inclusion criteria, 266 references were exported from Covidence as CSV files and exported to Zotero (open-source bibliographic software developed by the global community) for conversion into retained and converted plain text (TXT) files, acceptable file format for the bibliometric software. Thereafter, the downloaded TXT file was uploaded into the Bibliometrix online software (Biblioshiny) [24], an R package (version 4.3.2; Posit Software, PBC). The cleaned bibliographic data was loaded into Biblioshiny to conduct performance analysis and science mapping, and VOSviewer aided in the network visualization.

Performance Analysis

Performance analysis examines the output and impact of research constituents by quantifying their citation and publication-related metrics [19,20]. It summarizes the characteristics of studies by assessing their productivity (number of publications), impact (citations), and contributors (authors, journals, countries, institutions, subject areas, etc) [19,20,25]. This study first provides a descriptive summary of the selected articles and then presents metrics such as the annual number of scientific productions, top-cited articles, and most productive authors, journals, affiliations, and countries in the field of machine learning in HIV testing.

Various metrics were used to measure the bibliographic sample's productivity, influence, and impact. For instance, h-index and m-index were used to evaluate the performance of influential authors and journals. According to previous studies [23,25,26], the h-index is referred to as the "highest number of h-index, such that the individual has published 'h' papers that each has been cited 'h' times." This means that if an author has published 20 articles and each is cited 12 times, the author's h-index is 12 [26]. The m-index is a variation of the h-index, showing the h-index per year since the author's first publication [23]. These two metrics are suitable for measuring the impact of authors and journals [23,26]; thus, they were calculated in this study using the Bibliometrix software. Additionally, the number of global citations for the articles was also used to examine their impact. We further assessed the performances of the authors' countries and affiliations using the frequency and number of publications on studies related to machine learning in HIV testing between 2000 and 2024.

Science Mapping

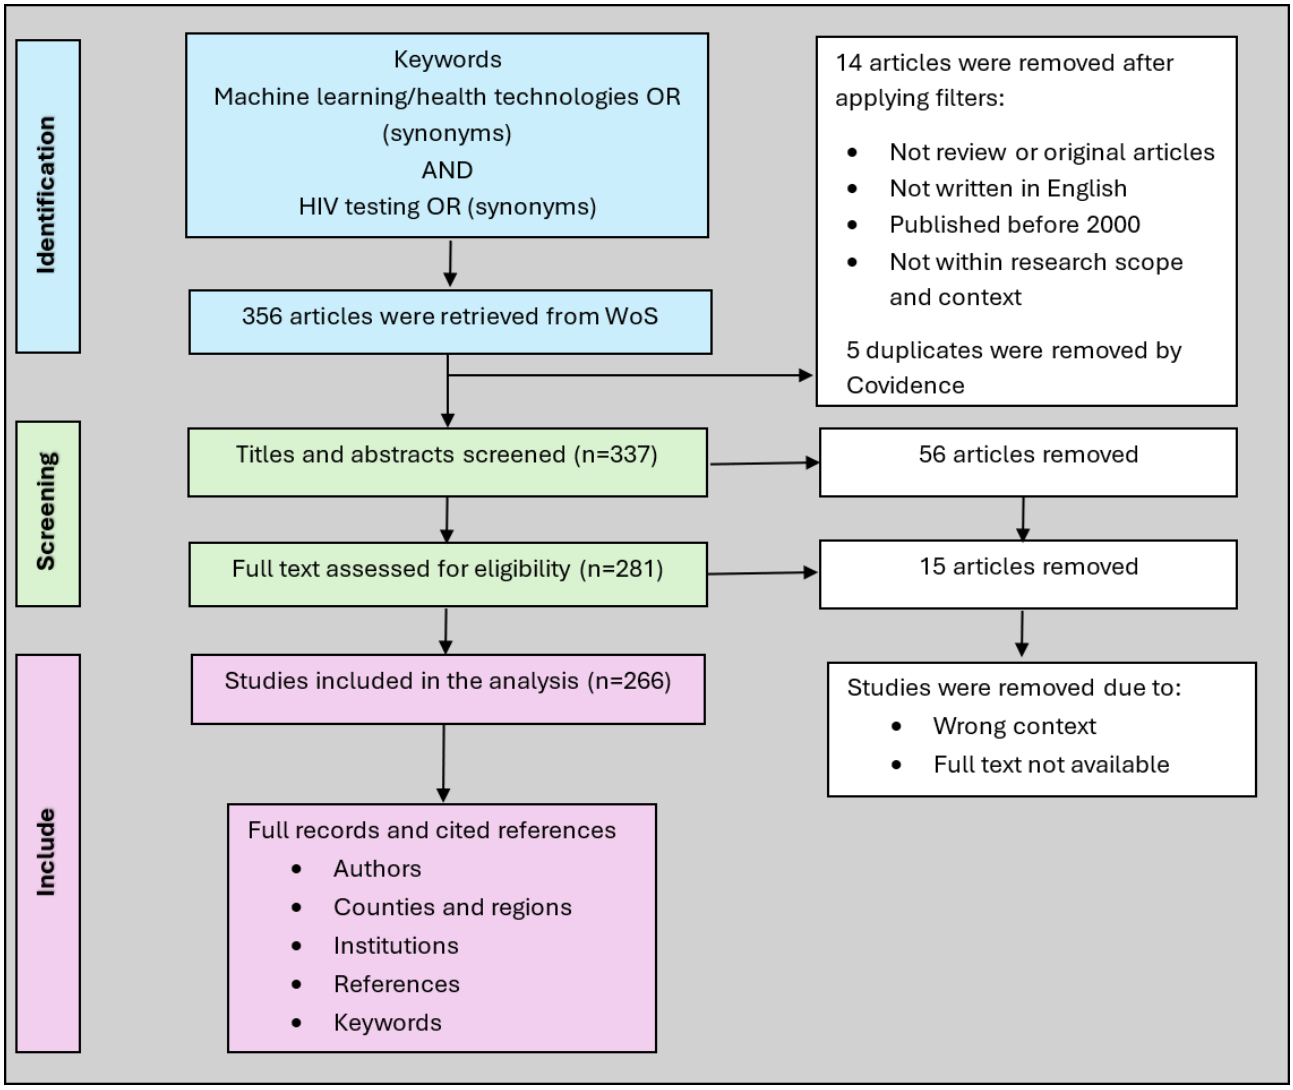
Science mapping, on the other hand, investigates the relationships between research constituents by analyzing the topic's conceptual, intellectual, and social structure [19,20]. We performed various analyses, including co-citation analysis of cited references, co-occurrence analysis of author keywords, and coauthorship analysis (international collaboration networks). These analyses explore the collaboration patterns between publications, citations, authors, institutions, and countries, as well as describe existing and future relations among topics [20]. These networks explain the research area's conceptual, intellectual, and social structures, forming the basis for developing key themes for this study. The VOSviewer software (version 1.6.20) provides a visualized and comprehensive understanding of the relationships between different networks within the dataset [20]. Normalization was applied at full counting for co-citation, co-occurrence, and international collaboration analyses. A maximum of 25 countries per document and a minimum of 5 documents per country were established as eligibility criteria, resulting in 53 eligible countries, of which 13 met the collaboration threshold. A total of 598 institutions appeared no more than 25 times in each document, with a minimum requirement of 10 documents per institution; ultimately, 16 institutions met this threshold. The minimum citation requirement for each cited reference was set at 15, and 11 of 8911 cited references satisfied this criterion. Additionally, with a minimum of 10 occurrences required per keyword, 19 of 700 keywords achieved the threshold for co-occurrence analysis. The research constituents, such as country, institution, keyword, author, and document source, were each represented by network nodes. The size of the nodes represents the occurrence frequencies, while the thickness of the links between the nodes determines the strength of the association between networks [23]. These analyses generated key concepts and thematic areas explored in the content analysis. Clustering was used to identify themes from author keywords and the names of the authors' institutions, as well as country names, within the same cluster in each network. The cluster size was set to 1 with a resolution of 1.00.

Content Analysis

The study explores the content of articles with the authors' most frequent keywords, which are also within the scope of the key themes generated by the keywords. The word cloud and co-occurrence analyses aided this process. By analyzing the authors' co-occurring keywords, we examined various clusters of relevant keywords that formed the basis of the content analysis. The content analysis aided in gaining deeper insights into the patterns and dynamics of the intersection between machine learning/health technologies and HIV testing, as well as suggested future directions from the identified gaps. A qualitative summary of the content analysis presented various topics, which can be found in the Results section.

Ethical Considerations

This study forms a part of a doctoral study by the first author (MJ) titled "Integration of machine learning algorithms to predict HIV testing associations using repeated cross-sectional survey data in an adult South African population: An HIV testing predictive model." The study was reviewed and approved by the University of Johannesburg (UJ) Research and Ethics Committee (REC; ethics approval number REC-2725 - 2024). Since no primary data were collected, the UJ REC gave a waiver for informed consent. Furthermore, the doctoral study falls under an umbrella project funded by the South African Medical Research Council (SAMRC) under the SAMRC/UJ Pan African Centre for Epidemics Research (PACER) Extramural Unit, titled "Harnessing big heterogeneous data to evaluate the



XSL•FO
RenderX

potential impact on HIV responses among the key populations in generalized epidemic settings in Sub-Saharan Africa" (ethics approval number REC-1504 - 2022).

Results

This study analyzed 266 articles following a comprehensive screening as shown in Figure 1.

Figure 1. Flowchart showing the search strategy and bibliometric analysis process. WoS: Web of Science.

Performance Analysis: Characteristics of the Study Sample

Table 2 summarizes the main characteristics of the articles included in this bibliometric analysis. The analyzed bibliographic dataset comprised 266 articles from 96 sources with 1658 authors and 8918 references. Most (91%) of the documents were original articles, while 9% were review articles. The results show a steady increase in the scientific production of studies using machine learning and emerging health technologies in HIV testing between 2000 and 2024, with an annual growth rate of 15.68%.

The output in Table 3 presents the top 10 most productive and influential journals that publish studies focused on machine learning and emerging health technologies in HIV testing–related topics. Among them, *AIDS and Behavior* ranked at the top of the list, marked by the highest h-index (10), number of citations (494), and number of publications (19). Other sources that are very productive and influential in this research area are *Journal of Medical Internet Research* (h-index=10), *JMIR mHealth and uHealth* (h-index=9), *JMIR Research Protocols* (h-index=8), *mHealth* (h-index 8), *AIDS Care-Psychological and Socio-Medical Aspects of AI* (h-index=6), and *BMC Public Health* (h-index=6), *PLOS One* (h-index=6), *AIDS Education and Prevention* (h-index=5), and *JMIR Formative Research* (h-index=5).

Table . Top 10 most productive publication sources by h-index.

Source	H-index	M-index	Total citations	Number of publications	Year of first included study
AIDS and Behavior	10	0.909	494	19	2014
Journal of Medical Internet Research	10	0.909	372	14	2014
JMIR mHealth and uHealth	9	0.818	310	14	2014
JMIR Research Protocols	8	1.333	264	18	2019
mHealth	8	1.6	138	10	2020

JMIR Formative Research	5	1.25	51	12	2021

In Table 4, the top 10 most productive and influential authors were ranked by h-index, and their scores were based on studies related to machine learning and emerging health technologies in HIV testing. Stephenson has the highest h-index (10), followed by Bauermeister and Sullivan, who each scored 9. Additionally, Hightow-Weidman (h-index=8), Horvath (h-index=8), Bukusi (h-index=7), and Muessig (h-index=7) are also very influential in this field. Stephenson has a total of 421 citations with 16 publications of articles centered on machine learning (technology) in conjunction with HIV testing.

Table . Top 10 most productive and influential authors by h-index.

Author	H-index	M-index	Total citations	Number of publications	First publication year of an included study
Stephenson R	11	1	421	16	2014
Bauermeister JA	9	1.125	176	11	2017
Sullivan PS	9	0.818	406	16	2014

In terms of the most impactful and influential articles, Table 5 presents the top 10 papers that have applied machine learning and emerging health technologies in HIV testing–related studies across the globe. A study by Schnall et al [27] published in the *Journal of Medical Internet Research* was the most influential paper with 129 total citations, 11.73 citations per year, and 1.36 normalized total citations.

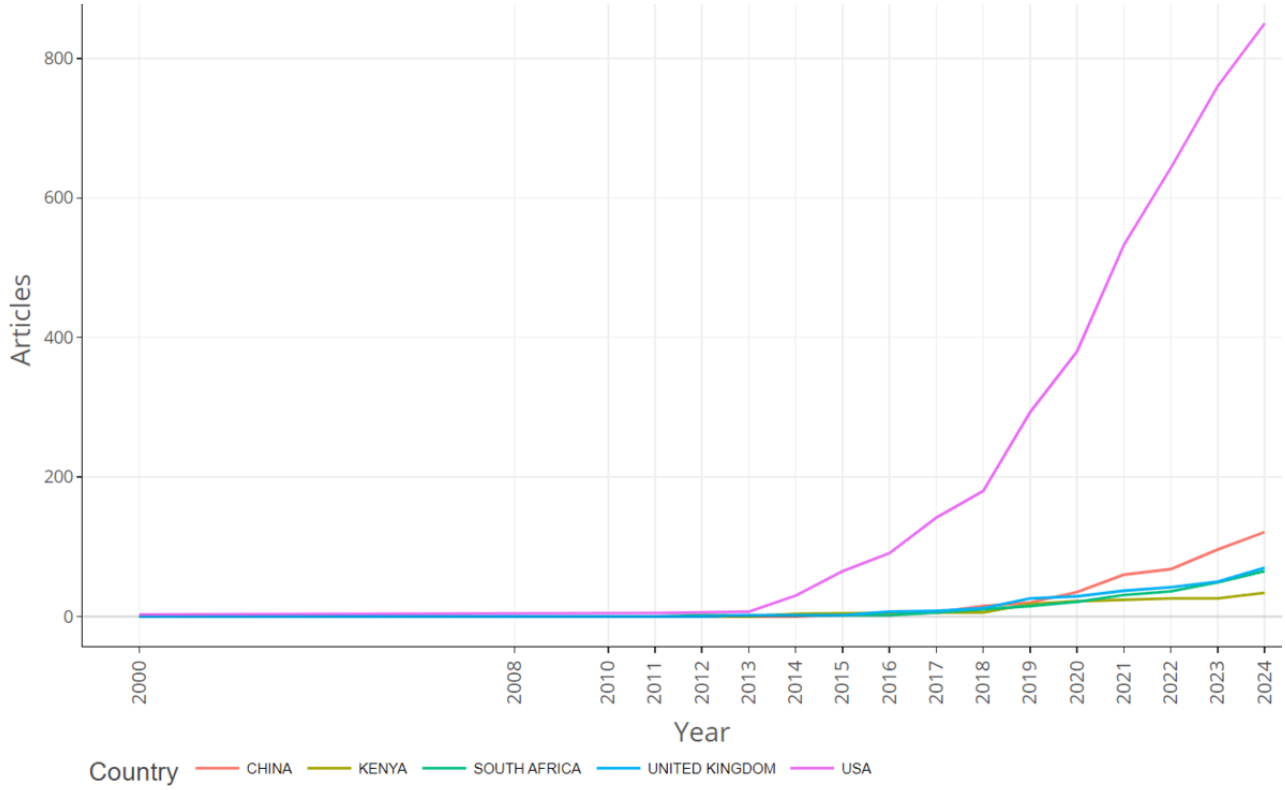
[a]TC: total citations.

This bibliometric analysis further examines the relevance of institutions and countries worldwide in terms of scientific productivity using publication metrics. Most of the articles included in this study were published by the University of California system (n=67), followed by the University of North Carolina (n=57), the University of North Carolina Chapel Hill (n=52), and the University of Washington (n=48; Table 6). Johns Hopkins University published the fewest studies among the top 10 institutions. As for countries' productivity, authors' correspondence information was used, with a total of 30 countries in the sample (Multimedia Appendix 1 ["Most Relevant Countries"] and Table 7). Of the 266 articles within the sample, the United States produced 59% (n=157) of the studies, ranking first (Table 7). There was a notable synchronicity between the United States and other countries regarding the frequency of publications of studies using machine learning in HIV testing from 2000 to 2024. After the United States, the next most publications were from China (n=27, 10.2%), South Africa (n=16, 6%), the United Kingdom (n=10, 3.8%), and Australia (n=7, 2.6%). The top 5 countries' scientific production in this field was relatively low before 2013 and steadily increased through 2024, as demonstrated in Figure 3. The United States outperformed all other countries, showing positive trends in the publications of studies on machine learning and health technologies in HIV testing from 2000 to 2024.

Table . Top 10 most relevant institutions by number of publications.



Institution	Articles, n (%)
University of California system	67

Science Mapping

International Collaboration Networks

Scientific collaborations between countries, institutions, and authors are shown at different levels. Figure 4 presents the most productive countries and their collaboration patterns when publishing studies focusing on machine learning in HIV testing. The country collaboration network shown in Figure 4 consisted of 13 productive countries, each with at least 5 documents. The network was divided into 6 clusters, wherein Canada, Rwanda, Switzerland, and Uganda are in cluster 1 (red). Cluster 2 (green) combines European and African countries such as Germany, the Netherlands, South Africa, and Tanzania. Australia, England, Nigeria, and China are in cluster 3 (blue), and Kenya, Peru, Thailand, and Zimbabwe are in cluster 4 (yellow). Cluster 5 (violet) comprises only European countries, including North Ireland, Norway, and Sweden. Cluster 6 (light blue) has 3 countries from different continents: Brazil, Malaysia, and the United States. The United States emerged as the most productive country, with a link strength of 118, and partnered with 100% of the countries, followed by England, which partnered with 77% of the 13 countries in the network. Australia and India have the lowest amount of country collaboration in studies applying machine learning and emerging health technologies in HIV testing (Figure 4).

XSL•FO
RenderX

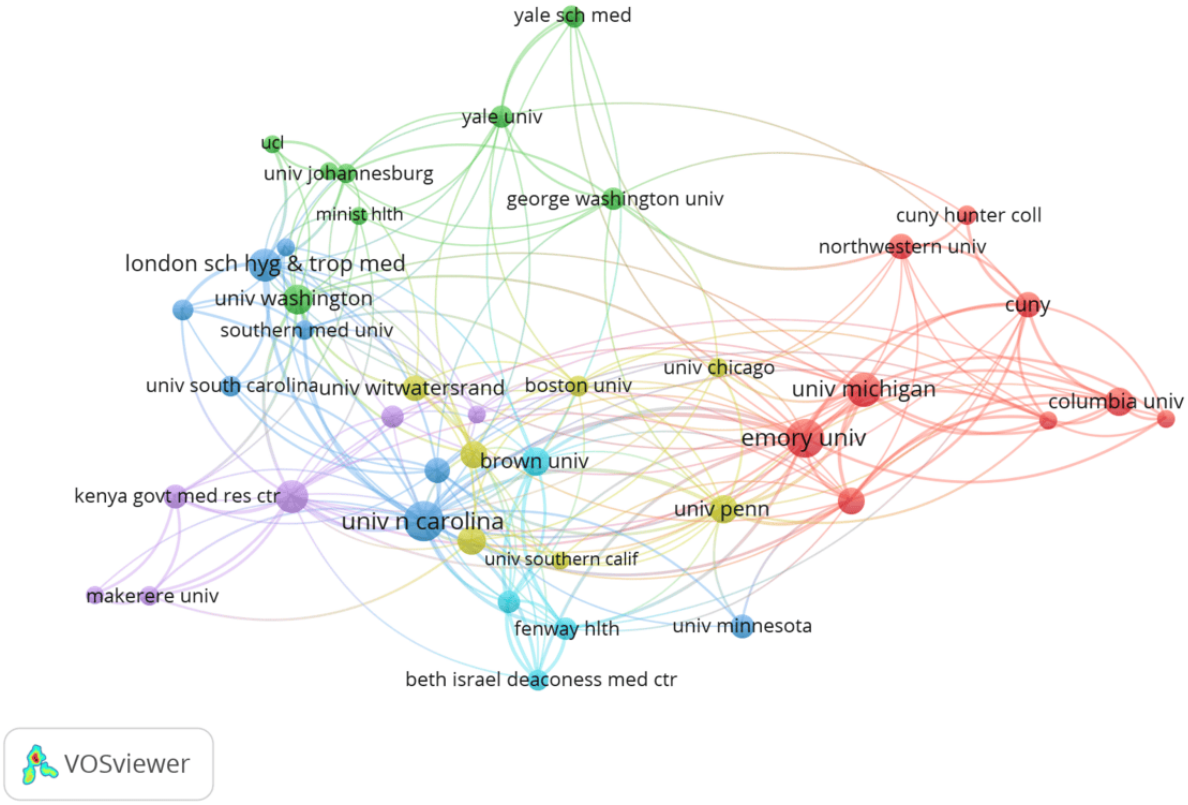

Figure 4. Country collaboration network. Peoples R China: People's Republic of China; USA: United States of America.

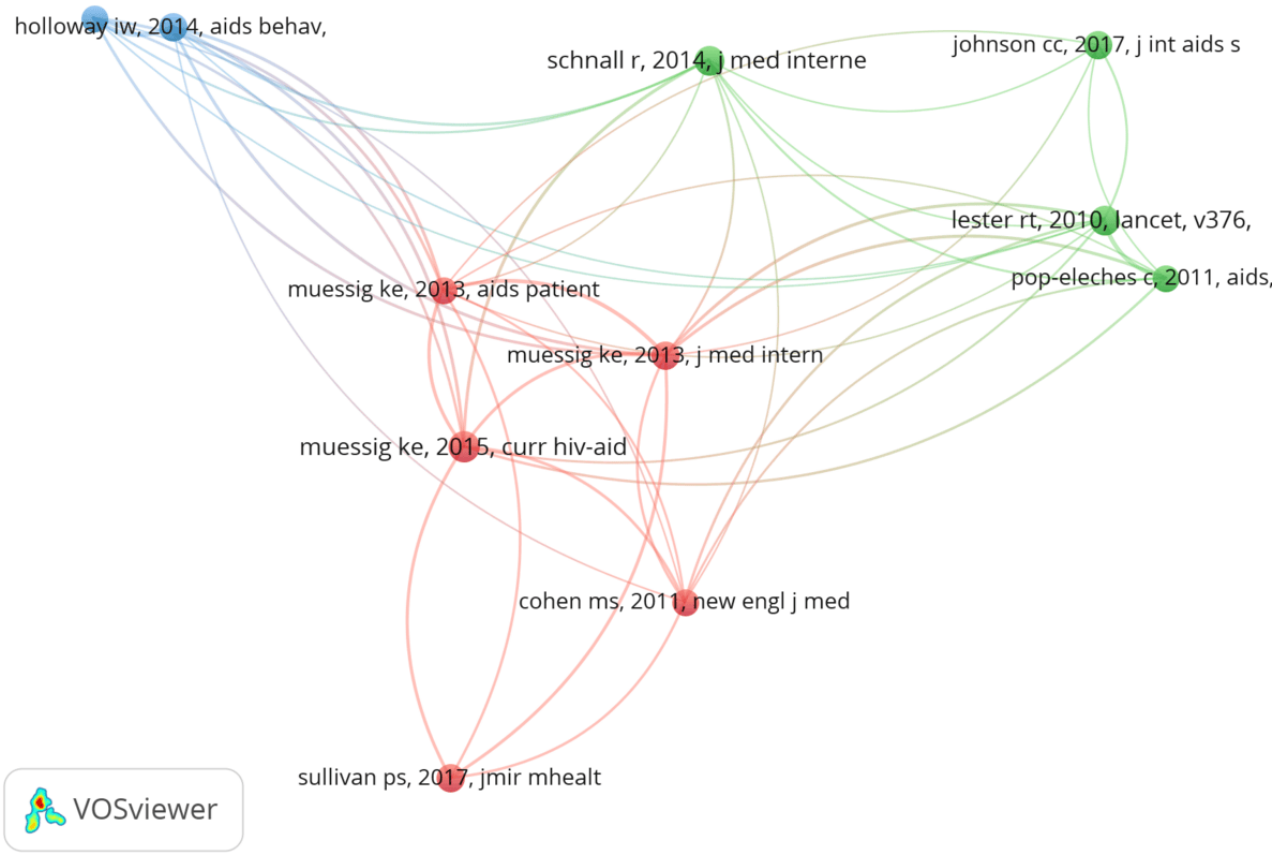
Regarding the institutional collaboration network, each institution was set to include at least 5 documents, resulting in 43 productive universities (Figure 5). The most productive universities are in the United States. In terms of link strengths, the University of North Carolina ranked the highest (n=77), with 922 citations, followed by Emory University (n=62), the University of Michigan (n=45), San Diego State University (n=41), and the University of Pennsylvania (n=38). The University of Witwatersrand in South Africa had the highest link strength (n=7) among the African universities, with 158 citations. Among the top 16 universities, the University of North Carolina, Emory University, the University of Pennsylvania, and the University of Michigan have each collaborated with >60% of the institutions within the network. The only African university with good performance is the University of Witwatersrand, exhibiting 19% coauthorship within the network of 43 best universities writing papers on machine learning and emerging health technologies in HIV testing.

XSL•FO
RenderX

Figure 5. Institutional collaboration network.

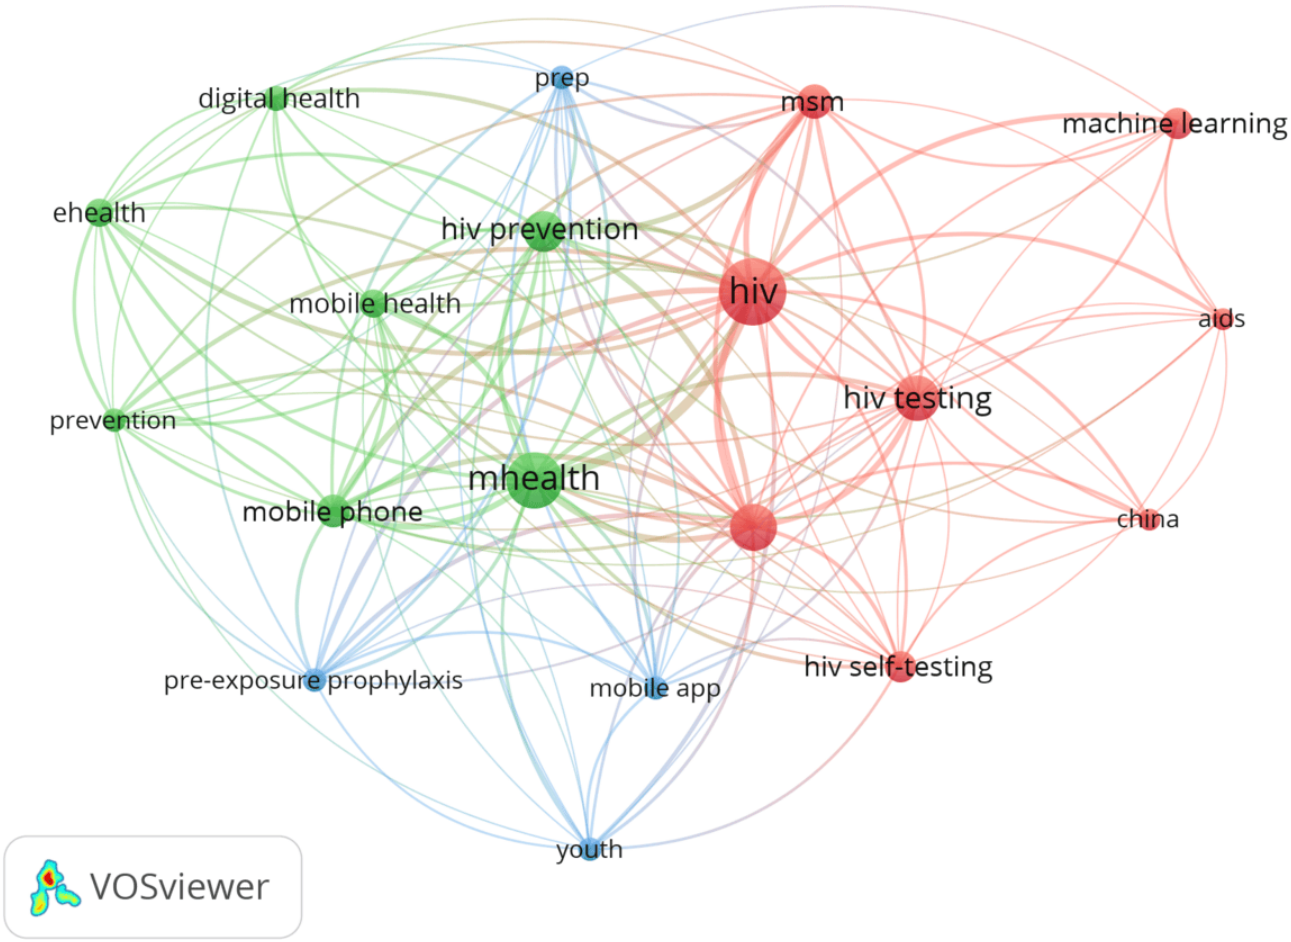


Co-Citation Analysis

A network of co-citation analysis in Figure 6 shows the relationship among cited publications within the research area. The network was set to include only articles with a minimum of 15 citations, in which 11 documents met the threshold. Each article within the network is represented by a node, and the links between the nodes indicate co-cited studies, wherein the studies' strengths and their co-citations are proportional to the nodes' sizes and links' thicknesses, respectively. The most cited document within the network was published by Muessig et al in 2015 [28] (25 citations), titled "A Systematic Review of Recent Smartphone, Internet, and Web 2.0 Interventions to Address the HIV Continuum of Care." The study synthesized evidence from observational and experimental studies focused on understanding the dynamics of technology toward the HIV care cascade, including HIV testing. Three thematic clusters were produced within the network map of co-cited references (Figure 6). Cluster 1 (red) relates to studies on applying machine learning (technology) in HIV prevention in the context of testing. Cluster 2 (green) is associated with studies using machine learning (technology) in HIVST, and the last (blue) cluster within the network focused on the application of mHealth to improve HIV testing among men who have sex with men (MSM). The most globally cited documents are summarized in Table 5 with their digital object identifiers (DOI).

XSL•FO
RenderX

Figure 6. Network of co-cited references.



Occurrence of Authors' Keywords

The analysis presents the most frequent keywords used by authors applying machine learning and emerging health technologies in HIV testing. The word cloud in Multimedia Appendix 2 shows the authors' 50 most frequent keywords in this research domain. The word's size in the cloud is proportional to the frequency at which it appears in the bibliographic sample. From the 50 frequently used keywords, HIV ranked the highest, with an occurrence of 93, followed by mHealth (n=65), MSM (n=46), HIV testing (n=41), HIV prevention (n=34), mobile phone (n=22), HIVST (n=21), and machine learning (n=20). These words established the thematic focus of the content analysis.

Figure 7 shows a network of co-occurrence of the authors' most frequent keywords, providing an understanding of their interrelatedness. Using a threshold of 10 for the number of keyword occurrences, a network of the 19 most relevant keywords highlights that HIV has the highest link strength (n=177), with 100% co-occurrence of the 19 keywords. The following keywords also exhibit high link strengths in co-occurrences: mHealth, HIV prevention, MSM, HIV testing, and machine learning. A total of 3 clusters consisting of words within closely related topics were derived from the 19 author keywords within the co-word analysis (Figure 7). Cluster 1 (red) is related to the use of machine learning in HIV testing among MSM, with HIV, AIDS, HIV testing, HIVST, and MSM being the top keywords. Cluster 2 (green) is associated with mHealth and HIV prevention–related topics, and the top keywords are mHealth, digital health, mobile health, and HIV prevention. Likewise, the third cluster (blue), which encompasses keywords such as mobile app, youth, and pre-exposure prophylaxis, also relates to digital health and HIV prevention interventions among youths.

XSL•FO
RenderX

Figure 7. Co-occurrence network.

Content Analysis

This bibliometric analysis explores studies that apply different machine learning techniques or technologies, including eHealth and mHealth, to improve HIV testing and provide insights into the research landscape. We reviewed the contents of 12 articles, with the most prominent authors' keywords presented in Figure 7. The content analysis qualitatively summarized the key findings of the reviewed studies, focusing on the main concepts and topics constructed by the word cloudand co-occurrences (Figure 7) of authors' keywords.

The Application of Technology in HIV Prevention Among Priority Populations

Priority populations consist of young people and the different categories of KPs who are highly susceptible to HIV [29]. Based on the themes generated in the bibliometric analysis, we focus mainly on young people and MSM as key drivers of HIV due to societal stigma and discrimination, lack of HIV knowledge, and engaging in risky behaviors [29]. On top of that, their HIV testing uptake remains low, increasing the spread of the virus and the number of people living with HIV with unknown status [29]. Priority populations' vulnerability to HIV makes them eligible for special interventions, and a variety of emerging technologies are being used to provide efficient and effective HIV prevention methods. We explored different studies addressing the gap within this thematic area. A machine learning technique predicted the internet health information–seeking behaviors of youths at risk of acquiring HIV by using their self-reported internet use data [30]. The study found that about 50% of the youths sought general health care information and sexual and reproductive health information, while 25% sought social services information [30]. In the same study, cisgender and transgender youths were less likely to seek health care information [30]. In another study conducted to predict HIV status among MSM in Zimbabwe, the authors applied different machine learning algorithms [31]. The findings showed that they could be used to enhance the early detection of HIV in order to establish targeted HIV testing for such hard-to-reach populations [31]. The two studies highlight the impact of societal stigma and that a lack of health care information impedes the success of HIV prevention and testing among young people and KPs and suggest the adoption of personalized HIV counseling and testing services [30,31]. Several machine learning and digital technologies, including those encompassed by eHealth and mHealth, have provided efficient HIV testing services by overcoming barriers related to privacy concerns among priority populations [32-37]. From identifying the most eligible candidates for HIV testing to enabling HIVST devices, these studies demonstrate how technology advancements have improved HIV prevention in the context of testing over the past 2 decades [32-37].

XSL•FO
RenderX

Enhancing HIV Self-Testing Using Machine Learning and mHealth Solutions

Self-testing enables people to test for HIV and get their results at home or privately, offering an opportunity to overcome privacy concerns associated with HIV testing, especially among KPs [38]. This is a promising approach to scale up HIV testing but also raises ethical concerns regarding HIV counseling and testing. Advancements in machine learning and mHealth technologies have been used to address this challenge. A feasibility and acceptability assessment of HIVST using conversational agents in South Africa showed substantial progress in this approach [39]. The study developed chatbots for smartphones that were able to give written informed consent to the study participants, allowing them to self-counsel and test for HIV [39]. Fascinatingly, 79% of the users stated that their experiences with the chatbot were preferable to a human counselor [39]. A pragmatic trial involving refugee adolescents and youth in Uganda examined the feasibility of HIVST with and without mHealth [40]. The study participants, who were cisgender and transgender men and women, exhibited increased self-reported HIV testing uptake with the mHealth HIVST approach [40]. Another study [41] also emphasized the critical role mobile phones and digital technology can play in improving HIVST and linkage to care. Despite the opportunity to combat HIV testing barriers among KPs, a review of technology, policy, and evidence regarding HIVST in SSA reported that there is limited delivery within the region [42]. Most of these studies were piloted in Southern and Eastern Africa, necessitating future feasibility studies of HIVST in other African subregions.

Discussion

Principal Findings

This bibliometric analysis provides comprehensive insights into the evolution of machine learning and related technologies in HIV testing interventions from 2000 to 2024. By examining the trends and patterns of research outputs in this field over the past 2 decades, the study shows that publications were relatively low before 2010. The number of publications applying machine learning and emerging health technologies in HIV testing increased rapidly starting in 2013 and was highest in 2021, indicating research progress in this field during this period. The advancement of technology, among other factors, has contributed to the recent rapid growth of publications in this field. Recent breakthroughs in AI have led to increased acceptance in health care [43]. In the past decade, robotics, speech recognition, and machine learning have created new potential for disease prediction, diagnosis, and treatment [44,45]. Machine learning research in health care is expected to grow exponentially, leading to more publications in the future [46]. Our findings are consistent with a bibliometric analysis demonstrating the current growth of AI in health care research [46], and the authors project that the publication rate will double in the next 5 years. Moreover, the surge of publications in different public health domains, including HIV, especially in 2021, was driven by the COVID-19 pandemic, and our topic is no exception [47].

This study showed that the geographical distribution of the scientific production (articles) and collaboration were unequal. The United States ranked the highest, followed by China, South Africa, the United Kingdom, and Australia. These countries are home to top global universities and are well-known for their remarkable advancements in technology-driven medical research. Our analysis further emphasizes that academic collaborations on machine learning and health technologies in HIV testing are more common among universities in high-income countries. The University of North Carolina, Emory University, the University of Michigan, San Diego State University, and the University of Pennsylvania, all within the United States, exhibited the highest collaboration. The only African university that performed well was the University of Witwatersrand in South Africa. Unfortunately, low-income countries, which are disproportionately affected by the HIV epidemic, are missing out on the opportunity to leverage machine learning to enhance HIV testing. A similar study by Amusa et al [23] titled “Big Data and Infectious Disease in Epidemiology: Bibliometric Analysis and Research Agenda” revealed that institutions in advanced countries such as the United States and China contribute the most publications to this field. Previous studies also demonstrated increased academic collaboration among institutions in high-income countries [21,23,48], highlighting the need for greater equity in research partnerships.

The lack of collaboration within and across different settings may jeopardize knowledge translation into evidence-based programs and policies. This increases the need for support from the most productive countries (United States, European countries) to enhance the application of evidence on machine learning and emerging technologies in HIV testing in different contexts (eg, in SSA). Hence, productive universities and/or initiatives within SSA countries should foster collaborative research across different regions and continents in the future.

Subjects related to machine learning, technology, and HIV testing are usually published in public health–related journals, as shown in the analysis. The *Journal of AIDS and Behavior* recorded the highest h-index (10), with 494 citations. *The Journal of Medical Internet Research*, *JMIR mHealth and uHealth*, *JMIR Research Protocols*, *mHealth*, *AIDS Care-Psychological and Socio-Medical Aspects of AI*, *BMC Public Health*, and *PLOS One* were also very influential in publishing studies on machine learning and health technologies in HIV testing. Similar findings were reported in bibliometric analyses focused on digital technologies and HIV research [21,22,48,49].

In analyzing the authors’ keywords, we identified themes and topics based on the frequency and co-occurrence of specific words. Keywords that appeared together within the same cluster indicated related topics. Frequent keywords such as HIV, HIV prevention, MSM, HIVST, HIV testing, mHealth, mobile app, youth, digital health, eHealth, and machine learning appeared in almost all the clusters in the co-word analysis, resulting in 2 thematic topics. These themes reflect the current focus of this field and suggest future research on machine learning and technology in connection with HIV testing. The content analysis, which focused mainly on the application of machine learning

XSL•FO
RenderX

and digital technologies in HIV prevention, including HIVST among KPs, gave comprehensive insights into the extent to which such technologies have enhanced HIV testing and identified limitations as well as suggestions for future studies. The analysis revealed that machine learning and digital technologies can significantly enhance HIV testing among priority groups, including young people and KPs like transgender people, cisgender people, and MSM. Key populations are becoming the center of focus when designing and implementing HIV prevention interventions [29-31]. Such groups are hard to reach due to societal stigma and legal issues, especially in SSA countries [29-31].

A recent systematic review highlighted that machine learning has significant potential to address privacy and accessibility gaps in HIV testing, particularly among KPs [50]. Although machine learning has proven to be highly accurate and effective in HIV testing, the study indicated that most interventions have focused on the Americas, as well as East and Southern Africa [50]. Consistently, our findings showed that machine learning has been used to predict health-seeking behaviors of high-risk populations [30], predict their HIV risk [31], and develop various options aimed at overcoming barriers to KPs accessing and using HIV testing. Among the developments, HIVST was identified as a viable option for conducting self-counseling and testing for HIV among KPs [38-42]. However, feasibility studies for machine learning and emerging technologies in HIV testing approaches have been piloted in only a few Southern and Eastern African countries. Furthermore, lack of expertise and inadequate infrastructure limit the application of advanced technologies and AI in HIV testing across many African countries [50]. This gap could leave the continent behind in meeting the UNAIDS 95-95-95 target despite bearing the brunt of the global HIV burden. Thus, these innovative techniques are essential for strengthening and should be implemented across SSA beyond piloting purposes.

Limitations

This bibliometric analysis encountered several limitations. First, the WoS database was used to gather articles, which might have excluded relevant studies from other databases. The WoS is a leading database for studies on machine learning and technology in health care and has been recognized as a legitimate platform for bibliometric analysis [18-23]. Second, we only selected studies published in English, potentially missing relevant studies published in other languages. Third, our sample size was relatively small and may not fully represent research outputs in machine learning and technology applications in HIV testing. However, our findings are relevant as they are consistent with publication trends in similar bibliometric analyses. Moreover, the Biblioshiny software could not determine authors' valid affiliations; a single author could have multiple affiliations in some instances. We chose the "Application Name Disambiguation" option to ensure the same affiliations were counted as one.

Future Research and Conclusions

This study showed that universities in high-income countries like the United States, the United Kingdom, and South Africa are very productive in applying machine learning technology to address health care issues, including HIV testing. Journals publishing articles on public health and infectious diseases were very influential in this analysis. The most frequent keywords in the sample were related to the application of digital technologies in HIV prevention, particularly HIV testing among KPs. Furthermore, the study found that incorporating machine learning in HIVST seems promising for the enhancement of HIV testing among KPs, especially MSM. These insights demonstrate improved academic engagement and productivity over the 2 decades, identifying opportunities and research gaps for future scholars to embark on.

This bibliometric analysis highlights a research gap between high-income and underresourced nations regarding applying machine learning and related technologies in HIV testing interventions. More than half of the studies analyzed were from the United States, and a handful of them came from other advanced countries. Many low-income countries, especially in SSA, are lagging in using advanced technologies to tackle health care challenges. There is a critical need to develop an enabling infrastructure that can facilitate the use of machine learning in HIV testing interventions. Furthermore, academic institutions should incorporate machine learning courses to equip future researchers with the essential skills needed in this area. Bridging the intercontinental gap is crucial for overcoming the barriers to HIV prevention interventions, ultimately contributing to the success of UNAIDS' goals to eradicate HIV/AIDS as a global health issue.

This bibliometric analysis clearly demonstrates a significant shift from conventional HIV testing methods to innovative approaches like HIVST. The WHO strongly endorses HIVST as an effective way to deliver personalized and context-specific HIV services that tackle the structural issues surrounding stigma and discrimination. Notably, both youth and KPs have expressed a clear preference for HIVST and mobile technology, which are crucial for improving linkage to care. Although HIVST is user-friendly and allows individuals to test conveniently at home, it presents a challenge in accurately monitoring national HIV testing rates. To address this issue, it is imperative that HIV policies implement robust tracking systems to ensure that individuals using home testing are included in national HIV testing data. This proactive approach is essential for effectively assessing and improving HIV care and services.

Machine learning models continually evolve to address stigma and discrimination, as well as privacy concerns related to HIV testing, proving to be efficient and effective despite implementation challenges. Future studies should assess the feasibility of various machine learning techniques to enhance HIV testing in low-income countries. Such insights will further identify solutions to the current gaps in research in low-income countries, particularly those in SSA. The study also highlights the need to improve collaboration among African universities to enhance research outputs using advanced methodologies. In today's world, utilizing AI, machine learning, and advanced technologies is essential for addressing critical challenges across all sectors, especially health care. Based on the gaps and opportunities highlighted in this study, the findings would inform program implementers to design more effective strategies for improving the use of machine learning and technology in

XSL•FO
RenderX

HIV testing. By increasing the use of machine learning and emerging technologies in HIV testing interventions, we can significantly boost the number of individuals who get tested for HIV. This will contribute to the success of the UNAIDS 2030 goal and result in improved health outcomes for our communities.

Acknowledgments

This study is part of the Boloka Project, which is funded by the South African Medical Research Council (SAMRC) under its Division of Research Capacity Development through the Mid-Career Scientist Programme, using funds allocated by the South African National Treasury. The authors, namely RNPM, EP, and MJ, are supported by the SAMRC. This study was conducted within the SAMRC/University of Johannesburg (UJ) Pan African Centre for Epidemics Research Extramural Unit framework. The bibliometric analysis also forms part of a doctoral study by MJ, whose study is funded by the UJ Global Excellence Stature 4.0 Scholarship. The authors are solely responsible for the views expressed in this work, and they do not necessarily reflect the official perspectives of the SAMRC or UJ.

Authors' Contributions

M.J., R.N.P.M., and E.P. conceived the study and reviewed the literature. M.J. and E.P. screened articles. M.J. wrote the first draft of the paper. M.J. and A.L.B. analyzed and visualized the data. R.N.P.M., E.P., Y.A.S., A.L.B., and H.T. reviewed the work. R.N.P.M., E.P., and Y.A.S. supervised the study. All authors have read and agreed to the published version of the manuscript.

Abstract

Background: Virtual reality (VR) has become a powerful tool for enhancing the experiences of patients with critical illnesses, particularly hospitalized children with leukemia. Since traveling is nearly impossible for them, St Jude has teamed up with the travel company Expedia to launch "Dream Adventures," a pilot program that offers immersive VR experiences, allowing children to explore new destinations from the comfort of the hospital.

Objective: The aim of this study was to evaluate the pleasurable experience of VR and its impact on healthy and hospitalized children's travel expectations and hope by using electrocardiography (ECG) and questionnaires to enhance research objectivity.

Methods: Participants were children aged 7-18 years, divided into 2 distinct groups: 30 healthy children and 18 hospitalized children with leukemia. Both groups received the same VR intervention and were assessed using a 1-group pretest-posttest design. The questionnaires were designed to assess differences in the children's sense of hope and travel expectations, and their physiological data were collected through ECG.

Results: The results indicated a statistically significant increase in hope levels from pre-VR to post-VR intervention in both healthy children (preintervention: mean 5.83, SD 0.87; postintervention: mean 6.36, SD 0.76; P=.002) and hospitalized children (preintervention: mean 5.51, SD 1.17; postintervention: mean 5.73, SD 1.15; P=.03), as determined by paired samples 2-tailed t tests. Furthermore, an independent samples 2-tailed t test revealed a significant difference in postintervention hope levels between the hospitalized children (mean 5.73, SD 1.15) and healthy children (mean 6.36, SD 0.76; P=.05). Then, we further compared the mean differences in hope scores from preintervention to postintervention. Healthy children demonstrated a greater increase (an increase of 0.53, from 5.83 to 6.36) than the hospitalized children (an increase of 0.22, from 5.51 to 5.73). In terms of physiological responses, ECG indicators such as SD of all normal-to-normal intervals and low-frequency power revealed significant differences in autonomic nervous system activity between the 2 groups. Healthy children exhibited higher sympathetic activation, suggesting greater emotional engagement during the VR experience, whereas hospitalized children demonstrated more attenuated responses. The consistency between physiological data and self-reported measures strengthens the construct validity of the instruments used and enhances the overall reliability of the study findings.

Conclusions: The VR intervention significantly increased hope levels in both healthy children and hospitalized children with leukemia, with a greater improvement observed among healthy participants. Therefore, this study suggests that when designing interventions for hospitalized children, more targeted emotional support strategies should be considered. Future studies are recommended to explore different types of VR content and the medical conditions of hospitalized children.

Introduction

Nowadays, virtual reality (VR) has gradually become a powerful tool for enhancing the patient experience in children's hospitals [1]. Immersive experiences allow individuals to fully engage in realistic environments created through digital technologies or designed settings, fostering deep emotional connections [2]. VR apps initially started with simple graphics for entertainment and research but are now widely used across many professional fields [3]. As VR technology continues to advance, its apps in the medical field are gaining increasing recognition. For instance, VR is being used in various medical domains [4], including medical education [5,6], clinical decision-making [7,8], preoperative planning [9], patient education [10,11], and surgical simulation [12].

As part of VR content creation, 360-degree video is an innovative medium that captures a scene from all directions using specialized cameras, allowing users to explore the environment as if they were physically present [13]. The sense of spatial presence created by 360-degree videos positions them as a form of immersive VR experience [14,15], particularly due to their ability to evoke strong emotions and make users feel surrounded by the content [16,17]. Previous studies in nonhospital settings have shown that VR has significant potential, as it can reduce psychological distress in young people across various situations [18-20] and elicit varying degrees of physical activity intensity in young healthy adults [21].

Additionally, there is a great potential for VR to address the unique medical care needs of hospitalized children [22]. For example, for children battling serious illnesses at St Jude Children's Research Hospital, traveling may seem out of reach. To bring the world to these young patients, St Jude has teamed up with the travel company Expedia to launch "Dream Adventures," a pilot program that offers immersive VR experiences, allowing kids to explore new destinations from the comfort of the hospital [23].

Mitsea et al [24] highlighted that VR-based positive mental imagery training, when combined with reward training, effectively reduced anhedonia while increasing pleasure and self-motivation skills. van Gelderen et al [25] implemented VR-based Eye Movement Desensitization and Reprocessing therapy, where patients walked on a treadmill while engaging with personal trauma-related images and relaxing music. The results indicated that such interventions could effectively reduce feelings of isolation and foster hope. Additionally, Bush et al [26] found that the Virtual Hope Box application enhanced users' hope and emotional regulation skills. Therefore, the aim of our study was to examine the effects of VR on pleasure, hope, and travel expectations in hospitalized children with leukemia and further compare them with healthy children.

Researchers have used videos to elicit specific emotions and collect emotion-related data. More recently, VR has been used to evoke particular emotional responses [27]. VR offers a more objective method for eliciting emotions by minimizing environmental interferences [28]. However, health care providers have perceived certain barriers to using VR, such as concerns about older adults with cognitive impairments [29]. Nevertheless, studies have suggested that VR apps are feasible for use in hospital wards and do not cause significant side effects [30,31]. Self-reported emotion measurements are susceptible to recall bias and cultural influences, whereas electrocardiography (ECG) provides a reliable, real-time evaluation of emotional variations.

Recent studies have demonstrated that ECG is a viable signal for measuring stress [32], and research in the study by Schmidt et al [33] has shown the feasibility of ECG-based stress assessment in a VR environment. Ahmad et al [34] collected ECG data from 9 participants experiencing a VR roller coaster. von Rosenberg et al [35] investigated the impact of mental stress on physiological responses using a wireless ECG. Furthermore, Kalatzis et al [36] examined whether VR scenarios could elicit specific affective states and developed a validated database to predict emotional states (eg, calm vs acute stress) using ECG. Additionally, Scherz et al [2] used VR as a significant stressor, analyzing heart rate and other physiological parameters through ECG. Their results indicated that while using a VR headset influenced heart rate and the root-mean-square of the successive differences in heartbeats, it did not significantly increase driving-related stress.

Therefore, the aim of this study was to evaluate the pleasurable experience of VR and its impact on hospitalized children's travel expectations and sense of hope by using ECG and questionnaires approach. This study incorporated the collection of physiological data through ECG to analyze and corroborate emotional changes in children based on physiological signals.

Methods

Study Design and Setting

This study used a quasi-experimental design to investigate the effects of VR on hope, pleasure, and travel expectations in children. The study included 2 distinct groups of participants: healthy children and hospitalized children with leukemia. Both groups received the same VR intervention and were assessed using a 1-group pretest-posttest design, in which outcome measures were collected immediately before and after the intervention within each group. This design allowed us to examine within-group changes in hope, pleasure, and travel expectations, as well as to compare the differential effects of the VR intervention between the 2 populations.

Participants

The experiment was conducted in 2 stages: a pilot test and a formal test. The purpose of the pilot test was to determine the VR destination. Five domestic tourist destinations (Park Lane by China Metal Products, National Museum of Natural Science, Dadu Blue Highway, Shalu Dream Street, and Dakeng Pink Valentine Bridge) and 6 international tourist destinations (the Pyramids of Egypt, the Eiffel Tower in France, Neuschwanstein Castle in Germany, Venice in Italy, Aphrodisias in Turkey, and the Space Station) were provided as options. Based on the results of the pilot test involving 12 children aged 7 -18 years, the Eiffel Tower was selected as the VR content due to its high ratings for engagement and recognizability. The content consisted of 8 scenes of the tower, captured from various angles and at

XSL•FO
RenderX

different times of day, and participants were able to switch between scenes freely using the VR device.

In the formal test, participants were included 2 distinct groups of participants: healthy children and hospitalized children with leukemia. The hospitalized children with leukemia were recruited from the pediatric ward of Taichung Veterans General Hospital in Taiwan based on inclusion and exclusion criteria recommended by the attending physician. These children often undergo strict regimens of chemotherapy, radiation, or other therapies, which limit their opportunities to travel and experience new places, particularly if they have spent significant time in the hospital. This context likely heightens their desire to engage in virtual travel experiences, making them a key focus of this study. Additionally, the healthy children were recruited from a local cram school, where they were enrolled in regular academic programs and had no known history of serious medical conditions. Recruitment procedures prioritized voluntary participation. The inclusion and exclusion criteria of formal experimental design are summarized in Textbox 1.

Textbox 1. Inclusion and exclusion criteria for participants in the formal study design.

Inclusion criteria

- Hospitalized children: hospitalized children with leukemia aged 7-18 years, in the midstage of treatment with stable vital signs.
- Healthy children: healthy children aged 7-18 years.

Exclusion criteria

- Hospitalized children: children unable to independently use virtual reality equipment or those diagnosed with epilepsy.
- Healthy children: children unable to independently use virtual reality equipment.

Ethical Considerations

All procedures performed in studies involving human participants adhered to the ethical standards of the institutional and national research committee, as well as the 1964 Declaration of Helsinki and its later amendments or comparable ethical standards.

This study was approved by the Institutional Review Board of Taichung Veterans General Hospital (CF20285A) on December 3, 2020, and was conducted from December 3, 2020, to June 30, 2021. Informed consent was obtained from all participants and their parents or guardians prior to the study, with signed consent forms collected. The consent process involved clearly communicating the study's objectives, procedures, and potential risks to ensure voluntary participation. All data were anonymized to protect participants' privacy.

To show appreciation for participants' involvement, each participant will receive a VR cardboard viewer (valued at approximately US $1.50) upon completing the experiment. This compensation allows them to continue experiencing VR content after the study. It does not affect their right to participate voluntarily or withdraw from the study at any time.

Instruments

This study adopted the pleasure measurement from the study by Bakhuis et al [37]. A higher score indicated that the subject experienced more pleasure from the stimulus as shown in Table 1.

Table . Scale items used to measure pleasure in response to virtual reality stimuli[a].

Items	Scores
1. Unhappy to happy	1 - 7
2. Unsatisfied to satisfied	1 - 7
3. Melancholic to cheerful	1 - 7
4. Despairing to hopeful	1 - 7
5. Bored to surprised	1 - 7

[a]From Schifferstein and Tanudjaja [38].

In addition, we measured children's hope using the scale developed by Snyder et al [39]. The scale was scored on a 7-point Likert scale, with responses ranging from 1 ("definitely disagree") to 7 ("definitely agree"). Travel expectations in this study were based on the anticipated outcomes a person expects to gain while traveling to a destination [40]. The items measuring children's hope and travel expectations are listed in Textbox 2.

XSL•FO
RenderX

Textbox 2. Scale items for measuring children's hope and travel expectations.

Items of measuring children's hope [39]:

1. My life is very good now.
2. I can think of many ways to get the things in life that are most important to me.
3. I am doing just as well as other kids of my age.
4. I have a lot of confidence in myself.
5. When I have a problem, I can come up with lots of ways to solve it.
6. I think the things I have done in the past will help me in the future.
7. Even when others want to quit, I know that I can find ways to solve the problem.
8. I think my life is full of hope.

Items of measuring travel expectations [40]:

1. I can learn new knowledge.
2. I can learn new culture.
3. I can experience different things.
4. I can see the beautiful view.

Procedure

The researcher tested 1 child at a time, with each session lasting approximately 40 minutes. Healthy children were tested individually in a classroom, while hospitalized children were tested in their hospital ward beds, as shown in Figure 1. The study prioritized participant safety during VR use. Potential risks associated with VR, such as motion sickness, visual discomfort, or dizziness, were considered during the design phase. To mitigate these risks, age-appropriate 360-degree VR content with calming visuals was selected. Participants were monitored throughout the session, and breaks were allowed if discomfort occurred.

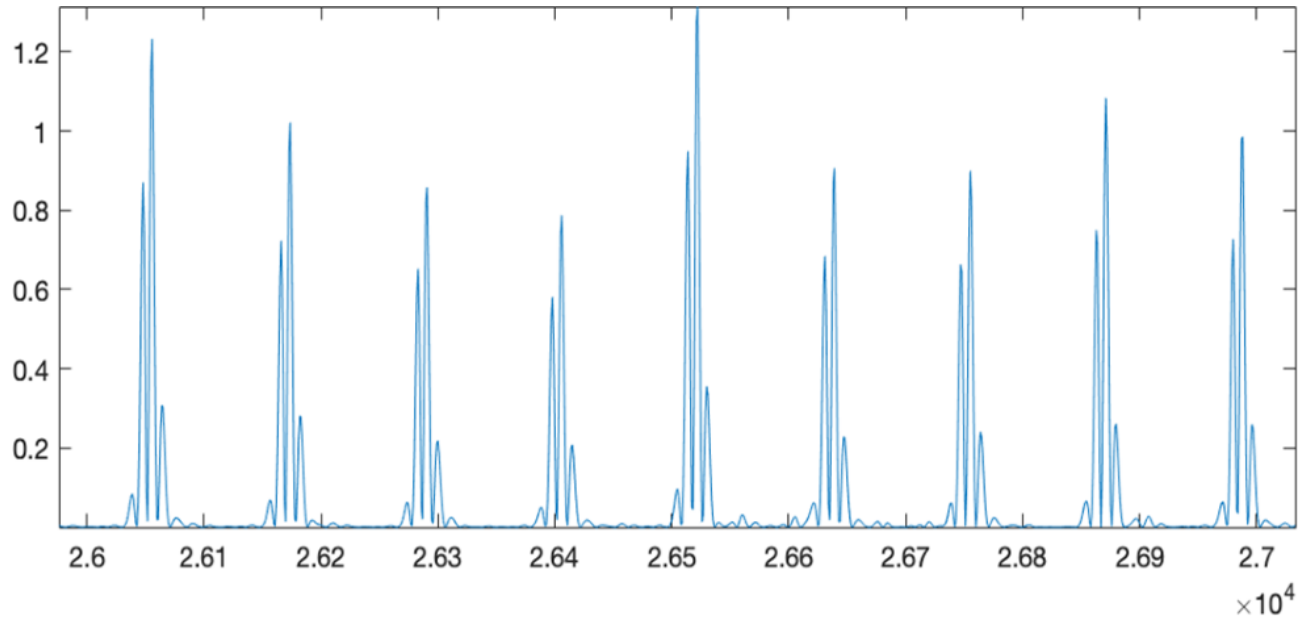
Figure 1. Hospitalized children were tested in a hospital ward bed.

As the participants were underage and part of a vulnerable group, the attending physician and researcher carefully explained the experiment and obtained consent from both the children and their parents. The study followed a structured procedure: (1) Collecting children's resting heart rate for baseline ECG data collection, followed by completing the pretest questionnaire to measure hope and travel expectations. (2) An 11-minute VR experience while ECG data were recorded. (3) Completing the posttest questionnaire to measure hope, travel expectations, and pleasure outcomes.

The experiment was conducted individually in classrooms (healthy children) or hospital wards (hospitalized children). .

Data Analysis

All scales were tested using SPSS software (version 20; IBM Corp). We assessed the reliability of the items by examining the Cronbach alpha values, all of which exceeded the common threshold of 0.70, suggesting adequate reliability [41]. The pleasure scale demonstrated strong internal consistency, with a Cronbach α value of 0.88. Similarly, the hope scale exhibited high reliability, with a Cronbach α value of 0.93. Additionally, the travel expectations scale showed adequate internal consistency, with a Cronbach α value of 0.73. To analyze the data related to hope, travel expectations, and pleasure—key factors for a successful VR intervention—the questionnaire findings were compared between groups using an independent



XSL•FO
RenderX

2-tailed *t* test. Additionally, post hoc analyses were conducted using MANOVA to examine differences between children who had traveled (once or more) and those who had not. Independent samples 2-tailed *t* tests were also performed to compare children with and with no prior VR experience.

An ECG typically requires a physiological signal length of 30 seconds to 5 minutes for heartbeat detection [42]; therefore, this study used 5 minutes as the benchmark. To extract the R-peak of the QRS complex (the QRS complex is the portion of the ECG that reflects the depolarization of the ventricles, marking the onset of ventricular contraction; it is composed of the Q, R, and S waves and is a key indicator of cardiac electrical activity), we applied the Pan-Tompkins open-source algorithm using MATLAB [43]. During the process of collecting physiological signals, the original signal is prone to noise interference, making the QRS complex of the ECG difficult to distinguish. To address this, a filter was used to remove unnecessary signals, enhancing the ECG waveform's characteristics.

Since heart rate variability is calculated based on the highest peak (R-peak) in the ECG, a Butterworth high-pass filter was applied to eliminate unwanted frequency bands and highlight the R-peak within the QRS complex. To detect the position of the R-peak, the differentiated signal was first segmented. Then, squaring was applied to amplify the signal, making high-frequency values more prominent, as shown in Figure 2.

Figure 2. Actual physiological signal after square.

Finally, the moving window integral method was used, with 30 samples (approximately 150 ms) as the window size. When both the difference threshold and the integration threshold met the required conditions simultaneously, an R-peak was detected, and the threshold was automatically updated.

As shown in Figure 3, the black line represents the noise threshold curve, the green line represents the automatically adapted threshold curve, and the red line represents the predicted R-peak curve. Finally, the results of the R-peak sequence were used to plot the pulse sequence onto the original waveform, as shown in Figure 4, which can be used to evaluate accuracy.

Results

Sample Characteristics

The participants included 18 hospitalized children and 30 healthy children, all aged between 7 and 18 years (see Table 2 for details). The hospitalized children were preselected by the attending physician and were patients with leukemia with stable health who were willing to participate in the experiment.

XSL•FO

Table . Descriptive statistics of participants in the formal test by group.

	Hospitalized children (n=18) , n (%)	Healthy children (n=30), n (%)
Gender		
Boy	11 (61)	23 (77)
Girl	7 (39)	7 (23)
Age (years)		
7 - 9	6 (33)	N/A[a]
10 - 12	3 (17)	18 (60)
13 - 15	6 (33)	12 (40)
16 - 18	3 (17)	N/A
Experience of traveling abroad		
0 times	8 (45)	11 (37)
1 - 5 times	6 (33)	17 (57)
5 - 10 or >10 times	4 (22)	2 (6)
Experience of using VR[b]		
Used	8 (44)	9 (30)
Never used	10 (56)	21 (70)

[a]N/A: not applicable.

[b]VR: virtual reality.

We use the MANOVA test for post hoc analyses to compare 2 different dependent variables (hope and travel expectations) among 3 groups based on their experience of traveling abroad (0 times, 1 - 5 times, and more than 10 times) in the hospitalized children. The output shows that there are no significant differences in hope among groups (experience of traveling abroad 0 times: mean 5.34, SD 1.15; 1 - 5 times: mean 5.44, SD 1.11; P=.99; and 0 times: mean 5.34, SD 1.15; more than 10 times: mean 5.34, SD 1.40; P>.99). Similarly, there are no significant differences in travel expectations among groups (experience of traveling abroad 0 times: mean 6.14, SD 0.85; 1 - 5 times: mean 5.75, SD 1.00; P=.70; and 0 times: mean 6.14, SD 0.85; 5 - 10 times: mean 6.31, SD 0.94; P=.94). Also, the results show that there are no significant differences in hope among groups in the healthy children.

In addition, we adopt an independent 2-tailed t test to analyze 2 different dependent variables (hope and travel expectations) between 2 groups based on their experience of using VR (used and never used) in hospitalized and healthy children, respectively. In the hospitalized children group, the results show that there are no significant differences in hope between the 2 groups (experience of using VR: used vs never used; t=0.57; P=.58), and no significant differences in travel expectations between the 2 groups (t_{17}=−0.04; P=.97). Similarly, the results show that there are no significant differences in hope and travel expectations in the healthy children group.

Hope, Pleasure, and Travel Expectations Results

First, there was no significant difference in the sense of hope between the hospitalized and healthy children before using VR (t_{46}=−1.02; P=.32). However, after using VR to experience tourist attractions, a significant difference was observed between the 2 groups (t_{46}=−2.06; P=.049) (Table 3).

XSL•FO
RenderX

Table . Levels of hope before and after watching virtual reality in the hospitalized and healthy children during the formal test[a].

Stage and group	Mean (SD)	*t* test (*df*)	*P* value[b]
Before watching VR[c]		−1.02 (46)	.32
Hospitalized children	5.51 (1.17)		
Healthy children	5.83 (0.87)		
After watching VR		−2.06 (46)	.049
Hospitalized children	5.73 (1.15)		
Healthy children	6.36 (0.76)		

[a]An independent samples 2-tailed *t* test was conducted to compare levels of hope between the hospitalized children and the healthy children before and after watching VR.

[b]Significance at .05 level.

[c]VR: virtual reality.

To further examine the degree of improvement in hope after the experiment, we conducted paired samples 2-tailed *t* tests for each group separately. The results showed significant differences in both the hospitalized children group (t_{17}=−2.46; *P*=.03) and the healthy children group (t_{29}=−3.46; *P*=.002). Furthermore, an independent samples 2-tailed *t* test revealed a significant difference in postintervention hope levels between the hospitalized and healthy children (t_{46}=−2.06; *P*=.049). Then, we further compared the mean differences in hope scores from preintervention to postintervention using an independent samples 2-tailed *t* test and found that the difference was statistically significant (t_{46}=2.18; *P*=.03). Healthy children demonstrated a greater increase in mean hope scores (an increase of 0.53, from 5.83 to 6.36) compared with the hospitalized children (an increase of 0.22, from 5.51 to 5.73). This suggest that using VR to experience tourist attractions may be more effective in enhancing the sense of hope in healthy children (Table 4). On the other hand, this result may also indicate that healthy children's sense of hope is more easily stimulated than that of hospitalized children.

Table . Comparison of hope levels before and after watching virtual reality within the hospitalized and healthy children during the formal test[a].

Group and stage		Mean (SD)	*t* test (*df*)	*P* value[b]
Hospitalized children			−2.46 (17)	.03
	Before watching VR[c]	5.51 (1.17)		
	After watching VR	5.73 (1.15)		
Healthy children			−3.46 (29)	.002
	Before watching VR	5.83 (0.865)		
	After watching VR	6.36 (0.756)		

[a]Paired samples 2-tailed *t* tests were conducted separately within the hospitalized children and healthy children to examine the change in hope levels before and after watching VR.

[b]Significance at .05 level.

[c]VR: virtual reality.

In addition, the results of the independent samples 2-tailed *t* test revealed a nonsignificant difference in pleasure (t_{46}=−1.116; *P*=.27) and travel expectations (t_{46}=−0.300; *P*=.77) between the hospitalized and healthy children. We inferred that both hospitalized and healthy children experienced pleasure when using VR, likely because it was a novel experience for them, and they had expectations about traveling.

Power and Effect Size for Independent Samples 2-Tailed *t* Test

For the independent samples 2-tailed *t* test, Cohen *d* is calculated by taking the mean difference between the 2 groups and dividing it by the pooled SD. Cohen *d* is an appropriate effect size measure when both groups have similar SDs and equal sample sizes. However, since our sample sizes differ, we used Hedges *g*, which adjusts for sample size differences. In this study, Hedges *g* was calculated as:

Hedges g=(6.4−5.7)0.967291=0.7

According to Zach [44], a *g* value of 0.2 represents a small effect size, 0.5 represents a medium effect size, and 0.8 represents a large effect size. Therefore, the effect size in this study (0.7) is close to a large effect size.

ECG Data Analysis Result

The resting state represents the baseline heartbeat. In this study, it was used to determine whether the heart rates of the 2 groups (hospitalized children and healthy children) were at the same level before the experiment. The results showed no significant difference between the groups before using VR.

XSL•FO
RenderX

However, when using VR, 5 indicators showed significant differences between the 2 groups: mean normal-to-normal intervals (t_{46}=−2.119; P=.04), normal-to-normal intervals (t_{46}=−2.856; P=.007), SD of normal-to-normal intervals (SDNN; t_{46}=2.189; P=.04), low-frequency (LF; t_{46}=2.834; P=.008), and high-frequency normalized units (HF_nu;t_{46}=2.297; P=.03). The results are summarized in Table 5.

Table . Differences in electrocardiography indicators between the hospitalized and healthy children while watching virtual reality[a].

Autonomic nervous system, indicator, and group		Mean (SD)	*t* test (*df*)	*P* value[b]
Parasympathetic nerves				
SDNN[c]			2.19 (46)	.04
	Group 1[d]	150.08 (43.75)		
	Group 2[e]	119.12 (38.59)		
HF_nu[f]			2.30 (46)	.03
	Group 1	74.82 (15.32)		
	Group 2	64.38 (11.03)		
Sympathetic nerve				
LF[g]			−2.83 (46)	.008
	Group 1	192.77 (220.48)		
	Group 2	443.64 (307.65)		

[a]This table shows the results of independent samples 2-tailed *t* tests comparing electrocardiography indicators between hospitalized children and healthy children during virtual reality viewing.

[b]Significance at .05 level.

[c]SDNN: SD of all normal-to-normal intervals.

[d]Group 1: hospitalized children.

[e]Group 2: healthy children.

[f]HF_nu: high-frequency normalized units.

[g]LF: low-frequency power.

In the ECG analysis, index calculations can be performed after obtaining the R-R interval. According to the literature, the autonomic nervous system (ANS) is mainly composed of the sympathetic nervous system (SNS) and the parasympathetic nervous system (PNS). If the ANS is biased toward the SNS, the PNS has a smaller effect. To illustrate, if the ANS were compared with a car, the SNS would represent the accelerator, and the PNS would represent the brake.

ECG indicators, such as SDNN and HF_nu, are related to the PNS, while LF is related to the SNS. In this study, the mean value of the SNS indicator (LF) in the hospitalized children (mean 192.77, SD 220.48) was significantly lower than the mean value of the SNS indicator (LF) in the healthy children (mean 443.64, SD 307.65). Conversely, the mean values of parasympathetic nervous indicators (SDNN, HF_nu) were significantly higher in the hospitalized children than those in the healthy children. Based on the significant results from LF, it appears that the SNS is highly active during VR exposure, indicating that healthy children experience VR in a more excited state. The results of the formal test are summarized in Table 6.

XSL•FO
RenderX

Table . Summary of formal test results comparing the hospitalized and healthy children across physiological and psychological measures.

Measurement and results		Significance
ECG[a]		
	Comparison of the ECG indicators of G1[b] and G2[c] when in a resting state.	Not significant
	Comparison of the ECG indicators of G1 and G2 when using VR[d].	Significant
Hope		
	Comparison of the state of hope in G1 and G2 before using VR.	Not significant (*P*=.32)
	Comparison of the state of hope in G1 and G2 after using VR.	Significant (*P*=.05)
	Improvement of G1's state of hope.	Significant (*P*=.03); the mean value rose by 0.22, from 5.51 to 5.73.
	Improvement of G2's state of hope.	Significant (*P*=.002); the mean value rose by 0.53, from 5.83 to 6.36.
Pleasure		Not significant (*P*=.27)
Travel expectations		Not significant (*P*=.77)

[a]ECG: electrocardiography.

[b]G1: hospitalized children with leukemia.

[c]G2: healthy children.

[d]VR: virtual reality.

Discussion

Summary of Key Findings

We assessed the effects of VR on hope, pleasure, and travel expectations in healthy and hospitalized children using ECG and questionnaires. The study demonstrated consistency between self-reported data and physiological measures, suggesting that VR effectively enhanced hope among both healthy and hospitalized children with leukemia, with a more pronounced effect in the healthy group. However, no significant changes were observed in pleasure or travel expectations in either group.

Clinical and Research Implications

While questionnaires captured subjective experiences, ECG objectively measured real-time physiological responses. Indicators such as SDNN and LF revealed differences in ANS activity. Healthy children exhibited higher sympathetic activation, reflecting greater engagement, while hospitalized children showed more subdued responses. This alignment validates the questionnaire measures and enhances the study's reliability. Beyond validation, ECG plays a crucial role in detecting subtle or unconscious emotional responses and tracking real-time fluctuations during VR exposure. By linking subjective perception with objective data, ECG strengthens methodological rigor and supports future VR-based emotional and physiological research.

We infer that this result possibly reflects hospitalized children's deeper psychological needs and the greater impact of long-term hospitalization stress. Their sense of hope may be more focused on overcoming illness and achieving milestone progress in treatment. It is likely linked to improvements in their health condition, disease remission, or the possibility of participating in activities they have missed due to their illness. Therefore, this suggests that when designing interventions for hospitalized children, more targeted emotional support strategies should be considered. This aligns with previous research, in which Napetschnig et al [45] proposed that promoting user motivation is one of the key quality criteria for developing user-centered VR.

Nevertheless, we found a significant difference in the mean hope scores before and after using VR, both in healthy children and in hospitalized children. VR is a promising technique for cognitive diversion and psychological rehabilitation support for patients with cancer [46], particularly when they experience boredom during hospitalization following treatment [47,48]. Such computerized technologies are especially appealing to this age group, which, in turn, increases their enthusiasm [46]. For example, the results revealed no significant difference in pleasure and travel expectations between the hospitalized and healthy children. We infer that this finding suggests that both hospitalized and healthy children experienced pleasure when using VR because it was a novel experience for them and sparked their expectations about traveling. Although some participants in the hospitalized children group had prior experience using VR, there were no significant differences in hope and travel expectations between those who had used VR before and those who had not. Therefore, we suggest that health care workers shift their focus from health to overall well-being [49] and incorporate immersive VR experiences into pediatric care as a form of distraction therapy. This approach can help children cope with long-term hospitalization and enhance their emotional well-being.

XSL•FO
RenderX

Study Limitations and Recommendations for Future Research

Some limitations of this study should be noted. First, the study examined differences between healthy children and hospitalized children with leukemia aged 7 - 18 years. Therefore, the results are applicable only to hospitalized children with leukemia in the midstage of treatment with stable vital signs and not to those with different medical conditions or from other age groups. Future studies should investigate the impact of VR apps on other age groups and medical conditions. Second, the VR experience content used in this research was primarily based on tourist attractions. Future studies could explore different VR content and experiences. Third, we acknowledge the limitations of ECG in differentiating specific emotional responses, as an increased heart rate can be associated with multiple emotions such as joy, surprise, or satisfaction. This is why we combined questionnaires to enhance the interpretation of emotional responses. Future studies could use more precise psychophysiological methods, such as functional magnetic resonance imaging, to improve the accuracy of emotional response assessments.

Conclusions

With the advancement of emerging technologies, this study aimed to evaluate the pleasurable experience of VR and its impact on hospitalized children's travel expectations and hope by using ECG and questionnaires. We examined the differences between healthy and hospitalized children in their perceptions of pleasure and hope to provide future scholars with a reference for research on hospitalized children. In this study, VR provides hospitalized children with a safe space and a more immersive way to explore the world. It also provides another way for children to experience the world in addition to books and photographs, and it gives children more opportunities to learn about the world. Through self-learning and adaptation, children can find ways to deal with their emotions and relieve their psychological pressure. VR apps are considered an accessible, low-risk, and cost-effective innovative approach for children with leukemia, particularly during repeated waves of the epidemic, as they minimize the risk of cross-infection [50].

Acknowledgments

The manuscript's English-language quality was enhanced using artificial intelligence–assisted proofreading tools, while maintaining the original content and meaning. The authors would like to thank the participants who joined the virtual reality experiment and the 2 research assistants who helped recording participants' electrocardiography data in the study. The authors also deeply appreciate Fang-Liang Huang, the director of Children's Medical Center, Taichung Veterans General Hospital, who provided valuable perspectives of the virtual reality experiment. This study was supported by the grants from Taichung Veterans General Hospital and Tunghai University (TCVGH-T1107809).

Abstract

Background: Exergaming, the combination of exercise and gaming, has emerged as an important area in physical activity (PA) research. By leveraging advances in video game technology, exergaming supports both physical and mental health. This growing interest in exergaming has increasingly attracted researchers over the years. Examining the development of exergaming research with a bibliometric approach is thought to offer valuable perspectives to researchers by revealing the trends and main contributions in the field.

Objective: This study aims to identify the most researched concepts and topics in the field of exergaming; track the changes of trending topics over the years; identify the most influential journals as well as the authors who have contributed the most to the field; identify groundbreaking studies and neglected topics that shape future work; and reveal the countries, institutions, and collaborations that have contributed the most to the field. It also aims to identify research gaps in the field of exergaming and provide important recommendations for future research.

Methods: A bibliometric analysis covering studies between 1997 and 2024 was conducted using the Web of Science database. The R-based Bibliometrix package and the Biblioshiny web interface were used for data analysis and visualization. The analysis included original research papers and reviews. These analyses provided insights into research trends, citation metrics, and thematic developments.

Results: A total of 1626 studies were analyzed, and the results indicated a steep rise in exergaming research since 2015, peaking in the years 2020 - 2021. Major high-impact journals publishing in this area include *Games for Health Journal* and *International Journal of Environmental Research and Public Health*. Researchers who have contributed significantly and enriched the knowledge base of the exergaming field included Gao Zan, Eling de Bruin, and Zeng Nan. The most cited studies were classified into 2 different clusters, namely, cluster 1 that focuses on the concepts of PA, exercise, energy expenditure, and children, while cluster 2 focuses on rehabilitation, balance, adults, and aging. Medicine, information technology, and intention are some of the emerging themes. From a research productivity perspective, there is an undisputed front-runner, the United States, but substantial contributions have definitely come from either the Swiss Federal Institute of Technology or the Karolinska Institute.

Conclusions: Despite significant growth in exergaming research over the last decade, research gaps remain, particularly in understanding how exergaming can be effectively integrated into long-term PA promotion and broader health outcomes. These gaps were identified by the absence or low representation of relevant keywords (eg, “cost-effectiveness,” “community-based intervention,” and “long-term health outcomes”) in thematic mapping and keyword trend analyses and limited citation density in these areas. Future work should explore these issues more systematically to advance the field.

KEYWORDS

exergaming; active video games; physical activity; health outcomes; bibliometric analysis

Introduction

Physical inactivity is a significant risk factor for noncommunicable diseases worldwide [1]. Exergaming plays an important role in preventing these diseases associated with physical inactivity and promoting healthy habits [2]. “Exergaming,” also known as active video games, are video games that incorporate physical activity (PA) into the gaming concept, requiring players to move physically [3].

XSL•FO
RenderX

Leisure-time PA can be influenced by social and environmental factors (lack of time, lack of willpower, lack of friends, unsafe living environments, adverse weather conditions, socioeconomic status, health status, physical disability, etc) [4]. In this regard, exergaming can provide indoor or home-based alternatives that make PA more enjoyable and fun, thereby increasing exercise motivation [5]. Furthermore, unlike traditional sedentary video games, exergaming provides players with an optimal level of PA and double the amount of light to moderate energy expenditure compared to sedentary video gamers [6]. Therefore, exergaming has been used to promote PA and health in healthy adults [7], different age groups [8], and those with pathological conditions [9].

Exergaming increases energy expenditure and PA, promoting an active lifestyle [10]. Exergaming helps with weight management [11] and improving mental health [12] and can prevent sedentary behaviors [13]. The American College of Sports Medicine describes exergaming as "the future of fitness," and numerous studies highlight its potential to increase PA, especially among children and adolescents [14]. Furthermore, exergaming offers innovative solutions for health and rehabilitation services [15]. A recent systematic review suggested that exergaming may be recommended for patients undergoing cancer treatment [16]. Furthermore, exergaming has been shown to be effective in the rehabilitation of Parkinson disease [17] and in reducing cancer-related fatigue in children undergoing chemotherapy for leukemia [18]. Studies evaluating older adults have shown that exergaming improves various functions such as mental health, cognitive motor skills, and balance [19]. Additionally, exergaming supports psychological health by making PA more enjoyable [20].

Although a growing number of systematic reviews and meta-analyses have examined the effects of exergaming on specific outcomes such as PA promotion in children [11], older adults or clinical populations [16], cognitive function [19], balance improvement [21], and motivation [12,22], these studies primarily provide syntheses of intervention effects or health-related outcomes. However, they do not provide an overview of the evolution, structure, and dynamics of scientific output in this field over time. In contrast, bibliometric analysis sheds light on the historical development of a research field, allowing the identification of scientific production, trends, gaps, and future directions [23,24]. It also enables researchers to assess patterns of authorship, collaboration networks, and thematic trends [25].

Despite the growing popularity of exergaming, bibliometric studies specifically mapping this field remain limited. The few existing studies have largely focused on adjacent or overlapping fields such as PA, virtual reality (VR), augmented reality (AR), or rehabilitation research [26,27]. However, exergaming encompasses a wider range of technologies and applications, including motion-sensing consoles, mobile apps, and digital fitness platforms, which have not been adequately addressed in these previous reviews. Therefore, bibliometric analysis focusing specifically on exergaming is necessary to better understand its thematic breadth, interdisciplinary contributions, and underexplored areas. This study aims to address this gap by providing a scholarly map of the exergaming literature from 1997 to 2024, offering valuable insights for researchers and practitioners interested in advancing this burgeoning field.

In line with the research objective, we have formulated our research questions (RQs) as follows:

- RQ1: What is the distribution of studies published on exergaming by year?
- RQ2: What are the most prolific journals in the field of exergaming?
- RQ3: How is the distribution of the number of publications of the authors who have done the most work in the field of exergaming according to years?
- RQ4: What are the most cited studies and trending topics in the field of exergaming?
- RQ5: What is the subject clustering of studies in the field of exergaming?
- RQ6: What are the most productive countries, institutions, authors, and their collaborations?
- RQ7: What are the past, current, and emerging trends, key contributors, and collaborative networks shaping the field of exergaming research?

Methods

Analysis Tool and Database

The bibliometric analysis was conducted in the open-access R-Based Bibliometrix package designed by Aria and Cuccurullo [28]. This has been favored due to its smooth interaction with Web of Science (WoS) and fully exploits the Keyword Plus property for a beautiful analysis of exergaming research [29].

Combining data from different databases can lead to inconsistencies in citation metrics, metadata, and affiliation information, which may negatively impact the accuracy and reliability of the analysis [30]. For this reason, in this research, we decided to use 1 database for the study, that is, the WoS. WoS offers comprehensive options for analysis due to its good citation metrics, elaborate metadata structure, and important tools like Keyword Plus, which provides an increased number of terminologies in addition to keywords provided by the authors [31].

Search Strategy
